Fault tree analysis (or HAZard ANalysis (HAZAN)) provides a powerful and commonly used example of a top-down procedure. The fault tree analysis begins with a hazardous outcome, known as the *top event*. The process formulates a logic diagram indicating the sequence of events leading to the top event; component probabilities are

then used to calculate the probability of the top event.

Performance monitoring and evaluation is a fundamental part of risk control. Measurement of performance involves comparisons with standards. Performance criteria should thus be established for plant, personnel, and management activities such as selection and training for the effectiveness of the overall system. Performance monitoring is therefore not restricted to the recording of accidents and incidents, which are the traditional parameters of “safety” but it is also an “active” process. This philosophy of safety measurement is concerned with actively seeking information on systems with a view to promoting positive actions.

Strategies for the reduction and management of errors have been developed by practitioners and researchers alike. Four potential error-handling strategies that draw upon some of the human factors issues considered in the previous sections include

1. intelligent decision support systems, i.e., safety-parameter display systems;
2. memory aids for maintenance personnel, i.e., portable interactive maintenance auxiliary (Reason [10]);
3. safety by design, i.e., designing out errors at the design phase of development; and
4. error management, i.e., promoting the positive and mitigating the negative effects of training errors in a systematic fashion (Frese [11]).

Summary

This paper has presented a brief exposition on the connection between safety and reliability. The paper has presented a systems approach to safety, reliability, and risk management that demonstrates the fundamental importance of good “people” management; this approach encourages organizations to consider the “human” factor and to develop systems which not only minimize accidents and incidents, but also make better safety inevitable.

Block Replacement

Introduction and Historical Perspective

The scientific interest in maintenance management originated only a few decades ago. The basis for the scientific support of maintenance is found in reliability engineering. Books by Barlow and Proschan [1] and Jorgenson and McCall [2] indicated the start of scientific interest in maintenance problems. In the early stages, maintenance was almost exclusively restricted to correcting failures. Later in the 1960s **preventive maintenance** programs were set up with the intention of avoiding failures. A main element in these programs is the preventive replacement of components. Although today there are many condition-based techniques to predict a required replacement, time-based preventive replacements (or hard-time replacements) are still common practice in many systems, like aircrafts, because of safety reasons. The timing of preventive replacements is therefore one of the key problems in this respect. The development of some simple but insightful models describing aging phenomena of technical components, as well as the choice of appropriate actions to cope with these phenomena, showed that a scientific approach can be useful. In the 1970s and early 1980s, the basic models were extended in several directions.

During the last 15 years substantial progress has been made in developing quantitative decision support systems for maintenance management of complex systems. Sophisticated systems are in operation nowadays in the oil industry (both for maintenance of refineries as well as offshore installations), road and railways maintenance, and electric power generation. They include the block-replacement model in one way or another.

Block Replacement

Block replacement is the preventive replacement of aging items after fixed intervals of time. Failures of items in between are covered by individual failure replacements and do not change the timing of the block replacement. Alternatives to block replacement are age replacement, where the replacement timing is based on the age of each component, and opportunity maintenance, where the timing of the maintenance

depends on the occurrence of opportunities for doing maintenance. For example, if a block replacement is scheduled on the first of May and the component involved fails and is replaced in February, the preventive replacement will still be done in May. The age-replacement policy, however, would reschedule the replacement. The block-maintenance policy is usually based on calendar time, but it can also be based on run-hours, kilometers driven, or number of takeoffs and landings; in this contribution we only treat the time base and assume that the other cases can be dealt with by transformations. We will next discuss the following issues relating to block replacement, *viz* characterizing the optimal block time, computation of the optimal block-replacement interval, comparison with other policies, and extensions.

Modeling

Consider a component which is subject to failures. Let the random variable X denote the time to failure, and assume that a cumulative distribution function (**cdf**) $F(\cdot)$ and probability distribution function (**pdf**) $f(\cdot)$ of X are available after statistical (data) analysis. Next assume that all components used for replacement have independent and identically distributed (i.i.d.) failure times. Let c_p, c_f be the cost of a preventive, corrective replacement respectively and let T be the time interval for block replacement. As each block replacement is a renewal of the system, the renewal reward theorem can be applied to derive a formula for the long-run average cost. A key quantity in this respect is the expected number of failures in the interval $[0, T]$. This is usually referred to as the *renewal function*, here indicated by $M(T)$. Now the long-run average costs $g(T)$ of a block-replacement policy with interval T are given by

$$g(T) = \frac{c_p + c_f M(T)}{T} \quad (1)$$

The first question is under which conditions there exists a finite optimum replacement interval, or in other words, whether preventive replacement is cost effective. The derivative of $g(T)$ is given by

$$\begin{aligned} g'(T) &= \frac{1}{T^2} \{c_f m(T)T - (c_p + c_f M(T))\} \\ &= \frac{1}{T} \{c_f m(T) - g(T)\} \end{aligned} \quad (2)$$

2 Block Replacement

where $m(T)$ indicates the renewal density $M'(T)$. To see whether $g'(T)$ has a zero point, we need to know more about the behavior of the renewal function. It is well known that under mild conditions we have the following asymptotic behavior of the renewal function

$$\lim_{T \rightarrow \infty} \left(M(T) - \frac{T}{E(X)} \right) = \frac{1}{2}(c_X^2 - 1) \quad (3)$$

where c_X^2 denotes the squared coefficient variation of X , i.e. $\text{Var}(X)/(E(X))^2$. Next remark that $\lim_{T \rightarrow \infty} m(T) = \frac{1}{E(X)}$ and that $\lim_{T \rightarrow \infty} g(T) = \frac{c_f}{E(X)}$. This does not indicate whether there exists a zero point of $g'(T)$ and another condition needs to be made. It appears that requiring

$$\lim_{T \rightarrow \infty} \left(M(T) - \frac{T}{E(X)} \right) > \frac{c_p}{c_f} \quad (4)$$

or, equivalently

$$\frac{c_p}{c_f} < \frac{1}{2}(c_X^2 - 1) \quad (5)$$

is sufficient for the existence of a finite optimum. For instance, if we assume that X follows a Weibull distribution, with cdf $F(T) = 1 - e^{-(T/\lambda)^\beta}$, then the requirement comes down to the failure rate being increasing (which is the case if the shape parameter $\beta > 1$) and the cost of preventive replacement be sufficiently lower than that of failure replacement. There may be multiple minima, but the first minimum is likely to be the overall minimum. Numerical evaluation of block-replacement policies does require the computation of the renewal function.

Renewal Function

Several characterizations have been developed for the renewal function (see e.g. Tijms [3]). We have a recursive integral formulation and an infinite series representation, i.e.

$$M(T) = F(T) + \int_0^T M(T-x) dF(x) \quad (6)$$

and

$$M(T) = \sum_{n=1}^{\infty} F^{(n)}(T) \quad (7)$$

where $F^{(n)}(T)$ denotes the n -fold convolution of $F(T)$, which can be interpreted as the probability of n or more failures in $[0, T]$. As lifetime distributions should have a positive support, the **normal distribution** has to be excluded. It appears that for many popular distributions in reliability, like the Weibull, taking the convolution can only be done numerically. For some specific distributions analytical expressions are available for the renewal function, viz

1. if X is exponentially distributed with mean $1/\lambda$, then $M(T) = \lambda T$;
2. if X follows a Coxian-2 distribution, that is with probability p it is an exponential distribution with rate λ_1 and with probability $(1-p)$ it is the sum of two exponential distributions with rates λ_1 and λ_2 , respectively, and so its pdf is given by

$$f(t) = \begin{cases} p\lambda \exp(-\lambda t) + (1-p)\lambda^2 t \times \exp(-\lambda t), & \lambda_1 = \lambda_2 = \lambda \\ \frac{p\lambda_1 - \lambda_2}{\lambda_1 - \lambda_2} \lambda_1 \times \exp(-\lambda_1 t) + \left(1 - \frac{p\lambda_1 - \lambda_2}{\lambda_1 - \lambda_2}\right) \lambda_2 \times \exp(-\lambda_2 t), & \lambda_1 \neq \lambda_2 \end{cases} \quad (8)$$

then its renewal function is given by

$$M(t) = \frac{\lambda_1 \lambda_2}{\lambda_1(1-p) + \lambda_2} t - \frac{\lambda_1(1-p)(\lambda_2 - p\lambda_1)}{(\lambda_1(1-p) + \lambda_2)^2} \times [1 - \exp\{-(\lambda_1(1-p) + \lambda_2)t\}] \quad (9)$$

For some distributions we can calculate the convolution easily. This is the case for Erlang distributions. For other distributions we have to apply numerical procedures. We would like to mention discretization of the distribution and using a recursive scheme for the convolutions. Other approaches work with cubic splines. There also exist very simple approximations, like $M(T) \approx F(T)$, for small T , but that does not work in the optimization as it will give an infinite optimal interval. It is however a good approximation for small T . This has led Smeitink and Dekker [4] to propose the following approximation

$$M(T) = F(T) + [\tilde{M}(T) - \tilde{F}(T)] \quad (10)$$

where for $\tilde{F}(T)$ a suitable distribution is chosen for which the renewal function can easily be evaluated and which has the same asymptotic behavior. The first can be done by choosing either mixed Erlang distributions or the hyper exponential and the latter by applying a two-moment fit.

Comparison with Other Policies

Age replacement is a natural competitor to block replacement. For a single component, age replacement is indeed easy to formulate: replace if the age of the part exceeds a critical age T . It avoids replacements of parts which have just been replaced in a failure replacement. Berg [5] showed that the optimal age-replacement policy has always lower average costs than the optimal block-replacement policy. The maximal difference is however, less than 10%. The comparison becomes more complex however, if multiple components have to be replaced. Several variants of multicomponent age replacement exist if there are set up costs involved. Variants can prescribe replacement of unfailed components also upon a failure or replacing a fixed or variable group preventively. However, in all cases the replacement policies depend on the individual component ages and such policies are much more complex, both in terms of description as well as in evaluation (see e.g. Dekker and Roelvink [6]). For multiple components block replacement however remains equally simple.

Although the term *block replacement* refers to component replacements, the model can also be used for cases where preventive maintenance is done which leads to a renewal of the component addressed, without really replacing it. Next the idea of fixed intervals can also be used for inspections.

Both block- and age-replacement policies involve a lifetime distribution which is obtained from data analysis or expert judgment. Quite often these distributions exhibit a large variation. Hence they are not that efficient and a lot of remaining life is thrown away. If one has specific information on the likelihood of the component on hand, one can better plan the replacement and avoid unnecessary preventive replacements. This is possible in the so-called condition-based maintenance, which focuses on monitoring techniques to predict failures, such as vibration monitoring, luboil analysis, and so on.

Practical Considerations

Although theoretically block replacement can be improved by age-types of replacement, it also has some other advantages. For example in age replacement one has to keep track of failure replacements of the individual components, which is more work than keeping track of the last execution of the preventive maintenance (PM) activity. A typical example is the replacement of fluorescent lamps in buildings. Another advantage of block replacement is the fact that it can be planned in advance, implying that all the necessary spare parts can be ordered in time and provisions can be made to ensure availability of appropriate manpower.

Extensions

Several extensions have been suggested to overcome the shortcoming of block replacement to replace relatively young components preventively. They have been termed *modified block replacement* (MBRP); see Archibald and Dekker [7]. Various options are available. Some authors suggest taking old unfailed components in failure replacements to lower costs and others to make the replacement flexible. In the so-called (t, T) MBRP one considers a preventive replacement every T time units, but at these times components are not replaced preventively if their age is below t time units. These policies are however, more difficult to analyze, but reasonable approximations are obtained by using the same interval as block replacement and taking t as about $T/2$.

System Downtime Distributions

Introduction

By system downtime we mean a period during which a system is not in a condition to perform its required function (see the glossary in [1]). In this article we examine the probability distribution of the system downtime, or system downtime distribution (SDD), considering two types of downtimes: the downtime in an interval and the downtime after a failure. The downtime in an interval is in general composed by the sum of the lengths of nonconnected subintervals during which the system is not functioning, whereas the downtime after a failure is the time it takes to complete the repair of the system and bring it back to the operating state.

Knowledge of the SDD can be useful for cost or risk analysis. The SDD in an interval would be used to calculate the expected cost of the out-of-service condition during the useful life of a system when the cost function is not a linear function of time. The 99th percentile of the SDD after a failure would give a repair time that is exceeded only with 1% probability, which is a useful information if long repair times involve some kind of risk (economic or of other nature).

This article is based mainly on the book by Aven and Jensen [2], where the authors give analytic formulas for both finite-time and asymptotic SDD. Such explicit solutions are obtained by assuming that the system can be partitioned into repairable and independent subsystems (or components) that evolve following an alternating renewal process [3, Chapter 3]. To our knowledge, reference [2] is the only systematic account giving a framework for addressing SDDs in complex systems. In [4] a dependence between failure time and repair time is allowed for, and the Laplace transform of the downtime in an interval is found, but for a system with one component only.

The expected downtime in an interval is related to system unavailability. In the next section we present a result on this, since it holds equally for one-component and multicomponent systems. Instead, in the successive sections we characterize the entire distribution of the downtime dealing with one-component systems and multicomponent systems

separately, beginning with the former, which are simpler.

It will be helpful to list some general notations at this point. More specialized notations will be introduced when needed. Let us denote by

- Y_u : a random variable representing the amount of time in $[0, u]$ during which the system is down;
- $\Phi(t)$: the structure function of the system, taking value 1 if the system is functioning at time t and value 0 otherwise;
- $A(t) = \Pr(\Phi(t) = 1)$: the availability of the system at time t , corresponding to the probability that the system is in operation;
- $F_i(\cdot)$ and $G_i(\cdot)$: the cumulative distribution functions of the failure time and of the repair time of component i , respectively, with finite expected values μ_{F_i} and μ_{G_i} , and variances $\sigma_{F_i}^2$ and $\sigma_{G_i}^2$.

In the systems we will be dealing with, the generic component i follows an alternating renewal process, with failure time distribution F_i and repair time distribution, G_i . The system starts with all components in operation. We assume that F_i is absolutely continuous with density f_i , whereas G_i can be any type of distribution. If the system has one component only, we suppress the index i .

Expected System Downtime in an Interval

In [2, Theorem 36] using the fact that the uptime in an interval is just the integral of the structure function of the system, one gets

$$Y_u = \int_0^u (1 - \Phi(t)) dt \quad (1)$$

and it can be shown that

$$E(Y_u) = \int_0^u (1 - A(t)) dt = \int_0^u \bar{A}(t) dt \quad (2)$$

This result is not very useful in practice, because the unavailability $\bar{A}(t)$ cannot be calculated explicitly even in the simplest cases. If there is only one component, an upper bound is given by

$$\bar{A}(t) \leq [\sup_{s \leq t} \lambda(s)] \mu_G \quad (3)$$

where $\lambda(s) = f(s)/\bar{F}(s) = f(s)/(1 - F(s))$ is the hazard function of F [2, Proposition 34]. As an

2 System Downtime Distributions

example, when F is Weibull, $\lambda(s) = \beta\lambda(\lambda s)^{\beta-1}$, for positive constants λ and β . If a cost function is proportional to the downtime through a constant C , an upper bound for the expected cost in the interval $[0, u]$ is given by $C \cdot (\lambda u)^\beta \cdot \mu_G$, for $\beta \geq 1$.

If a more general result is needed, we must resort to asymptotic approximations. Obviously, as $u \rightarrow \infty$, the expected downtime in $[0, u]$ will tend to infinity. However, the expected portion of time the system is down has the limiting unavailability as its limit, that is [2, Theorem 36],

$$\lim_{u \rightarrow \infty} \frac{E(Y_u)}{u} = \lim_{t \rightarrow \infty} \bar{A}(t) \equiv \bar{A} \quad (4)$$

Therefore, when the cost is proportional to the downtime, the expected cost over a long period of time can be approximated by $C \cdot u \cdot \bar{A}$, and the problem is now finding the limiting availability.

The availability topic is covered elsewhere in this encyclopedia (*see System Availability*). Very briefly, the limiting availability of a system of independent components is a function of the limiting availabilities of the components [2, Theorem 39]. The form of this function can be determined either from the **fault tree** or from the reliability block diagram representations of the systems. For example, the limiting availability of a series system with n independent components is given by $A = \prod_{i=1}^n A_i$, and $\bar{A} = 1 - A$. The limiting unavailability of another system with the same n components in parallel is $\bar{A} = \prod_{i=1}^n \bar{A}_i$. By the Key Renewal Theorem [3, Theorem 3.10], it can be shown that

$$A_i = \frac{\mu_{F_i}}{\mu_{F_i} + \mu_{G_i}} = \frac{\frac{1}{\mu_{G_i}}}{\frac{1}{\mu_{G_i}} + \frac{1}{\mu_{F_i}}} \quad (5)$$

The second expression of A_i is the ratio between the expected number of repairs per unit of repair time and the expected number of events (failures and repairs) per unit of calendar time. If the former is relatively large, it means that repairs are very short, so that it is likely to find the system in an operating state at inspection.

If we are not satisfied with the expected value of the system downtime, we should try to recover its entire distribution, and this is what we set out to do in the following sections.

SDD of a One-Component System

The SDD after a failure of a one-component system coincides trivially with G .

The SDD in an interval has an infinite series expansion, from [2, Theorem 37]:

$$\Pr(Y_u \leq y) = \sum_{n=0}^{\infty} G^{*n}(y) [F^{*n}(u - y) - F^{*(n+1)}(u - y)] \quad (6)$$

where G^{*n} and F^{*n} are the n -fold convolutions of G and F , respectively. To understand this formula, consider that $Y_u \leq y$ if and only if there are at least $u - y$ units of operating time in the interval $[0, u]$. During the first $u - y$ units of operating time one can observe any number n of failures, with probability $F^{*n}(u - y) - F^{*(n+1)}(u - y)$, which is derived from the properties of the renewal process determined by the failure times only. Then, for Y_u to be lower than or equal to y , the n repairs relative to these failures must take no more than y units of time, which happens with probability $G^{*n}(y)$, considering the renewal process of repair times alone.

Equation (6), while being elegant, is not of immediate use. As in the previous section, an asymptotic approximation is available as $u \rightarrow \infty$ [2, Theorem 38]:

$$Y_u \sim N(u\bar{A}, u\tau^2) \quad (7)$$

where

$$\tau^2 = \frac{\mu_F^2 \sigma_G^2 + \mu_G^2 \sigma_F^2}{(\mu_F + \mu_G)^3} \quad (8)$$

SDD of a Multicomponent System

SDD after a Failure of a Parallel System

In a multicomponent system there are many combinations of the states of the components that correspond to a failure state of the system. Hence the form of the SDD after a failure is not trivial. A building block for the derivation of approximate expressions for it is the SDD after a failure of a **parallel system**, which we will now briefly illustrate.

Consider a parallel system of n independent components, which fails at time t . Suppose we know that component i has caused the failure, meaning

it was the last component to fail: then the conditional SDD is the distribution of the minimum of the repair time of component i and the forward recurrence times in the failed state of the other components. The unconditional SDD is the weighted sum of the conditional SDDs. To express this formally we need some additional notation. We denote by

- Y : the downtime of the system after a failure;
- N_t : the counting process of failures of the system;
- $\Delta N_t = N_t - N_{t-}$: a quantity that is always zero except at jump times of N_t , when system failures occur;
- $\alpha_i(t)$: the forward recurrence time of component i , $i = 1, \dots, n$;
- $c_i(t)$: the probability that component i caused the system failure knowing that it has failed at time t .

The SDD after a failure for a parallel system is then

$$\begin{aligned} \Pr(Y \leq y \mid \Delta N_t = 1) \\ = \sum_{i=1}^n c_i(t) \left[1 - \bar{G}_i(y) \prod_{k \neq i} \bar{G}_{\alpha_i(k)}(y) \right] \end{aligned} \quad (9)$$

with Y indicating the downtime, and $G_{\alpha_i(k)}$ being the distribution of the forward recurrence time of component k in the failed state.

If the components are all identical, then $c_i(t) = 1/n$ for all values of i and

$$\Pr(Y \leq y \mid \Delta N_t = 1) = 1 - \bar{G}(y) [\bar{G}_{\alpha_i}(y)]^{n-1} \quad (10)$$

In the general case, it is still possible to write down a closed-form expression for the $c_i(t)$'s. Reading the proof of [2, Theorem 57], one finds that

$$c_i(t) = \frac{m_i(t) \prod_{k \neq i} \bar{A}_k(t)}{\sum_{j=1}^n m_j(t) \prod_{k \neq j} \bar{A}_k(t)} \quad (11)$$

where $m_i(t)$ is the renewal density of the modified renewal process of component i , that is, the process where the first failure time has distribution F_i and the interevent times between successive failures have distribution $G_i * F_i$. The renewal density $m(t)$ can be interpreted as the expected number of failures

per unit of time in an infinitesimal interval centered around t [2, Theorem 117]. We see that the numerator of equation (11) is in fact the expected number of system failures per unit of time caused by failures of component i in a tiny interval around time t .

The finite-time expression of equation (9) supplemented by equation (11) is not practically useful, because of the difficulty of calculating the quantities involved for specific lifetime and repair distributions. Taking the limit as $t \rightarrow \infty$, the unavailabilities tend to the limiting unavailabilities as in equation (5), $m_i(t)$ tends to the long-run frequency of failures, being $1/(\mu_{F_i} + \mu_{G_i})$ [2, Theorem 118], and $\bar{G}_{\alpha_i(k)}$ tends to

$$\bar{G}_{k,\infty}(y) = \frac{\int_y^\infty \bar{G}_k(x) dx}{\mu_{G_k}} \quad (12)$$

The asymptotic form of the SDD after a failure for a parallel system is then

$$\begin{aligned} \lim_{t \rightarrow \infty} \Pr(Y \leq y \mid \Delta N_t = 1) \\ = \sum_{i=1}^n c_i \left[1 - \bar{G}_i(y) \prod_{k \neq i} \bar{G}_{k,\infty}(y) \right] \end{aligned} \quad (13)$$

where

$$c_i = \frac{1/\mu_{G_i}}{\sum_{k=1}^n 1/\mu_{G_k}} \quad (14)$$

In the simplest possible case, that is when G_k is an exponential distribution for all k 's, the SDD takes the following form

$$\begin{aligned} \lim_{t \rightarrow \infty} \Pr(Y \leq y \mid \Delta N_t = 1) \\ = \sum_{i=1}^n c_i \left[1 - e^{-\left(\sum_{k=1}^n \frac{1}{\mu_{G_k}} \right) y} \right] \\ = 1 - e^{-\left(\sum_{k=1}^n \frac{1}{\mu_{G_k}} \right) y} \end{aligned} \quad (15)$$

that is, a mixture of exponential distributions, where each component of the mixture is the distribution of the minimum of n exponentially distributed variates. Since all the components of the mixture are the same, the SDD is simply an exponential.

SDD after a Failure of a Coherent System

We now turn to the more general case of a coherent system (see **Coherent Systems**), still with binary

4 System Downtime Distributions

components. Consider the collection of all the minimal cut sets of the system, K_j , $j = 1, \dots, J$ (see **Path Sets and Cut Sets in System Reliability Modeling**). Since the cut sets are minimal, one of them can cause system failure only if all its components fail, hence any minimal cut set can be considered as a parallel system and its asymptotic SDD after a failure is given by equation (13). In Figure 1 we show a very simple system with two minimal cut sets, $K_1 = \{C_1, C_2\}$ and $K_2 = \{C_1, C_3\}$, which will be helpful to illustrate the ideas that follow.

Now denote by $\{\Delta K_j(t) = 1\}$ the event that cut set K_j fails at time t , then we can state that

$$\{\Delta N_t = 1\} = \{\Delta K_1(t) = 1\} \cup \dots \cup \{\Delta K_J(t) = 1\} \quad (16)$$

Indeed, if a system failure occurs at time t , then at least one minimal cut set must have entered the failed state, and *vice versa*. However, the collection of events on the right-hand side is not a partition of $\{\Delta N_t = 1\}$ (in Figure 1, both $\{\Delta K_1(t) = 1\}$ and $\{\Delta K_2(t) = 1\}$ include the event that the cut set $\{C_1, C_2, C_3\}$ fails at time t) and the following inequality holds:

$$\begin{aligned} \Pr(Y \leq y \mid \Delta N_t = 1) \\ \leq \sum_{j=1}^J \Pr(Y \leq y \mid \Delta K_j(t) = 1, \Delta N_t = 1) \\ \times \Pr(\Delta K_j(t) = 1 \mid \Delta N_t = 1) \end{aligned} \quad (17)$$

To take advantage of our previous result on parallel systems, we substitute each term $\Pr(Y \leq y \mid \Delta K_j(t) = 1, \Delta N_t = 1)$ by $G_{K_j}(y)$, that is, the downtime distribution after a failure of the cut set K_j considered in isolation. When the failed cut set K_j is repaired, this does not imply that the system is repaired, whereas the converse is true, therefore, the downtime of K_j is lower than the downtime of the system, and we can state that $\Pr(Y \leq y \mid \Delta K_j(t) = 1, \Delta N_t = 1) \leq G_{K_j}(y)$. With reference to

Figure 1 A three-component system

Figure 1, if C_2 and C_3 are failed and C_1 fails at time t , then both $\{\Delta K_1(t) = 1\}$ and $\{\Delta K_2(t) = 1\}$ occur simultaneously. If C_2 is repaired first, then K_1 is repaired, but the system is not.

Finally, let us examine $\Pr(\Delta K_j(t) = 1 \mid \Delta N_t = 1)$. This is the probability that K_j failed at the same time as the system, given that the latter failed at time t . As in equation (11), this quantity is given by the ratio of the expected frequency of system failures where cut set K_j also fails, divided by the expected frequency of all failure modes of the system at time t . Referring once more to Figure 1, letting $\lambda_i = (\mu_{F_i} + \mu_{G_i})^{-1}$, $i = 1, 2, 3$, we see that, as $t \rightarrow \infty$

$$\begin{aligned} \lim_{t \rightarrow \infty} \Pr(\Delta K_1(t) = 1 \mid \Delta N_t = 1) \\ = \frac{(\bar{A}_2 A_3 + \bar{A}_2 \bar{A}_3) \lambda_1 + \bar{A}_1 A_3 \lambda_2}{(A_2 \bar{A}_3 + \bar{A}_2 A_3 + \bar{A}_2 \bar{A}_3) \lambda_1 + \bar{A}_1 A_2 \lambda_3 + \bar{A}_1 A_3 \lambda_2} \\ = \frac{\bar{A}_2 \lambda_1 + \bar{A}_1 A_3 \lambda_2}{(A_2 \bar{A}_3 + \bar{A}_2) \lambda_1 + \bar{A}_1 A_2 \lambda_3 + \bar{A}_1 A_3 \lambda_2} \end{aligned} \quad (18)$$

If the components are highly available, we may approximate A_i by 1, $i = 1, 2, 3$, and equation (18) becomes

$$r_1 = \frac{\bar{A}_2 \lambda_1 + \bar{A}_1 \lambda_2}{(\bar{A}_3 + \bar{A}_2) \lambda_1 + \bar{A}_1 (\lambda_3 + \lambda_2)} \quad (19)$$

This is the asymptotic frequency of failures of the minimal cut set K_1 considered in isolation, normalized with the sum of such frequencies of minimal cut sets K_1 and K_2 , and it is much easier to calculate than equation (18). In the general case, supposing K_j has n_j components, we obtain

$$r_j = \frac{\sum_{l=1}^{n_j} \lambda_l^{(j)} \prod_{k \neq l} \bar{A}_k^{(j)}}{\sum_{j=1}^J \sum_{l=1}^{n_j} \lambda_l^{(j)} \prod_{k \neq l} \bar{A}_k^{(j)}}, \quad j = 1, \dots, J \quad (20)$$

where the necessary reindexing of components for the j th cut set is signaled by the superscript (j) . Then, the final asymptotic approximation to the SDD after a failure is

$$\Pr(Y \leq y) \simeq \sum_{j=1}^J r_j G_{K_j}(y) \quad (21)$$

where

$$G_{K_j}(y) = \sum_{i=1}^{n_j} c_i^{(j)} \left[1 - \bar{G}_i^{(j)}(y) \prod_{k \neq i} \frac{\int_y^\infty \bar{G}_k^{(j)}(x) dx}{\mu_{G_k^{(j)}}} \right] \quad (22)$$

Here $G_k^{(j)}$ denotes the repair time distribution of component k of cut set K_j , and $\mu_{G_k^{(j)}}$ is its mean.

The probabilities $c_i^{(j)}$, relative to K_j , are found from equation (14). We are not sure of the inequality sign in equation (17) anymore, because we do not know in general whether the coefficients r_j approximate by excess or by deficit.

SDD in an Interval

Let us reconsider equation (6). Suppose F is an exponential distribution with mean $\mu_F = 1/\lambda_F$. Then the SDD is

$$\Pr(Y_u \leq y) = \sum_{n=0}^{\infty} G^{*n}(y) \frac{[\lambda_F(u-y)]^n}{n!} e^{-\lambda_F(u-y)} \quad (23)$$

which says that the number of failure occurring in the operational time $u - y$ is Poisson distributed with mean λ_F . This would prompt us to consider an approximation to the SDD for a system with more than one component, where λ_F is substituted by the asymptotic frequency of system failures in operational time and G is replaced by the downtime distribution after a failure found in equations (21) and (22). This approach is justified in [2, Section 4.6], and we refer the reader to it for details, because, as in the case of a one-component system, this formula is not of immediate use.

There exists an asymptotic normal approximation that generalizes equation (7) under the assumption that the stochastic process of the joint states of the components is regenerative (see [3, Section 5.4]). In this case, let S denote the length of a regeneration cycle, and let Y_S be the downtime during the cycle, then

$$\bar{A} = \frac{E(Y_S)}{E(S)} \quad \text{and} \quad \tau^2 = \frac{\text{Var}(Y_S - \bar{A}S)}{E(S)} \quad (24)$$

The limiting unavailability $\bar{A}$ can be found starting from the structure function of the system or by considering the regeneration cycles directly. It can be

seen immediately that for a one-component system we reobtain the quantities in equation (7) with this latter approach. For **coherent systems**, when components are highly available, $\tau^2 \approx \lambda E(Y_1^2)$, where λ is the asymptotic frequency of system failures and Y_1 is the downtime after the first system failure. The asymptotic system failure rate is found as a weighted sum of the failure rates of each component. Each weight is the probability that, by failing, the component causes a system failure, for any state of the other components. The expression for λ is then

$$\lambda = \sum_{i=1}^n \frac{h(A_1, \dots, A_{i-1}, 1, A_i, \dots, A_n) - h(A_1, \dots, A_{i-1}, 0, A_i, \dots, A_n)}{\mu_{F_i} + \mu_{G_i}} \quad (25)$$

where

$$\begin{aligned} h(A_1, \dots, A_n) &= \lim_{t \rightarrow \infty} h(A_1(t), \dots, A_n(t)) \\ &= \lim_{t \rightarrow \infty} \Pr(\Phi(t) = 1) \end{aligned} \quad (26)$$

is the limiting **system availability** A . With regard to $E(Y_1^2)$, this can be further approximated via the asymptotic SDD after a failure in equations (21) and (22).

Coherent Systems with Multistate Components

So far we have considered systems of binary components. Every time a component changes its state, a new sojourn time in that state is chosen from the relevant distribution. With more than two states we must allow for a (possibly random) rule for the transitions among the states and a duration distribution for each state. This leads us to systems of independent components where each component evolves as a semi-Markov process (see **Markov Renewal Processes in Reliability Modeling**; [3, Chapter 5]). We may call these *semi-Markov systems*. Van Casteren *et al.* [5], Pievatolo and Valadè [6], and Pievatolo *et al.* [7] examined semi-Markov systems in the context of power system reliability. In [6] only the mean time between system failures is calculated, and the downtime distribution is found by simulation. In [5], the authors give analytic expressions for the duration distribution of each system state. Finally, in [7] an analytic approximation for the SDD after a failure is given, obtaining a result that is more general

than that of [5] because the system's out-of-service condition often corresponds to a set of system states, and not just to a single state. The analytic expression for the SDD resembles equations (21) and (22) closely, with two main differences: the concept of minimal cut set is extended to a set of component states where no state can be changed or no component can be removed without it losing its status of cut set; the probability that a cut set causes a failure given a system failure depends both on the transition matrix of the Markov chain and on the means of the duration distributions. The accuracy of this approximation is shown *via* a simulation study on the specific case. We refer the reader to these papers where analytic results are detailed without reference to the specific applications.

Intensity Functions for Nonhomogeneous Poisson Processes

Introduction

The nonhomogeneous **Poisson process** (NHPP) has been used and developed for reliability development modeling since Duane [1] identified that plotting the cumulative number of a system's failures against cumulative time on log-log paper produced a straight-line relationship. Crow [2] developed this work for the US MIL HDBK-189 [3] in the late 1970s showing that the Duane model was an NHPP with a power law rate of occurrence of failures (ROCOF). Rigdon [4] subsequently showed that this was not the case. Parzen [5] presented the background theory to NHPPs and this has been developed further by Willis [6], Cox and Isham [7], and Thompson [8]. Cox and Lewis [9] stated a log-linear ROCOF and derived its maximum-likelihood estimates. Earlier, Rosner [10] had been looking into a software-applicable ROCOF and developed the IBM model, but only the power law ROCOF produces simple to calculate parameter estimates.

Definitions

An NHPP satisfies the following conditions

1. Since events start at $t = 0$, $N(0) = 0$.
2. The process $\{N(t), t \geq 0\}$ has independent increments. The time t is the cumulative time from zero.
3. For any $t > 0$, $0 < \text{Prob}(N(t) > 0) < 1$.
4. The number of failures in any interval of length t is distributed as a Poisson distribution with parameter $M(t) = E(N(t))$, also known as the *mean value function* and the expected cumulative number of failures in time t [11].
5. Only one event can occur at any one time.
6. $\lim_{h \rightarrow 0} \frac{P(N(t+h) - N(t) \geq 1)}{h} = \lambda(t)$.

This term $\lambda(t)$ is known as the *intensity*, *peril rate*, *ROCOF*, or *instantaneous failure rate* (not to be confused with hazard rate), which at the end

of a system development program is the failure rate which should remain constant through production and service use, if no more systematic design or manufacturing failures are encountered. Thompson [8] shows that if there are no simultaneous arrivals then $M(t) = \int_0^t \lambda(x) dx$, thus $\lambda(t) = \frac{dM(t)}{dt}$. So, as far as the models are concerned $E(N(0)) = 0$ and $\lim_{t \rightarrow \infty} E(N(t)) = \int_0^\infty \lambda(u) du \leq \infty$, where the less than sign usually applies to **software reliability** NHPPs. Also, another term used in calculations and for parameter **estimation** purposes is the *cumulative failure rate*, $\gamma(t_i) = \frac{M(t_i)}{t_i}$. The likelihood for a time-terminated process (at t_0 after the n th event is $L = (\prod_{i=1}^n \lambda(t_i)) \exp(-\int_0^{t_0} \lambda(x) dx)$. Discussion of sufficiency (of the log-linear model) appears in [9].

Parzen [5] and Thompson [8] discuss three distinct concepts of time between arrivals and results from these references are presented to highlight the difference between data, which is independently and identically distributed (i.i.d) and the NHPP. The distribution function of the first waiting time to failure is $F(w_1) = 1 - \exp(-M(w_1))$; however, the distribution function of w_r (the r th waiting time to failure) given the first $r - 1$ events is $F(w_r/T_i = t_1, \dots, T_{r-1} = t_{r-1}) = 1 - \exp(-M(t_r) + M(t_{r-1}))$. So, the first failure time is distributed with a **probability density function** (pdf) that can be derived from the intensity function but subsequent times will have different pdfs, however, all hazard rates are applicable intensities within the NHPP. The probability of n events in time t is $P(N(t) = n) = \frac{M(t)^n e^{-M(t)}}{n!}$ [12].

There is an inconsistency in naming intensities. For instance, the Duane model is also known as the *AMSAA model*, the *power law process*, and the *Weibull process*. If we decide to call the process by the hazard function of the first waiting time, then the Weibull process seems to be the most appropriate; however, the software Weibull model appears later in this contribution, and so we will refer to it as the *power law process*. Similarly, the log-linear model should be entitled the *Gompertz process* after Gompertz [13] and the IBM model or the Smiths Industries Ltd (SIL) model (see subsequently) should be known as the *Makeham process* after Makeham [14], although Gompertz and Makeham were actually working in actuarial science.

We shall address the following intensity functions in the areas where they have typically received the first usage.

The Simplest Models

The homogeneous Poisson process is given by $\lambda(t_i) = h(w_i) = b$ (ROCOF and hazard rate are a constant) and the expected number of failures is a linear function of cumulative time $M(t_i) = bt_i$ where $\lambda(t_i) = b$ (the exponential distribution). The cumulative failure rate also gives $\gamma(t_i) = b$. A check for data exhibiting **reliability growth** or decay is done by plotting number of failures against cumulative time and checking for curvature. Extensions to these are the linear ROCOF model: $\lambda(t_i) = at_i + b$ for which $M(t_i) = \frac{a}{2}t_i^2 + bt_i$ and $\gamma(t_i) = \frac{a}{2}t_i + b$ and the quadratic ROCOF model $\lambda(t_i) = 3at_i^2 + 2bt_i + c$ with $M(t_i) = at_i^3 + bt_i^2 + ct_i$ and $\gamma(t_i) = at_i^2 + bt_i + c$.

The Two Best-Known Models

Duane [1] and Crow [2] discuss the model $\lambda(t_i) = abt_i^{b-1} = b \frac{M(t_i)}{t_i} = b\gamma(t_i)$ so the ROCOF is the cumulative failure rate scaled by the shape parameter. This is straightforward to draw onto log-log paper commonly known as a *Duane plot*. The mean value $M(t_i) = at_i^b$ can also be plotted on log-log paper so that parameters a and b can be estimated. The approach to analysis of a Duane plot should follow procedures similar to those for the well-known Weibull **probability plot**, i.e., evidence of two or more slopes, curvature, outliers, and so on. Further work on this model appears in [4, 15–19].

The log-linear model [9] is given by $\lambda(t_i) = e^{a+bt_i}$ $M(t_i) = \frac{e^a}{b}(e^{bt_i} - 1)$. Writing this as $M(t_i) = \frac{a}{b}(e^{bt_i} - 1)$, we get the ROCOF as a linear function of the expected number of failures, $\lambda(t_i) = a + bM(t_i)$. Reasonably straightforward programming provides maximum-likelihood estimates of the parameters. Nonlinear least-squares estimates can be calculated easily for this model.

We can consider the various hardware ROCOFs as having the same functional form as hazard functions and determine their pdfs. Addressing the hazard rate for the log-linear model, we get the pdf $f(w_i) = e^{a+bw_i} \exp(-\frac{e^a}{b}(e^{bw_i} - 1))$, an extreme-value (or Gumbel [20]) distribution [21, p. 139] with a Gompertz hazard rate (see below). Thus, the two best-known models give rise to the type I and type III extreme-value distributions. For completeness, a type II intensity can be

based on the arctangent survival distribution [22], where $\lambda(t_i) = \frac{a}{(\tan^{-1}(a(b-t_i)) + \frac{\pi}{2})(1+(a(t_i-b))^2)}$ and $M(t_i) = \ln\left(\frac{\tan^{-1}ab}{\tan^{-1}a(b-t_i)}\right)$, $0 < t_i < b$. Another trigonometric intensity $\lambda(t_i) = a(1 + b \sin ct_i)$ was developed by Willis [6], who showed that the expected number of events between t and $t + \tau$ is $a\left(\tau + \frac{2b}{c} \sin c\left(t + \frac{\tau}{2}\right) \sin \frac{c\tau}{2}\right)$.

Extensions to the log-linear model are in [23] $\lambda(t_i) = e^{a+bt_i+ct_i^2}$ and [24] $\lambda(t_i) = e^{\sum_{j=0}^k at_i^j}$. Simpler extensions of this latter one are given by $\lambda(t_i) = ae^{bt_i}(1 + abt_i)$, $M(t_i) = at_i e^{bt_i}$, $\gamma(t_i) = ae^{bt_i}$ and the simple exponential model $M(t_i) = at_i e^{-bt_i}$, $\gamma(t_i) = ae^{-bt_i}$ and least-squares estimates can be obtained from $\ln(\gamma(t_i)) = \ln a + bt_i$, $\ln(\gamma(t_i)) = \ln a - bt_i$, respectively.

Extensions to the power law process include the square root model [25], which is the power law process with $b = 0.5$: $\lambda(t_i) = \frac{a}{\sqrt{t_i}}$, $M(t_i) = 2a\sqrt{t_i}$ and the modified Duane model [26]: $\lambda(t_i) = abc^b(c + t_i)^{-b-1}M(t_i) = a\left(1 - \left(\frac{c}{c+t_i}\right)^b\right)$. An extension of this software reliability model is the hardware equivalent: $\lambda(t_i) = \frac{b(M(t_i)+a)}{c+t_i}$, $M(t_i) = a\left(\left(\frac{c+t_i}{c}\right)^b - 1\right)$. This intensity is of a similar functional form to the hazard rate developed in [27]: $h(w_i) = \frac{ab}{(c-w_i)^{b-1}}$, $0 < w_i < c$.

Reference [16] contains a model $\lambda(t_i) = act_i^{a-1}e^{bt_i}$, which incorporates both the best-known ones, but requires some programming to calculate the parameter estimates.

NHPPs Derived from Actuarial Studies

Historically, much work has been carried out on hazard rates in the actuarial field and some NHPPs are given below based on the best-known models in this field.

Gompertz [13] initially defined a hazard rate $h(w_i) = ab^{w_i}$, which we can write as the ROCOF $\lambda(t_i) = ab^{t_i}$ giving $M(t_i) = \frac{a}{\ln b}(b^{t_i} - 1)$. Makeham [14] extended this to $h(w_i) = c + ab^{w_i}$, which provides the ROCOF $\lambda(t_i) = c + ab^{t_i}$ with $M(t_i) = ct_i + \frac{a}{\ln b}(b^{t_i} - 1)$ described by Ascher [28].

Now, denote $T_1 = \sum t_i$, $T_2 = \sum t_i^2$, $B_1 = \sum b^{t_i}$, $B_2 = \sum b^{2t_i}$, $B_3 = \sum t_i b^{t_i}$, $B_4 = \sum t_i b^{2t_i}$, $B_5 = \sum t_i^2 b^{t_i}$, $M_1 = \sum m_i$, $M_2 = \sum m_i t_i$, $M_3 = \sum m_i t_i^2$, $M_4 = \sum m_i b^{t_i}$, and $M_5 = \sum m_i t_i b^{t_i}$.

We can obtain the Ascher model least-squares estimates for b by numerically solving

$$\frac{M_5(B_3 - T_1) - M_2(B_4 - B_3)}{B_5(B_3 - T_1) - T_2(B_4 - B_3)} = \frac{(M_4 - M_1)(B_4 - B_3) - M_5(B_2 - 2B_1 + n)}{(B_3 - T_1)(B_4 - B_3) - B_5(B_2 - 2B_1 + n)},$$

$$\text{then solve } c = \frac{M_5(B_3 - T_1) - M_2(B_4 - B_3)}{B_5(B_3 - T_1) - T_2(B_4 - B_3)}$$

$$\text{and finally } a = \frac{M_5 - cB_5}{B_4 - B_3}.$$

Rosner [10] describes the IBM model $\lambda(t_i) = c + abe^{bt_i}$ with $M(t_i) = ct_i + a(e^{bt_i} - 1)$ latter renamed the *SIL model* [29]. If we write $b^{t_i} = e^{t_i \ln b}$ in the Makeham model, we get the IBM model.

Other actuarial hazard rates discussed in Benjamin and Pollard [30] and converted to ROCOFs include $\lambda(t_i) = a + bt_i + cd^{t_i}$, (an addition of a linear model with time with a Gompertz process); $\lambda(t_i) = e^{a+bt_i} + e^{c+dt_i}$, (an addition of two log-linear ROCOFs);

Perk's process

$$\lambda(t_i) = \frac{a+bc^{t_i}}{1+dc^{t_i}} \text{ with } M(t_i) = \alpha + \beta t_i + \delta \ln(1 + \varepsilon c^{t_i});$$

Perk's process (extended)

$$\lambda(t_i) = \frac{a+bc^{t_i}}{Kc^{-t_i} + 1 + dc^{t_i}} \text{ with } M(t_i) = \alpha \ln \frac{c^{-t_i} + \beta}{1 + \beta} + \delta \ln \frac{c^{-t_i} + \phi}{1 + \phi}; \text{ and}$$

Barnett's process

$$\lambda(t_i) = \frac{-H + Bc^{t_i} \ln c}{1 + A - Ht_i + Bc^{t_i}} \text{ (original notation used)}$$

with $M(t_i) = \ln \left(\frac{1 + A - Ht_i + Bc^{t_i}}{1 + A + B} \right).$

The **repairable systems** bathtub curve [31] can be modeled by the following intensities which are based on the nonrepairable bathtub functions mentioned in [32] and [33], respectively: $\lambda(t_i) = a + bt + \frac{c}{t_i + d}$, $M(t_i) = at_i + bt_i^2 + c \ln \left(\frac{t_i + d}{d} \right)$, and $\lambda(t_i) = at + \frac{c}{1 + bt_i}$ (bathtub shaped for $0 < a < bc$) and $\lambda(t_i) = ab(at_i)^{b-1} \exp(at_i^b)$ (see the software Weibull model below).

The NHPPs Associated with Well-Known Probability Density Functions

The list below gives the ROCOFs for some well-known distributions:

The lognormal ROCOF $\lambda(t_i) \propto \frac{\phi(\ln(t_i))}{1 - \Phi(\ln(t_i))}$, where $\Phi(\cdot)$ is the standardized normal integral.

The gamma process [34, 35], $\lambda(t) = \frac{t^{\psi-1} e^{-\gamma t}}{\int_t^\infty u^{\psi-1} e^{-\gamma u} du}$

The Erlang process (based on the hazard rate in [36]) $\lambda(t_i) = \frac{(t_i/a)^{b-1}}{a((b-1)!)} \left(\sum_{i=0}^{c-1} \frac{(t_i/a)^i}{i!} \right)$

The generalized Wald process [37]

$$\lambda(t_i) = a + \frac{b}{(1 + ct_i)(1 + \ln(1 + ct_i))},$$

$$M(t_i) = at_i + b \ln(1 + \ln(1 + ct_i))$$

The Burr process based on the Burr distribution [38] is

$$\lambda(t_i) = \frac{abt_i^{b-1}}{c + t_i^b}, M(t_i) = a \ln \left(\frac{c + t_i^b}{c} \right)$$

The log-logistic process [39] $\lambda(t_i) = \frac{abt_i^{b-1}}{1 + at_i^b}$, $M(t_i) = \ln(1 + at_i^b)$ is the Burr process with $c = 1$. We may plot $\ln(e^M - 1)$ versus $\ln t$ to obtain least-squares estimates of the parameters.

The Pareto process $\lambda(t_i) = ab(1 + bt_i)^{-1}$, $M(t_i) = a \ln(1 + bt_i)$ is the same as $\lambda(t_i) = \frac{ab}{1 + at_i}$, $M(t_i) = b \ln(1 + at_i)$ [39] and is similar to the logarithmic model by Musa and Okumoto [40] $\lambda(t_i) = a(1 + abt_i)^{-1}$, $M(t_i) = \frac{1}{b} \ln(1 + abt_i)$.

The inverse Exponential process intensity [37] is $\lambda(t_i) = \frac{abe^{-b/t_i}}{t_i^2}$, $M(t_i) = ae^{-b/t_i}$. We plot $\ln M(t_i) = \ln a - \frac{b}{t_i}$ for parameter estimates.

The inverse Gaussian process intensity is

$$\lambda(t_i) = \frac{\left(\frac{a}{b} \right)^{1/2} \exp \left(-\frac{ab(t_i - \frac{1}{b})^2}{2t_i} \right)}{\left[1 - \Phi \left[\left(\frac{a}{bt_i} \right)^{1/2} (-1 + bt_i) \right] \right] \left[-e^{2a} \Phi \left[-\left(\frac{a}{bt_i} \right)^{1/2} (1 + bt_i) \right] \right]}$$

where $\Phi(\cdot)$ is the standardized normal integral.

Some Logarithmic Models

The simple logarithmic process [39] has intensity $\lambda(t_i) = \frac{a}{t_i}$ with $M(t_i) = a \ln(bt_i) = a \ln b + a \ln(t_i)$, $t \geq 1$. We can plot $M(t_i)$ against t_i on log-linear paper to obtain estimates of a, b . Weitz and Fraser

[41] also considered the hazard rate $h(w_i) = \frac{a}{1-aw_i}$, which if also considered as the intensity $\lambda(t_i) = \frac{a}{1-at_i}$ produces a logarithmic mean value function of $M(t_i) = -a \ln(1 - at_i)$.

Another model based on the hazard rate [42] is given by $\lambda(t_i) = at_i(b^2 + t_i^2)^{-1}$ with $M(t_i) = \frac{a}{2} \ln\left(1 + \frac{t_i^2}{b^2}\right)$.

A two-parameter logarithmic intensity function was developed as a hazard rate by Dhillon [43] as $\lambda(t_i) = \frac{(a+1)(\ln(1+bt_i))^a}{1+bt_i}$, which has mean value function $M(t_i) = \frac{1}{b}(\ln(1+bt_i))^{a+1}$.

Five variations of this model include

1. $\lambda(t_i) = a \ln(t_i) + a + b = \frac{M(t_i)}{t_i} + a$,
 $M(t_i) = at_i \ln(t_i) + bt_i$, $\gamma(t_i) = \frac{M(t_i)}{t_i} =$
 $a \ln(t_i) + b$ since as $t \rightarrow 0$,
 $\lim(t \ln t) = \lim\left(\frac{\ln t}{t^{-1}}\right) = \lim\left(\frac{1/t}{1/t^2}\right) =$
 $\lim(t) = 0$ so $M(0) = 0$; however, for calculation of λ we require $t \geq 1$.

2. A reduced form is

$$\lambda(t_i) = a \ln(t_i) + a = \frac{M(t_i)}{t_i} + a = \gamma(t_i) + a,$$

$$M(t_i) = at_i \ln(t_i), \gamma(t_i) = a \ln(t_i).$$

3. The logarithmic NHPP [44] intensity is

$$\lambda(t_i) = a \ln(1 + bt_i) + c \text{ with}$$

$$M(t_i) = \frac{a}{b}(1 + bt_i) \ln(1 + bt_i) + (c - a)t_i$$

4. Pievatolo *et al.* [45] used

$$\lambda(t_i) = \frac{a \ln(1 + bt_i)}{1 + bt_i}, M(t_i) = \frac{a}{2b}(\ln(1 + bt_i))^2$$

in the modeling of underground train failures.

5. Xie and Zhao [39] came up with

$$\lambda(t_i) = \frac{ab \ln(t_i)^{b-1}}{t_i}, M(t_i) = a \ln(t_i)^b, t \geq 1 \text{ and}$$

$$\lambda(t_i) = \frac{ab \ln(t_i + 1)^{b-1}}{t_i + 1}, M(t_i) = a(\ln(t_i + 1))^b,$$

$$t \geq 0.$$

Estimates of the parameters can be obtained from plotting $\ln M(t_i)$ against $\ln(\ln(t_i + 1))$.

Software Models and Creating a Nonrepairable Hazard Rate from them

The well-known software NHPPs have the distinction of a ROCOF, which does not tend to infinity as operational time does. So the ROCOF of the first failure time is not a hazard rate. Some of the well-known ones are listed below. The parameter a is the expected number of initial defects as $t \rightarrow \infty$.

The Littlewood model [46] $\lambda(t_i) = abc(1 + bt_i)^{-c-1}$, $M(t_i) = a(1 - (1 + bt_i)^{-c})$ is similar to the “initial defects” model (generalized version) [47] $\lambda(t_i) = \frac{b}{a} \left(\frac{a}{a+t_i}\right)^{b+1}$, $M(t_i) = a \left(1 - \left(\frac{a}{a+t_i}\right)^b\right)$.

This is Littlewood’s modified Duane model with $c = a$ [26].

In the Musa [48] $\lambda(t_i) = ae^{-bt_i}$, $M(t_i) = \frac{a}{b}(1 - e^{-bt_i})$ and Goel–Okumoto [49] $\lambda(t_i) = abe^{-bt_i}$, $M(t_i) = a(1 - e^{-bt_i})$ models, the number of faults would have a Poisson distribution with mean a , the n th interval having a pdf of $f_n(t) = (a - n + 1)be^{-(a-n+1)bt}$, ($1 \leq n \leq a$). Thompson [8] showed that the probability that the number of errors remaining equal to some value x given that y errors have been found would be a Poisson distribution with mean $a - M(t)$, and that the expectation of the errors remaining, given y errors have been found is $a - M(t)$, which is independent of y .

The logarithmic Poisson model described in detail in Musa *et al.* [50] is $\lambda(M(t_i)) = ae^{-bM(t_i)}$, where $M(t_i) = \frac{1}{b} \ln(abt_i + 1)$ with the t metric being execution time.

The S-shaped inflection [51] $\lambda(t_i) = \frac{ab(c+1)e^{-bt_i}}{(1+ce^{-bt_i})^2}$, $M(t_i) = \frac{a(1-e^{-bt_i})}{(1+ce^{-bt_i})}$. The S-shaped model as proposed by Yamada *et al.* [52] $\lambda(t_i) = ab^2t_i e^{-bt_i}$, $M(t_i) = a(1 - (1 + bt_i)e^{-bt_i})$, the bounded intensity model [53] $\lambda(t_i) = a(1 - (1 + at_i)^{-1}) = \frac{a^2t_i}{1+at_i}$, $M(t_i) = at_i - \ln(1 + at_i)$ and the log-logistic reliability growth model [54] $\lambda(t_i) = ab \frac{(ct_i)^{b-1}}{(1+(ct_i)^b)^2}$, $M(t_i) = a \frac{(ct_i)^b}{1+(ct_i)^b}$ offer different shapes to the intensity function. The latter model is a special case of the model $\lambda(t_i) = ah(t_i)$.

Other models discussed in [26] are characterized by the intensity $\lambda(t_i) = af(x)$ where a is the mean of the Poisson random variable N and X_i are i.i.d. with pdf $f(x)$, e.g., $\lambda(t_i) = abc(c + t_i)^{-b-1}$, the modified inverse power law (see [46]). The software Weibull model [40], [55] $\lambda(t_i) = abct_i^{c-1}e^{-bt_i^c}$, $M(t_i) = a(1 - e^{-bt_i^c})$ also comes into

this category. A classification of software reliability models is given in [50].

It is possible to make pdfs from these models by multiplying by functions of time, which tend to infinity as operational time tends to infinity. As an example, if we take the software Weibull model (not to be confused with the Weibull process/distribution) and multiply the mean value function by $e^{bt_i^c}$, we obtain $M(t_i) = a(e^{bt_i^c} - 1)$, which then provides us with a pdf of $f(w_i) = abcw_i^{c-1}e^{-bw_i^c}e^{-a(e^{bw_i^c}-1)}$ which, to avoid confusion, should be known as the *Musa–Okumoto distribution*. Dhillon [43] and Smith and Bain [56] discussed exponential power distributions, which were characterized by the hazard rate (intensity) $\lambda(t_i) = ab(at_i)^{b-1} \exp at_i^b$ and it can be seen that the software Weibull model in [40] is of a similar form.

Some Other Models

Some other models are listed below which require some development and application:

Ascher and Feingold [31] discuss three differential equation models (all NHPPs can be written as differential equations in $\frac{dM}{dt}$) and there is scope for more development here.

Exponential single-term power series model [57]: $\lambda(t_i) = a \left(\frac{(1 + bt_i)}{(1 - ce^{-bt_i})} - \frac{bt_i}{(1 - ce^{-bt_i})^2} \right)$, $M(t_i) = at_i(1 - ce^{-bt_i})^{-1}$, $\gamma(t_i) = a(1 - ce^{-bt_i})^{-1}$ [21]: $\lambda(t_i) = \frac{t_i(bt_i - 2a)}{(bt_i - a)^2}$, $t_i \geq \frac{2a}{b}$, $M(t_i) = \frac{t_i^2}{bt_i - a}$, $t_i \geq \frac{a}{b}$, $\gamma(t_i) = \frac{t_i}{bt_i - a}$ [58]: $\frac{1}{\gamma(t_i)} = ae^{-b/t_i}$. This model requires b to be negative for $M(0) = 0$. If we rewrite the model as $M(t_i) = at_i e^{-b/t_i}$, then $\lambda(t_i) = ae^{-b/t_i} \left(1 + \frac{b}{t_i} \right)$ and $\gamma(t_i) = ae^{-b/t_i}$. Parameter estimates can be obtained by plotting $\ln \gamma(t_i)$ against $\frac{1}{t_i}$.

Other differential equation models include $\lambda(t_i) = \frac{ae^{ct_i}}{1 + \frac{ab}{c}(e^{ct_i} - 1)}$, $M(t_i) = \frac{1}{b} \ln(1 + \frac{ab}{c}(e^{ct_i} - 1))$

$\lambda(t_i) = at_i M(t_i) + b$ as $M(t_i) = be^{\frac{at_i^2}{2}} \sqrt{\frac{\pi}{2a}} \int_0^{\sqrt{\frac{a}{2}t_i}} e^{-x^2} dx$ shown by [59].

Reference [60] lists a table of other differential equation forms. Other truncated models are discussed in [37].

Extensions

In many applications, where work has been carried out on the hazard rate, there is usually a reference to work on the intensity. A nonparametric estimate of intensity is given by [61] and other intensity estimates appear in [62–64]. Proportional intensity modeling (PIM) references are [65–67]. Aalen [68] discusses multiplicative intensities in depth. Bayesian inference references include [60, 69–72]. Tests and **confidence intervals** for parameters are covered in [31], and [73]. Martingales and intensities are discussed in [74, 75]. A review which includes topics for further study is provided by Lindqvist [76].

Repairable Systems: Bayesian Analysis

Introduction

The typical Bayesian paradigm, whether it is applied to repairable or nonrepairable systems, is to:

1. Formulate a prior distribution $p(\theta)$ that expresses our degree of belief in a parameter θ before any data are collected. Note that θ could be a vector.
2. Collect data $\mathbf{x}$ and form the likelihood function $L(\theta|\mathbf{x}) = f(\mathbf{x}|\theta)$.
3. Apply Bayes theorem to obtain the posterior distribution

$$p(\theta|\mathbf{x}) = cp(\theta)L(\theta|\mathbf{x}) \quad (1)$$

4. Use the posterior distribution to make inference for θ . For example, a point estimate for θ_k (the k th component of θ , if θ is a vector) is often taken to be the posterior mean

$$\hat{\theta}_k = E(\theta|\mathbf{x}) = \int \dots \int \theta_k p(\theta|\mathbf{x}) d\theta \quad (2)$$

We begin by presenting a Bayesian analysis for the homogeneous Poisson process, the simplest model for repairable systems. We then discuss the power law process (PLP). The concept of availability follows next and we present a Bayesian analysis of availability for the homogeneous **Poisson process** with gamma repair times. For multiple systems, we present **empirical Bayes** and hierarchical Bayes methods.

The Homogeneous Poisson Process

If we define $N(t)$ to be the (random) number of failures in the interval $[0, t]$, and more generally, $N(a, b)$ to be the number of failures in the interval (a, b) , then the homogeneous Poisson process is characterized by the following:

1. $N(0) = 0$ (the system begins with no failures).
2. If $a < b \leq c < d$, then $N(a, b)$ and $N(c, d)$ are independent random variables. This is called the *independent increments* property.

3. $\lim_{\Delta t \rightarrow 0} \frac{P(N(t, t + \Delta t) = 1)}{\Delta t} = \lambda$ and λ is independent of t .
4. $\lim_{\Delta t \rightarrow 0} \frac{P(N(t, t + \Delta t) \geq 2)}{\Delta t} = 0$. This precludes simultaneous failures.

These assumptions imply that the number of failures in an interval $[a, b]$ has a Poisson distribution with mean $\lambda(b - a)$. Note that the expected number of failures in an interval depends only on λ and the length of the interval, not on when the interval occurs. A consequence of this is that the number of failures in an interval of length t does not depend on whether the time interval covers the period when the system is young or old. Thus, the homogeneous Poisson process cannot be used to model systems that are improving or deteriorating.

Suppose now that the number n is predetermined and the system is observed until n failures occur. This is called *failure truncation*. We observe the failure times $t_1 < t_2 < \dots < t_n$ or the times between failures $x_1 = t_1, x_2 = t_2 - t_1, \dots, x_n = t_n - t_{n-1}$. The times between failure are independent exponential random variables with mean $1/\lambda$, so the likelihood function is

$$L(\mathbf{x}|\lambda) = \lambda^n \exp\left(-\lambda \sum_{i=1}^n x_i\right) = \lambda^n \exp(-\lambda t_n) \quad (3)$$

where t_n is the sum of the x_i 's and is a sufficient statistic. The conjugate prior for λ is the $\Gamma(a, b)$ distribution, which has probability density function (pdf)

$$p(\lambda) = \frac{b^a \lambda^{a-1}}{\Gamma(a)} e^{-b\lambda}, \quad \lambda > 0 \quad (4)$$

For this distribution, the mean and variance are

$$\mu = \frac{a}{b} \quad \text{and} \quad \sigma^2 = \frac{a}{b^2} \quad (5)$$

Thus, if we have prior knowledge about the parameter λ , especially concerning the mean and variance, then we can solve these equations for a and b to get

$$a = \frac{\mu^2}{\sigma^2} \quad \text{and} \quad b = \frac{\mu}{\sigma^2} \quad (6)$$

Combining equations (3) and (4) through Bayes theorem, we obtain the posterior

$$p(\lambda|\mathbf{x}) = c \lambda^{a+n-1} \exp[-(b + t_n)\lambda], \quad \lambda > 0 \quad (7)$$

2 Repairable Systems: Bayesian Analysis

which is seen to be the $\Gamma(a + n, b + t_n)$ distribution. Here c is the constant, independent of λ , that makes $p(\lambda|\mathbf{x})$ integrate to one. Inference is then based on this posterior distribution which reflects our knowledge about λ after seeing the data $\mathbf{x}$. For example, the posterior mean can be a point estimate of λ :

$$\hat{\lambda} = E[\lambda|\mathbf{x}] = \frac{a + n}{b + t_n} \quad (8)$$

The posterior variance can be used to assess the uncertainty in λ :

$$V[\lambda|\mathbf{x}] = \frac{a + n}{(b + t_n)^2} \quad (9)$$

A posterior probability interval for λ can be obtained using a normal approximation for the posterior distribution

$$\hat{\lambda} \pm z_{\alpha/2} \sqrt{V[\lambda|\mathbf{x}]} \quad (10)$$

If little or no prior information about λ is known, we can use the noninformative prior

$$p(\lambda) = \frac{1}{\lambda}, \quad \lambda > 0 \quad (11)$$

Combining equations (11) and (4), again using Bayes theorem, we obtain the posterior distribution

$$p(\lambda|\mathbf{x}) = c\lambda^{n-1} \exp[-t_n\lambda], \quad \lambda > 0 \quad (12)$$

showing that $\lambda|\mathbf{x}$ has a $\Gamma(n, t_n)$ distribution. Point and interval estimates for λ can be obtained from this result.

If testing of the repairable system stops at a predetermined time τ , rather than after a predetermined number of failures, then the sufficient statistic is $N(\tau)$, the number of observed failures. This is called *time truncation*. The likelihood is therefore

$$L(n|\lambda) = \frac{(\lambda\tau)^n e^{-\lambda\tau}}{n!}, \quad n = 0, 1, 2, \dots \quad (13)$$

Once again, the gamma distribution is the conjugate prior for λ . If this conjugate prior is chosen, then the posterior distribution has the form

$$p(\lambda|n) = c\lambda^{a+n-1} \exp[-(b + t)\lambda] \quad (14)$$

which is the $\Gamma(a + n, b + t)$ distribution.

Predicting the Number of Failures in a Future Interval

Suppose that a repairable system, whose failures are modeled by the homogeneous Poisson process, is observed until the time of the n th failure, t_n . The number of failures in the next τ time units, $N(t_n, t_n + \tau) = M$, is a random variable that has a Poisson distribution with mean $\lambda\tau$. Predicting the value of M then involves the randomness of this random variable *and* the uncertainty about the parameter λ . How can we combine these two sources of uncertainty? This is a difficult problem in the classical or frequentist framework, but it is straightforward in the Bayesian framework.

We can write the posterior of (λ, m) given the observed times of failure $\mathbf{t}$ as

$$p(\lambda, m|\mathbf{t}) = p(\lambda|\mathbf{t}) P(M = m|\lambda) \quad (15)$$

The marginal posterior distribution for m can then be obtained by integrating out λ :

$$p(m|\mathbf{t}) = \int_0^\infty p(\lambda|\mathbf{t}) P(M = m|\lambda) d\lambda \quad (16)$$

For the case of the noninformative prior $p(\lambda) = 1/\lambda$, it can be shown, (Rigdon and Basu [1]), that the posterior for M has the negative binomial distribution

$$P(M = m|\mathbf{t}) = \binom{m + n - 1}{m} \left(\frac{t_n}{t_n + \tau}\right)^n \left(\frac{\tau}{t_n + \tau}\right)^m, \quad m = 0, 1, 2, \dots \quad (17)$$

Point and interval predictions can be based on this marginal posterior distribution. Beiser and Rigdon [2] have shown that the coverage rates for these Bayesian intervals are slightly above the nominal levels when the noninformative prior is used.

Power Law Process

The assumptions for a nonhomogeneous Poisson process (NHPP) are the same as described in the section titled “The Homogeneous Poisson Process” above, except $\lim_{\Delta t \rightarrow 0} \frac{P(N(t, t + \Delta t) = 1)}{\Delta t} = \lambda(t)$ that is, the intensity is time dependent. The PLP is an NHPP whose **intensity function** has the parametric form

$$\lambda(t) = \frac{\beta}{\theta} \left(\frac{t}{\theta}\right)^{\beta-1}, \quad t > 0 \quad (18)$$

The Bayesian approach for the PLP follows the same general paradigm as described in the previous sections. The β parameter has a nice interpretation as a measure of improvement or deterioration:

1. $\beta = 1$ implies a constant intensity and there is no deterioration (or improvement),
2. $\beta < 1$ means that the intensity is decreasing and therefore there is reliability improvement, and
3. $\beta > 1$ means that the intensity is increasing and therefore there is reliability deterioration.

It may be reasonable to give prior information about the parameter β directly. The interpretation of the θ parameter is more difficult, especially in the absence of knowledge about β . ($\theta^{-\beta}$ can be interpreted as the expected number of failures through time $t = 1$, but this expression depends on both θ and β .) Guida *et al.* [3] have suggested that prior information about β and θ can be obtained, not directly, but rather in the following way. First, select a (marginal) prior distribution $g(\beta)$ for β . Then select some time T and consider the expected number of failures before time T . The expected number of failures η is

$$\eta = E(N(T)) = \int_0^T \lambda(t) dt = \left(\frac{T}{\theta}\right)^\beta \quad (19)$$

In a practical situation, it may be more reasonable to have prior information about η than about θ directly. We can then select a gamma prior distribution for η :

$$h(\eta) = \frac{b^a \eta^{a-1}}{\Gamma(a)} e^{-b\eta}, \quad \eta > 0 \quad (20)$$

We can select a and b to match the mean and variability of our prior knowledge about η .

If we assume independence regarding β and η , then

$$p(\beta, \eta) = g(\beta) h(\eta) \quad (21)$$

Since $\theta = T/\eta^{1/\beta}$, we can use the Jacobian to find that the joint prior for (β, θ) is

$$p(\beta, \theta) = g(\beta) \frac{\beta b^a}{\theta \Gamma(a)} \left(\frac{T}{\theta}\right)^{\beta a} \exp\left[-b \left(\frac{T}{\theta}\right)^\beta\right], \quad \beta > 0, \theta > 0 \quad (22)$$

The joint posterior can then be written as

$$p(\beta, \theta | \mathbf{t}) = c p(\beta, \theta) L(\beta, \theta | \mathbf{t})$$

$$= c g(\beta) \left(\frac{\beta}{\theta}\right)^n \left(\frac{P_n}{\theta^n}\right)^{\beta-1} \left(\frac{T}{\theta}\right)^{\beta a} \frac{\beta b^a}{\theta \Gamma(a)} \times \exp\left[-\left(\frac{t_n}{\theta}\right)^\beta - b \left(\frac{T}{\theta}\right)^\beta\right] \quad (23)$$

where

$$P_n = \prod_{i=1}^n t_i \quad (24)$$

Point and interval estimates for θ and β can be obtained from the joint posterior distribution.

The value of the intensity function at time t is often important, especially if t is the time of the conclusion of testing. If no further improvements are made to the system (which would be the case, for example, with software) then this would be the constant value of the intensity after release. Since $\lambda(t) = (\beta/\theta) (t/\theta)^{\beta-1}$, the posterior mean

$$E(\lambda(t) | \mathbf{t}) = \int_0^\infty \int_0^\infty (\beta/\theta) (t/\theta)^{\beta-1} p(\beta, \theta | \mathbf{t}) d\beta d\theta \quad (25)$$

would serve as a point estimate for $\lambda(t)$.

Other Models

The Bayesian methods described in the previous section can be applied to other models for repairable systems. The Bayesian approach will be the same in principle, but details will differ. For example, if the Weibull renewal process is assumed, then a prior would be placed on the parameters of the Weibull and the posterior distribution would then be computed *via* Bayes theorem. There are numerous other models that can be applied to repairable systems. See Ascher and Feingold [4] and Rigdon and Basu [1]. Also, *see Repairable Systems Reliability*.

Assessment of System Performance

There are often measures of system performance that involve more than one type of input. For example, the availability of a repairable system depends on both the failure process and the repair process, both of which must be estimated from the available data. It is often more straightforward to assess the uncertainty of such an estimate using the Bayesian paradigm.

4 Repairable Systems: Bayesian Analysis

Consider for example, the situation where the failure process is a homogeneous Poisson process with intensity λ , which is unknown, and the repair times are gamma random variables with pdf

$$g(x|\alpha, \beta) = \frac{\beta^\alpha x^{\alpha-1}}{\Gamma(\alpha)} e^{-\beta x}, \quad x > 0 \quad (26)$$

where α and β are also unknown. Suppose that the prior distribution for λ , the parameter of the failure process, is $p_1(\lambda)$ and the joint prior for (α, β) , the parameters of the repair process, is $p_2(\alpha, \beta)$. Suppose further, that we have observed the failure times $t_1 < t_2 < \dots < t_n$ (measured in operating time, which excludes repair times) and repair times $x_1, x_2, \dots, x_m$. Assuming independence between the failure process and the repair process, and also between the prior information about λ and (α, β) , we find that the posterior distribution for (λ, α, β) is

$$\begin{aligned} p(\lambda, \alpha, \beta | \mathbf{t}, \mathbf{x}) &= c p_1(\lambda) L(\lambda | \mathbf{t}) p_2(\alpha, \beta) L(\alpha, \beta | \mathbf{x}) \\ &= c p_1(\lambda) \lambda^n \exp[-\lambda t_n] \\ &\quad \times p_2(\alpha, \beta) \frac{\beta^{m\alpha} \left(\prod_{j=1}^m x_j \right)^{\alpha-1}}{[\Gamma(\alpha)]^m} \\ &\quad \times \exp \left[-\beta \sum_{j=1}^m x_j \right] \end{aligned} \quad (27)$$

The steady-state availability is

$$\begin{aligned} A_\infty &= \lim_{t \rightarrow \infty} P(\text{system works at time } t) \\ &= \frac{E(\text{time between failure})}{E(\text{time between failure}) + E(\text{repair time})} \\ &= \frac{1/\lambda}{1/\lambda + \alpha/\beta} = \frac{\beta}{\beta + \alpha\lambda} \end{aligned} \quad (28)$$

If we had exact values for λ , α , and β , we would have an exact value for A_∞ , but we have just estimates of these parameters. We can obtain a point estimate for A_∞ as the posterior mean,

$$\begin{aligned} \hat{A}_\infty &= E \left(\frac{\beta}{\beta + \alpha\lambda} \middle| \mathbf{t}, \mathbf{x} \right) \\ &= \int_0^\infty \int_0^\infty \int_0^\infty \frac{\beta}{\beta + \alpha\lambda} p(\lambda, \alpha, \beta | \mathbf{t}, \mathbf{x}) d\lambda d\alpha d\beta \end{aligned} \quad (29)$$

We could also find the posterior variance

$$\hat{V} = E \left(\left(\frac{\beta}{\beta + \alpha\lambda} \right)^2 \middle| \mathbf{t}, \mathbf{x} \right) - \hat{A}_\infty^2 \quad (30)$$

and use its square root (the posterior standard deviation) to assess the uncertainty in our estimate of the availability. Assessing the uncertainty in our estimate $\hat{A}_\infty$ would be difficult in the frequentist paradigm.

See **Queues in Reliability** for a description of how **queues** are used in reliability, especially regarding system performance measures such as availability. Bayesian methods offer a practical method for assessing system performance in such cases.

Empirical and Hierarchical Bayes Models

So far we have assumed that there is just a single repairable system. Suppose now that there are k copies of a system and all are simultaneously under test. The appropriate analysis depends on the assumptions about the similarity or dissimilarity of the systems.

To illustrate, suppose that the homogeneous Poisson process applies to each system. The following assumptions can be made:

1. All systems are the same. Times between failures are independent and identically distributed (i.i.d.) exponential random variables with mean $1/\lambda$ for all systems (λ is the same for all systems). In this case, we can combine the likelihood for each of the systems, along with the prior distribution for λ to obtain the posterior. This essentially leads to the superposition of point processes (see Pievatolo and Ruggeri [5]).
2. Systems are all different. Each system has its own failure rate λ and we have a prior distribution for each. In effect, we would analyze these systems separately, using Bayes theorem for each system.
3. Systems are different but similar enough that we may assume that the failure rates $\lambda_1, \lambda_2, \dots, \lambda_n$ are i.i.d. from some prior distribution $p(\lambda)$. If this prior distribution contains the parameter ϕ (which could be a vector), then we would write $p(\lambda|\phi)$. Figure 1 illustrates this situation.

If we assume that ϕ is fixed, but unknown, then we would have an empirical Bayes model. We could estimate ϕ by the method of maximum likelihood

Figure 1 An empirical Bayes model for system failure intensities

and then we would obtain an estimated posterior distribution for each system:

$$p_i(\lambda_i | \mathbf{t}) = p(\lambda_i | \hat{\phi}) L(\lambda_i | \mathbf{t}) \quad (31)$$

where $\mathbf{t}$ is the array of all failure times. Note that the λ 's are unobservable random variables in this case.

Alternatively, we might assume that the hyperparameter ϕ is also unknown and place a prior $g(\phi)$ on it. This is a fully Bayesian model and is called a *hierarchical Bayes model*. See Figure 2. From this setup, we can obtain the marginal posterior distributions for λ_i , $i = 1, 2, \dots, k$.

If the PLP, rather than the homogeneous Poisson process were assumed, the approach would be similar, but a bit more involved. In Figure 1, the prior distribution would be for the pair (β, θ) , so we would write $p(\beta, \theta | \phi)$. An alternative assumption, reasonable for some situations, would be that the β parameter is the same for all systems, but the θ 's vary from system to system; we might further assume that $\theta_1, \theta_2, \dots, \theta_k$ are i.i.d. from some prior distribution $p(\theta | \phi)$. This would lead to an empirical Bayes model where the (fixed but unknown) parameters would be (β, ϕ) . Various other empirical Bayes

Figure 2 A hierarchical Bayes model for system failure intensities

or hierarchical Bayes models are possible. See Rigdon and Basu [1], Chapter 5 for a further discussion.

Flowgraph Models

Flowgraph Models

Flowgraph models are multistate models that are used to describe longitudinal, time-to-event data. They model stochastic processes that progress through various stages. Today's complex systems make the analysis of multistate models very important in reliability. Flowgraphs model potential outcomes, probabilities of outcomes, and waiting times for the outcomes to occur. Flowgraphs provide a natural model for complex engineering systems and reliability. A recent book on the subject is [1].

Examples of processes that have been modeled using flowgraphs include the internal mechanisms of cellular telephone networks [2], stages in the maintenance and repair of aircraft, or improving stages of assembly and rework in a manufacturing process. For example, modeling the stages of the cellular telephone network begins with a fully functioning network that proceeds through a series of degradations to a partially functioning network and eventually to a fully failed network. The network itself may be a local network composed of only a few cells or it may be composed of subsystems that comprise a network over an entire state or country. In aircraft maintenance, the macro level process can be represented by five main systems. However, each system consists of subsystems with thousands of elements that represent tasks involved in repair and maintenance. Data may be available in detail for the entire process or, more realistically, data may be available only partially at the component, subsystem, or system level. Combining such information across various levels of a system has become increasingly important in complex systems (*cf.* [3]).

Flowgraphs allow each component or set of components to have its own distribution, and flowgraph algebra provides a way to combine these varied distributions. The examples of the previous paragraph involve modeling the time until the occurrence of some event or events. The main interest is in modeling large, complex systems or subsystems of such systems.

Figure 1 presents a flowgraph model for a complex system. The states of the system, 0, 1, and 2,

represent the *functioning*, *degraded*, and *failed* system respectively. Alternatively, each of these nodes could also represent a subsystem. Our interest is in modeling the time to total failure, partial failure, or repair of the system. In addition we may also be interested in the number of times the system must be repaired after failure. We may also have various types of data on the system. We may have data on all of the transitions but the data may be censored, or we may have data on portions of the system but missing transition information. All of these situations can be handled by a flowgraph model. The end result from a flowgraph is a Bayes predictive density, survivor/reliability function, and hazard function. Additional quantities such as availability can also be calculated. If one prefers, the maximum-likelihood estimates can be computed.

This article begins by providing an introduction to the analysis of basic flowgraph series-parallel-loop systems. Then we analyze the complex system of Figure 1 and describe the notation used in the figure. The labels on the branches are transition probabilities, p_{ij} 's, and moment generating functions (MGFs), $M_{ij}(s)$'s, of the waiting time distributions for transitions to occur. These are ultimately used with flowgraph algebra to obtain the MGF of the distribution of the waiting time of interest. We also present a general rule to analyze larger systems. Most of the basic flowgraph analysis software is available on the web site associated with [1].

Series, Parallel, and Loop Systems

In a flowgraph model, the states or nodes represent outcomes. This is distinct from a graphical model where the nodes represent random variables. Flowgraphs are outcomes graphs, whereas graphical models are variables graphs. The nodes are connected by directed line segments called *branches*. Each branch has a transition probability and waiting time distribution associated with a transition from its beginning and ending nodes. The branches are labeled with *transmittances*, which involve probabilities and MGFs. In engineering, block diagrams are analyzed using Laplace transforms of functional blocks and the primary interest is system stability. In statistics, we

2 Flowgraph Models

Figure 1 Flowgraph model for an overview of a complex system

Figure 2 Flowgraph model for a series system

are interesting in quantities based on probability distributions so we use the MGF in place of the Laplace transform.

Series Systems

Figure 2 shows a series system with states 0, 1, and 2 representing functioning, degraded, and failed system states respectively.

Let Y_0 be the random waiting time in state 0 until the system reaches the degraded state, 1. Let Y_1 , independent of Y_0 , be the random waiting time in state 1 until the system fails, state 2. Starting in state 0, the system degrades with probability 1, so the transition probability from $0 \rightarrow 1$ is $p_{01} = 1$. The associated waiting time is represented by its MGF, $M_{01}(s) = E(e^{sY_0})$, provided that the expectation exists for s in an open neighborhood of 0. Once in state 1, the system eventually fails so that $p_{12} = 1$ and the waiting time MGF of the time until state 2 is reached is $M_{12}(s) = E(e^{sY_1})$. The overall waiting time, time to system failure, has MGF $M_{01}(s)M_{12}(s)$. This is exactly what one would do to compute the sum of two independent random variables, $Y_0 + Y_1$.

A few other definitions that are useful when working flowgraphs are those of a transmittance and a path. A *transmittance* consists of the transition probability multiplied by the MGF of the waiting time distribution. An *overall transmittance* is the transmittance of the entire flowgraph from the initial

to the end state. A *path* from state i to state j is any possible sequence of nodes from i to j that does not pass through any intermediate state more than once. A *path transmittance* is the product of all the branch transmittances for that path. In the simple flowgraph of Figure 2, there is only one path, $0 \rightarrow 1 \rightarrow 2$, the transmittance of the $0 \rightarrow 1$ branch is $1 \cdot M_{01}(s)$, and the overall transmittance is the same as the MGF of the overall waiting time distribution.

Flowgraph Models for Parallel Structures

The next basic component of a flowgraph is one where branches are in parallel (see Figure 3). In a parallel flowgraph, transition from a state is allowed to one of a set of outcomes.

State 0 represents the functioning system and from this state, we wait for one of three possible outcomes: state 1, 2, or 3. This flowgraph represents a *competing-risks* situation. The flowgraph models the observable parts of the competing-risks distribution, that is, the actual competitive waiting times and the probabilities of each outcome. The time to each individual type of failure is given by the branch transmittances. The time to failure regardless of type has MGF given by $p_{01}M_{01}(s) + p_{02}M_{02}(s) + p_{03}M_{03}(s)$. Series and parallel flowgraphs can be combined to model more complex processes.

Closed Parallel System

Figure 4 shows a closed parallel system. State 0 represents the functioning system, and states 1 and 2 represent the degraded and the failed system. The path $0 \rightarrow 1 \rightarrow 2$ is a series system and it is in parallel with the direct path from $0 \rightarrow 2$.

Figure 3 Flowgraph model for a parallel system

Figure 4 Flowgraph model for a closed parallel system

This three-state model is a classic competing-risks model and is also called the *illness–death model* in the multistate models literature [4].

We solve this flowgraph for the MGF of the overall time to system failure by first considering the upper path. Note that the path $0 \rightarrow 1 \rightarrow 2$ is a series flowgraph. Thus the transmittance of this path is $p_{01}M_{01}(s)M_{12}(s)$, where $p_{12} = 1$. We can replace the original flowgraph with the one in Figure 5, a flowgraph that has two paths in parallel.

We reduce this further by treating the flowgraph as having just two branches in parallel, as in Figure 3. If transition to state 1 occurs prior to transition to state 2, the $0 \rightarrow 1$ branch is taken with probability p_{01} , leading to the series path through the flowgraph. If transition to state 2 occurs prior to state 1, the transition is direct passage from $0 \rightarrow 2$. Solving this gives the overall MGF,

$$M(s) = p_{01}M_{01}(s)M_{12}(s) + p_{02}M_{02}(s) \quad (1)$$

Series and parallel elements are two basic components of flowgraphs. Series elements lead to distributions of sums of independent random variables, whereas parallel elements lead to finite mixtures of distributions of independent random variables. The

feedback loop is the third basic element of a flowgraph model. A *loop* is any closed path that returns to the initiating state without passing through any state more than once. Feedback loops arise naturally in the engineering setting and are generally used to represent recurrent events such as repairs to a system or a part.

Series Model with Feedback

Consider a portion of the system of Figure 1 given in Figure 6. This is a series system with feedback that allows for repair of the system.

To solve this flowgraph for the MGF of T , $M_T(s)$, we set up a balance equation at state 0. A balance equation equates the inputs into a state with the outputs of the state. In our case, the input into state 0 is $p_{10}M_{10}(s)$. The output from state 0 is $M_{01}(s)$. This is magnified by the factor $M_T(s)$, which is the MGF of the loop that is fed back into itself. In systems analysis, this factor is called the *gain* of the system. The balance equation for state 0 in Figure 6 is

$$M_T(s) = M_{01}(s)p_{10}M_{10}(s)M_T(s) + M_{01}(s)p_{12}M_{12}(s) \quad (2)$$

4 Flowgraph Models

Figure 5 Reduced flowgraph model for a closed parallel system

Figure 6 Flowgraph model with feedback

Note that the term $M_{01}(s)$ appears in both terms on the right-hand side since it is a transmittance passed through the system. Solving for $M_T(s)$ gives

$$M_T(s) = \frac{p_{12}M_{01}(s)M_{12}(s)}{1 - p_{10}M_{01}(s)M_{10}(s)} \quad (3)$$

where $p_{12} + p_{10} = 1$. This is the overall MGF of the distribution of T .

Complex Systems: Automated Analysis

In this section we present a detailed solution of the flowgraph of Figure 1. Note that this flowgraph has a combination of series, parallel, and loop structures, requiring several steps for reducing the flowgraph to solve for the overall waiting time MGF of interest. Mason [5] developed a rule in the context of graph theory for solving systems of linear equations. In its original implementation, Mason's rule did not involve probabilities or MGFs. However, flowgraph models can be solved by applying Mason's rule to the branch transmittances. This provides a systematic procedure for computing the transmittance of a flowgraph from any state i to any state j .

Mason's rule entails enumerating the paths and loops involved in traversing the system from any state i to any other state j . Often i and j are taken to be the input and output respectively but

that is not a requirement. In Figure 1, there are two paths from 0 to 2: $0 \rightarrow 1 \rightarrow 2$ and direct passage from $0 \rightarrow 2$. The transmittances of these paths are $p_{01}p_{12}M_{01}(s)M_{12}(s)$ and $p_{02}M_{02}(s)$. A first-order loop is any closed path that returns to the initiating state without passing through any state more than once. In Figure 1, $0 \rightarrow 1 \rightarrow 0$ constitutes a first-order loop. In general, a j th-order loop consists of j nontouching first-order loops. There are no loops of order 2 or more in Figure 1. The transmittance of a first-order loop is the product of the individual branch transmittances involved in the path. The transmittance of a higher-order loop is the product of the transmittances of the first-order loops it contains.

The general form of Mason's rule gives the overall transmittance, i.e. the MGF from input to output, as

$$M(s) = \frac{\sum_i P_i(s) \left[1 + \sum_j (-1)^j L_j^i(s) \right]}{1 + \sum_j (-1)^j L_j(s)} \quad (4)$$

where $P_i(s)$ is the transmittance for the i th path, $L_j(s)$ in the denominator is the sum of the transmittances over the j th-order loops, and $L_j^i(s)$ is the sum of the transmittances over j th-order loops sharing no common nodes with the i th path. For this system, $P_1(s) = p_{01}p_{12}M_{01}(s)M_{12}(s)$ and $P_2(s) =$

$p_{02}M_{02}(s)$. There is only one first-order loop and it touches both the paths at node 0 so that $L_1(s) = p_{01}p_{10}M_{01}M_{10}$ and $L_j^i(s) = 0$. Using equation (4), the overall waiting time from 0 to 2 is

$$M(s) = \frac{p_{01}p_{12}M_{01}(s)M_{12}(s) + p_{02}M_{02}(s)}{1 - p_{01}p_{10}M_{01}(s)M_{10}(s)} \quad (5)$$

In general, for systems with many states, paths, and loops, equation (4) is programmed using symbolic algebra. When the interest is in partial passage from state i to state j , equation (4) must be modified for the event of interest conditional on the occurrence of the event of interest. The conditional MGF in this case is

$$\frac{M_{ij}(s)}{M_{ij}(0)}$$

for partial passage from $i \rightarrow j$. While such flowgraph algebra provides the MGF of interest, it must be converted to a waiting time density, reliability, or hazard function in order to be useful. This can be performed *via* either a Laplace transform inversion routine [6] or a saddle point approximation [7].

Bayesian Prediction with Flowgraphs

The Bayes predictive density of a future observable Z given data $\mathcal{D}$ is

$$\begin{aligned} f_Z(z|\mathcal{D}) &= \int f_Z(z, \theta|\mathcal{D}) d\theta \\ &= \int f_Z(z|\theta)\pi(\theta|\mathcal{D}) d\theta \\ &\equiv E_{\theta|\mathcal{D}}[f_Z(z|\theta)] \end{aligned} \quad (6)$$

where Z has density $f_Z(z|\theta)$ and $\pi(\theta|\mathcal{D})$ is the posterior distribution of θ .

The flowgraph model gives us the MGF of the density $f_Z(z|\theta)$, so that for computational purposes, equation (6) can be written as

$$f_Z(z|\mathcal{D}) = \frac{\int f_Z(z|\theta)\mathcal{L}(\theta|\mathcal{D})\pi(\theta) d\theta}{\int \mathcal{L}(\theta|\mathcal{D})\pi(\theta) d\theta} \quad (7)$$

Parametric assumptions about the flowgraph allow us to specify the likelihood function for complete data. *Complete data* on the flowgraph model

consists of having complete transition information for each observation; however, the associated waiting time may be censored. *Incomplete data* refers to data with incomplete transition information in addition to censoring. For example, if an observation on the system is made in state 0 and 2 and we have additional information that the system did degrade to state 1, but we do not know when that occurred, we have incomplete data. In that case, likelihood construction is required [8].

Numerical Example: Bayes Predictive Distribution

For illustration we use the flowgraph of Figure 1 with simulated data. This example appears as a brief illustration in [9] with full details in [1]. The $0 \rightarrow 1$ waiting time is $IG(\lambda_1, \lambda_2)$ with mean λ_1/λ_2 , the $0 \rightarrow 2$ and $1 \rightarrow 0$ waiting times are $\Gamma(\alpha_1, \beta_1)$ (with mean α_1/β_1) and $\Gamma(\alpha_2, \beta_2)$ (with mean α_2/β_2), and the $1 \rightarrow 2$ waiting time is $Exp(\mu)$ (with mean $1/\mu$). The corresponding MGFs for the parametric distributions are

$$M_{01}(s) = \exp\{\lambda_1\lambda_2 - [\lambda_1^2(\lambda_2^2 - 2s)]^{1/2}\} \quad \text{for } s < \frac{\lambda_2^2}{2} \quad (8)$$

$$M_{02}(s) = \left(\frac{\beta_1}{\beta_1 - s}\right)^{\alpha_1} \quad \text{for } s < \beta_1 \quad (9)$$

$$M_{10}(s) = \left(\frac{\beta_2}{\beta_2 - s}\right)^{\alpha_2} \quad \text{for } s < \beta_2 \quad (10)$$

$$M_{12}(s) = \frac{\mu}{\mu - s} \quad \text{for } s < \mu \quad (11)$$

For real data, we use censored data histograms [10] to assist in choosing a parametric model for each branch waiting time in the flowgraph. Fifty runs of the system were simulated with parameter values $p_{01} = 0.7$, $p_{10} = 0.4$, $\lambda_1 = 3$, $\lambda_2 = 5$, $\alpha_1 = 4$, $\beta_1 = 6$, $\alpha_2 = 2$, $\beta_2 = 3$, and $\mu = 0.2$. Approximately 20% of the realizations were randomly right censored. For these data, all of the censored observations were in state 1. The system made 54 transitions from $0 \rightarrow 1$, 24 transitions from $0 \rightarrow 2$, 15 transitions from $1 \rightarrow 2$, and 28 transitions from $1 \rightarrow 0$. There were 11 censored observations.

Let $f_{gh}(\cdot)$ and $F_{gh}(\cdot)$ be the density and cumulative distribution function (**cdf**), respectively, of the waiting time in state g until transition to state h .

Figure 7 Bayes predictive density using slice sampling for the reversible illness–death model

Let x_{igh} be the i th uncensored observation from state g to state h , and let x_{jg}^* be the j th censored observation where censoring occurred in state g . Let n_{gh} be the number of individual transitions from state g to state h , and let n_g^* be the number of observations censored in state g . For this example, $n_0^* = 0$ and $n_1^* = 11$. Then the likelihood function is

$$\begin{aligned}
 \mathcal{L}(p_{01}, p_{10}, \lambda_1, \lambda_2, \alpha_1, \beta_1, \alpha_2, \beta_2, \mu | \mathcal{D}) \\
 &= \prod_{i=1}^{n_{01}} p_{01} f_{01}(x_{i01} | \lambda_1, \lambda_2) \prod_{i=1}^{n_{12}} (1 - p_{10}) f_{12}(x_{i12} | \mu) \\
 &\quad \times \prod_{i=1}^{n_{10}} p_{10} f_{10}(x_{i10} | \alpha_2, \beta_2) \\
 &\quad \times \prod_{i=1}^{n_{02}} (1 - p_{01}) f_{02}(x_{i02} | \alpha_1, \beta_1) \\
 &\quad \times \prod_{j=1}^{n_0^*} \left\{ 1 - [p_{01} F_{01}(x_{j0}^* | \lambda_1, \lambda_2) \right. \\
 &\quad \left. + (1 - p_{01}) F_{02}(x_{j0}^* | \alpha_1, \beta_1)] \right\} \\
 &\quad \times \prod_{j=1}^{n_1^*} \left\{ 1 - [p_{10} F_{10}(x_{j1}^* | \alpha_2, \beta_2) \right. \\
 &\quad \left. + (1 - p_{10}) F_{12}(x_{j1}^* | \mu)] \right\}
 \end{aligned} \tag{12}$$

The MGF of the overall survival time from $0 \rightarrow 2$ is found using the symbolic algebra software maple. We use noninformative priors on $\theta = (p_{01}, p_{10}, \lambda_1, \lambda_2, \alpha_1, \beta_1, \alpha_2, \beta_2, \mu)$. A *Unif*(0, 1) prior is used for both p_{01} and p_{10} . Each of the remaining parameters has a $\Gamma(1/1000, 1/1000)$ prior. Sampling from the posterior was done using slice sampling [11], a **Markov chain Monte Carlo** method that is globally applicable to flowgraph models. The resulting Bayes predictive density function is presented in Figure 7. Notice that the mixture of the inverse Gaussian and gamma distributions creates a very skewed overall waiting time distribution. Other functions of interest such as the reliability function, hazard function, availability function, or specific **quantiles** of the cdf can also be calculated as required. Maximum-likelihood estimates of these quantities can also be calculated. Software for flowgraph models is freely available at the web site associated with [1].

Summary

Flowgraph models provide a data analytic technique to model complex systems. Flowgraph models are semi-**Markov processes** but the transform methodology used with flowgraphs circumvents the difficulty associated with semi-Markov processes. The method is dynamic in that the systems and sub-systems are allowed to change and be updated

as the requirements change. The method allows for the incorporation of time-to-event and transition information data at all levels of the system, which makes it more than just a probabilistic method. The flowgraph models observable waiting times and does not make a proportional hazards assumption.

Queues in Reliability

Introduction

A queuing system is a mathematical model to characterize situations where certain units, called *customers*, arrive in continuous time in order to receive a service or facility provided by other units, called *servers*. When customers arrive, they are immediately served if there is an empty server. Otherwise, the customers must spend some time waiting in line for service until a server becomes available. Queuing theory is the methodology devoted to the stochastic description of queuing systems and the study of their performance measures, such as the queue length, waiting times, and so on. Some essential references on queuing theory are found in [1–5].

Queuing theory can be very useful in solving many complex reliability problems. Component failures or machine breakdowns can be treated as arrivals of customers and the repair or replacement of failed components may be seen as the service facility in a queuing system. The number of repair facilities or maintenance crews is equivalent to the number of servers. It is useful to find the analogies between reliability and queuing theory because it is frequently found in practice that a given reliability problem has been previously studied with an equivalent problem in queuing theory [6]. For example, the number of failed components corresponds to the *queue length* and the time elapsed from a failure to repair is equivalent to the waiting time in the system or *sojourn time*. Note that the notion of repair may also refer to preventive maintenance activities performed before system failures. For example, a deteriorated machine can be repaired to an upgraded status before it fails.

A queuing model is completely described by six characteristics that, following Kendall's notation [7], are given by $A/B/c/K/m/R$, where A and B describe the arrival and service pattern, respectively, c the number of servers, K the system capacity or maximum number of customers allowed in the system, m the size of the customer population, and R the discipline or the order in which customers are selected for service. Different symbols are traditionally used for the type of distribution of A and B . For example, M denotes exponential (Markovian) random variables, D degenerate (constant) variables,

and G general distributions. For instance, the $M/G/1$ queue denotes a single-server system with exponential interarrival times and general service time distribution. Note that when nothing is said about K , m , and R , it is assumed that there is an infinite capacity, an infinite customer population, and a first-come-first-served discipline.

In the case of reliability, the main characteristic of queues is that requests for service are usually generated by a finite customer population, that is, $m < \infty$. This is because, in general, there is a limited number of units (machines, devices, etc.) which can fail, and when they are all in the system (being repaired or waiting for repair), no more can arrive. Then, the arrivals of requests do not form a renewal process as the arrivals may depend on the number of units staying at the system. This is an essential difference from typical queuing systems, where the population of potential arrivals can be considered to be effectively limitless. For example, in telephone operations the number of customers is usually large enough that the probability of having all of them wanting service at once is extremely small. However, in repair of machinery, the whole set of machines may be simultaneously out of order. Queuing systems with finite population are known as *finite source queues*, which have been extensively studied in the queuing literature, see e.g., [8] and the detailed bibliography provided in [9]. Finite-source queuing models are used to describe the classical *machine repairmen problem* which is described in the following section.

The Machine Repairmen Problem

Consider a repairable system (see **Repairable Systems Reliability**) consisting of r machines which operate independently of each other and may eventually fail. When a machine breaks down, it has to be repaired by one of the c repairmen, if there are any available. Otherwise, it has to wait for service until a server becomes available. Thus, the operating machines are outside the queuing system and enter the system only when they break down and require repair, as shown in Figure 1. Machine lifetimes and repair times are independent random variables with rates λ and μ , respectively. Then, the so-called mean time between failures (MTBF) and mean time to repair (MTTR) are given by $1/\lambda$ and $1/\mu$, respectively.

2 Queues in Reliability

Figure 1 Machine repairmen/interference problem

This model is known as *the machine repairmen problem* or the *machine interference problem* since the machines interfere with each other when all the servers are busy and new requests for service arrive. It can be used to describe a large variety of real situations, such as manufacturing systems (see e.g., [10]), telecommunication traffic (see e.g., [11]), computer systems (see e.g., [12]), inventory models (see e.g., [13]), and so on. This broad range of applications has motivated a large amount of research on this problem in the literature. For two reviews, see [14, 15].

The simplest machine repairmen model supposes that both lifetimes and service times are exponentially distributed, there is no limit in the waiting room, the repair is carried out by a first-in-first-out discipline and after having been served, each machine starts working again as good as new. The queuing model describing this system is denoted by $M/M/c/r/r$ or, equivalently, $M/M/c//r$. Note that there is an important difference from the notation used for the arrival process in infinite source queues, such as the $M/M/c$ queue, where the symbol M indicates a Poisson arrival process. However, in the $M/M/c/r/r$ queue, the time between failures of each machine is exponential but the arrival of failures from the whole set of machines does not follow a **Poisson process** because, as mentioned before, these arrivals depend on the number of machines waiting for repair. In particular, when the number of machines waiting for service increases, the arrival rate of further service demands decreases. More specifically, when n machines are “down” for repair, there are $(r - n)$ operating machines and the time until the next breakdown is the minimum of $(r - n)$ exponential distributions with rate λ , which is also an exponential distribution of rate $(r - n)\lambda$. Then, given that there

are n machines being repaired or waiting for repair, the arrival rate or average number of fails per unit time is given by,

$$\lambda_n = \begin{cases} (r - n)\lambda, & \text{if } 0 \leq n \leq r \\ 0, & \text{if } n \geq r \end{cases} \quad (1)$$

and the average number of repaired machines per unit time is given by,

$$\mu_n = \begin{cases} n\mu, & \text{if } 0 \leq n \leq c \\ c\mu, & \text{if } n \geq c \end{cases} \quad (2)$$

Thus, it can be shown that the number of machines in the $M/M/c/r/r$ system follows a birth–death process, in which an arrival of a failure is interpreted as a birth and the completion of a repair is interpreted as a death, see e.g., [3]. Then, the long-run probability of having n machines in the system can be shown to be,

$$p_n = \begin{cases} \binom{r}{n} \left(\frac{\lambda}{\mu}\right)^n p_0, & \text{if } 1 \leq n \leq c \\ \binom{r}{n} \frac{n!}{c^{n-c}c!} \left(\frac{\lambda}{\mu}\right)^n p_0, & \text{if } c \leq n \leq r \end{cases} \quad (3)$$

where p_0 is obtained from $p_0 + \dots + p_r = 1$. Using these probabilities, we can calculate for example the mean number of machines in the system (being repaired or waiting for repair), L , and the mean number of machines waiting in the queue for repair, L_q , using,

$$L = \sum_{n=1}^r np_n \quad \text{and} \quad L_q = \sum_{n=c+1}^r (n - c) p_n \quad (4)$$

As noted in equation (1), the arrival rate, given that the system is in state n , is $(r - n)\lambda$. Then, the unconditional average rate at which machines arrive to the system (also called the *effective mean arrival Rate*) is given by,

$$\lambda_{\text{eff}} = \sum_{n=0}^{r-1} (r - n)\lambda p_n = \lambda(r - L) \quad (5)$$

Thus, we can also obtain the mean waiting time, W , a machine spends in the system (from failure to recovery) and the mean queuing time, W_q , a machine

waits in the queue for repair using the well-known Little's formulas,

$$L = \lambda_{\text{eff}} W \quad \text{and} \quad L_q = \lambda_{\text{eff}} W_q \quad (6)$$

Moreover, it is also possible to derive the distribution functions of the waiting time and queuing time in addition to their mean values, W and W_q , see e.g., [2, 3]. Some other performance measures such as the probability that a broken machine must wait for repair can also be obtained. Finally, it is worth observing that these results also hold even though the lifetimes are not exponentially distributed. That is, equation (3) is also valid for the $G/M/c/r/r$ queuing system. Furthermore, equation (3) also holds for systems with exponential lifetimes, general service times, and the same number of repairmen as machines, i.e. for the $M/G/c/c/c$ queue, see [3].

These results have also been extended to more complicated situations where the lifetimes and repair durations follow more general distributions than the exponential one, such as the Erlang distribution, mixtures of exponentials, Coxian and phase-type distributions (see e.g., [16, 17]). Many other features have been introduced to extend the applicability of the machine repairmen problem, including for example *vacation* models where the servers can take a vacation of random duration when the system is empty (see e.g., [18]), *retrial* models where machines that find all the servers busy do not enter the queue but instead reapply for service at random intervals (see e.g., [19]), *unreliable* servers that may themselves break down (see e.g., [20]), *priority* models where a group of machines are served with priority over the others (see e.g., [21]), *k-out-of-r* systems where at least k machines must be functioning for the whole system to work properly (see e.g., [22]), heterogeneous failure modes (see e.g., [23]), and so on. Another important extension is the use of *sparers*, also called *stand-by* or *sparing redundancy* (see **Reliability of Redundant Systems**), which is introduced in the following section.

The Machine Repairmen Problem with Sparers

Assume now that in addition to the r working machines considered previously, there is another set of s machines standing by as spares such that, when a working machine fails, it is immediately substituted by a spare machine if any is available. When a machine is repaired, it becomes a spare unless the

number of working machines is less than r , in which case the repaired machine is restarted immediately.

Consider an $M/M/c/r/r$ with s spares where the lifetimes and repair times are exponentially distributed with rates λ and μ , respectively. Then, given that there are n machines being repaired or waiting for repair, the arrival rate is now given by,

$$\lambda_n = \begin{cases} r\lambda, & \text{if } 0 \leq n \leq s \\ (r + s - n)\lambda, & \text{if } s \leq n \leq s + r \\ 0, & \text{if } n \geq s + r \end{cases} \quad (7)$$

and μ_n is the same as given in equation (2). Thus, this model can also be described by a birth-death process [3]. And then, it can be shown that the probability of having n machines in the system when $c \leq s$ is given by,

$$p_n = \begin{cases} \frac{r^n}{n!} \left(\frac{\lambda}{\mu}\right)^n p_0, & \text{if } 1 \leq n \leq c \\ \frac{r^n}{c^{n-c} c!} \left(\frac{\lambda}{\mu}\right)^n p_0, & \text{if } c \leq n \leq s \\ \frac{r^s r!}{(r + s - n)! c^{n-c} c!} \left(\frac{\lambda}{\mu}\right)^n p_0, & \text{if } s \leq n \leq s + r \end{cases} \quad (8)$$

and when $c > s$,

$$p_n = \begin{cases} \frac{r^n}{n!} \left(\frac{\lambda}{\mu}\right)^n p_0, & \text{if } 1 \leq n \leq s \\ \frac{r^s r!}{(r + s - n)! n!} \left(\frac{\lambda}{\mu}\right)^n p_0, & \text{if } s \leq n \leq c \\ \frac{r^s r!}{(r + s - n)! c^{n-c} c!} \left(\frac{\lambda}{\mu}\right)^n p_0, & \text{if } c \leq n \leq s + r \end{cases} \quad (9)$$

Using these probabilities, we can obtain the mean number of machines in the system and in the queue, L and L_q , respectively, as in equation (4). Also, we can obtain the effective mean arrival rate to the system by,

$$\begin{aligned} \lambda_{\text{eff}} &= \sum_{n=0}^{s-1} r\lambda p_n + \sum_{n=s}^{s+r} (r + s - n)\lambda p_n \\ &= \lambda \left(r - \sum_{n=s}^{s+r} (n - s) p_n \right) \end{aligned} \quad (10)$$

which allows us to obtain the mean waiting time in the system and the mean queuing time, W and

W_q , respectively, using Little's formula given in equation (6).

An interesting particular case appears when the number of spares, s , is very large. Then, the arrival rate λ_n given in equation (7) will be essentially constant and equal to λr , so that the arrival process will be well approximated by a Poisson process of rate λr . Thus, the system will converge to an infinite source $M/M/c$ model, whose stationary distribution can be obtained as the limit of equation (8) when s goes to infinity [2, 3], that is,

$$p_n = \begin{cases} \frac{(\lambda r)^n}{n! \mu^n} p_0, & \text{if } n \leq c \\ \frac{(\lambda r)^n}{c^{n-c} c! \mu^n} p_0, & \text{if } n \geq c \end{cases} \quad (11)$$

As shown in this case, infinite-source queues are in general much simpler than finite-source queues and consequently, queuing theory on infinite systems is much more developed. Thus, in practice, it may be convenient to assume an infinite source if the customer population is finite but large. Note that this will be a good approximation when the arrival process depends only in a negligible way on the number of customers already in the system.

Inference for Queues

Failure and repair times are random variables and the distributions and parameters describing their behavior are unknown in practice. Thus, the use of statistical methods (*see Repairable Systems: Statistical Inference*) becomes necessary to estimate the quantities of interest in the system. First, an experiment to collect data from the system must be designed. If we assume independence between the lifetimes and repair durations, a simple experiment providing complete information about the system consists in observing independently n lifetimes $\{x_1, \dots, x_n\}$ and m repair times $\{y_1, \dots, y_m\}$. Using these data, the traditional approach to queuing inference is based on **maximum-likelihood estimation** of the failure and service parameters. For example, the likelihood function of the parameters in the $M/M/c/r/r$ queue is given by,

$$l(\lambda, \mu) \propto \lambda^n \exp\left(-\sum_{i=1}^n x_i\right) \mu^m \exp\left(-\sum_{i=1}^m y_i\right) \quad (12)$$

and then, the maximum-likelihood estimators of λ and μ are given by $\hat{\lambda} = \bar{x}^{-1}$ and $\hat{\mu} = \bar{y}^{-1}$, respectively, where $\bar{x}$ and $\bar{y}$ denote the means of the lifetimes and repair times, respectively. These estimators can be plugged in to obtain estimations of the performance measures. For example, the stationary probabilities, p_n , can be estimated by replacing λ and μ by $\hat{\lambda}$ and $\hat{\mu}$, respectively, in equation (3). However, using this classical approach, it is often difficult to obtain measures of the uncertainty in the estimated performance measures.

An alternative approach is the use of the Bayesian methodology (*see Repairable Systems: Bayesian Analysis*), which is specially well suited for queues [24]. Consider again the $M/M/c/r/r$ model and assume independent gamma **prior distributions** for λ and μ ; say $\lambda \sim G(\alpha_0, \beta_0)$ and $\mu \sim G(a_0, b_0)$. From equation (12), it is easy to see that the posterior distributions are also independent gamma distributions, $\lambda | \text{data} \sim G(\alpha, \beta)$ and $\mu | \text{data} \sim G(a, b)$, where $\alpha = \alpha_0 + n$; $\beta = \beta_0 + \sum_{i=1}^n x_i$; $a = a_0 + m$; $b = b_0 + \sum_{j=1}^m y_j$. Using these posterior distributions, we can approximate the posterior predictive distributions of any performance measure. For example, we can simulate K values $\{\lambda^{(k)}, \mu^{(k)}\}_{k=1}^K$ from the joint posterior distribution of (λ, μ) , and approximate the posterior mean of p_n with,

$$E[p_n | \text{data}] \approx \frac{1}{K} \sum_{k=1}^K p_n^{(k)} \quad (13)$$

where $p_n^{(k)}$ is the value of p_n for $\lambda = \lambda^{(k)}$ and $\mu = \mu^{(k)}$. Analogously, we can easily approximate the posterior variance, **percentiles**, and credible intervals of p_n . For further details of Bayesian methods for the $M/M/c/r/r$ model, see [25]. Also, Bayesian analysis of more general queues, where the exponential assumption for arrivals and services is relaxed, can be found in e.g., [26] and the references therein.

Imperfect Repair, Counting Processes

Introduction

The effect of a failure and a subsequent repair on the performance of a repairable system is what distinguishes many models for **repairable systems**. For example, if the repair brings the system to the condition just before the failure, then the repair is said to be minimal. This leads to the nonhomogeneous **Poisson process** (NHPP). By contrast, if a unit is replaced with a new one, then the times between failure are independent and identically distributed (i.i.d.). Such a repair is called a *renewal* and the resulting process is called a *renewal process*. **Imperfect repair** models are ones in which a renewal is performed with a specified probability; otherwise **minimal repair** is done. Many models are compromises between renewal and minimal repair. For example, the modulated power law process (MPLP) assumes that a repaired unit is in better condition after a repair than just before the failure, but is not as good as new. Another class of models, called *reduction of failure intensity models*, is another compromise between renewal and minimal repair. These models are discussed further in the following sections.

Minimal Repair and the NHPP

Let $N(t)$ denote the number of failures of the system through time t . The assumptions behind the NHPP are

1. $N(0) = 0$ (the system begins with no failures).
2. If $a < b \leq c < d$, then $N(a, b)$ and $N(c, d)$ are independent random variables. This is called the *independent increments* property.
3. $\lim_{\Delta t \rightarrow 0} \frac{P(N(t, t+\Delta t)=1)}{\Delta t} = \lambda(t)$.
4. $\lim_{\Delta t \rightarrow 0} \frac{P(N(t, t+\Delta t) \geq 2)}{\Delta t} = 0$, precluding simultaneous failures.

Repair time is negligible, or is not included in operating time. The **intensity function** in 3 above is independent of the previous history of the process. Thus, it does not matter whether a failure occurred just **moments** before time t , or whether there has

been no failure since the initial start-up of the system. The failure intensity will be the same in either case. The repair does nothing to the performance of the system except to bring it back to the state just before the failure. Such a model is often called *bad-as-old*, because a repairable system is as bad as it was just before the failure. Models for which the system is renewed after each failure, in other words, **renewal processes**, are sometimes called *good-as-new*.

If $\mathcal{H}_t$ denotes the entire failure history of the process, then we call

$$\lambda(t|\mathcal{H}_t) = \lim_{\Delta t \rightarrow 0} \frac{P(N(t, t + \Delta t) = 1|\mathcal{H}_t)}{\Delta t} \quad (1)$$

the *generalized intensity function*. Thus, for the NHPP,

$$\lambda(t|\mathcal{H}_t) = \lambda(t) \quad (2)$$

irrespective of the failure history, and for the renewal process,

$$\lambda(t|\mathcal{H}_t) = \lambda(x) \quad (3)$$

where x is the time since the most recent failure ($x = t - t_n$, where t_n is the time of the most recent failure). There are models, called *self-exciting processes*, for which the failure history affects the status of the system in a more direct way (see [1]).

A common form for the intensity function is

$$\lambda(t) = \frac{\beta}{\theta} \left(\frac{t}{\theta} \right)^{\beta-1}, \quad t > 0 \quad (4)$$

An NHPP with this intensity is called the *power law process* (see **Repairable Systems: Statistical Inference**). Typically, β and θ are unknown parameters that must be estimated from the observed failure times.

Imperfect Repair

Brown and Proschan [2] developed a model under the following assumptions. Failures occur according to an NHPP with intensity function $\lambda(t)$. When a failure occurs, the repair is minimal (in the sense of the previous section) with probability p , and the repair is perfect with probability $q = 1 - p$. Thus, the system is brought to a bad-as-old condition with probability p , and to a good-as-new condition with probability q . Of course, special cases include

$$p = 0 \Rightarrow \text{NHPP} \quad (5)$$

$$p = 1 \Rightarrow \text{Renewal process} \quad (6)$$

The time epochs of perfect repairs are regeneration points. If $0 < p \leq 1$, then the system will eventually renew itself; in fact, it will renew itself infinitely many times.

Brown and Proschan developed a number of properties for this imperfect repair model, including the following. If $\lambda(t)$ is the intensity function for the NHPP, then the intensity function for the next renewal (measured in terms of times since the previous renewal) is an NHPP (not a renewal process) with intensity function

$$\lambda_p(t) = p\lambda(t) \quad (7)$$

The survival function for the next renewal is

$$\begin{aligned} S_p(t) &= P(\text{no renewals in } [0, t]) \\ &= \exp\left(-\int_0^t \lambda_p(x) dx\right) \\ &= \exp\left(-p \int_0^t \lambda(x) dx\right) = [S(t)]^p \end{aligned} \quad (8)$$

Many of the monotonicity properties of the intensity (e.g., increasing intensity, increasing intensity on average, etc.) follow from this result and from the fact that $\lambda_p(t) = p\lambda(t)$.

Block *et al.* [3] generalized the Brown–Proschan minimal repair model by allowing for the probability p of perfect repairs to depend on the age t of the system. This model is called the *age-dependent minimal repair model*. Block *et al.* [3] showed that the successive renewal times form a renewal process with cumulative distribution function (cdf)

$$F_p(t) = 1 - \exp\left(-\int_0^t p(x) S^{-1}(x) dF(x)\right) \quad (9)$$

where we have assumed that the failure process is an NHPP with intensity function $\lambda(t)$ and

$$S(x) = \exp\left(-\int_0^x \lambda(u) du\right) \quad (10)$$

and

$$F(x) = 1 - S(x) \quad (11)$$

Block *et al.* showed that if $p(t)$ is increasing, then many of the monotonicity properties of F_p , such as increasing failure rate, increasing failure rate on average, new better than used, and so on, hold whenever they hold for F .

Other Imperfect Repair Models

Berman [4] proposed a class of models where shocks affect a system, and a failure occurs not at every shock, but at every κ th shock, where κ is a positive integer. If the shocks occur according to an NHPP with intensity function $\lambda(t)$ and mean function $\Lambda(t)$, then the joint **probability density function** (pdf) of the first n failure times (or the likelihood function, depending on the perspective) is

$$\begin{aligned} f(t_1, t_2, \dots, t_n) &= \left\{ \prod_{i=1}^n \lambda(t_i) [\Lambda(t_i) - \Lambda(t_{i-1})]^\kappa \right\} \\ &\quad \times [\Gamma(\kappa)]^{-n} \exp(-\Lambda(t_n)) \end{aligned} \quad (12)$$

This is a density as long as $\kappa > 0$, so we may drop the assumption that κ is an integer.

Lakey and Rigdon [5] proposed a special case of Berman's inhomogeneous Poisson process as a model for repairable systems. The model, called the *modulated power law process*, assumes that the intensity function is

$$\lambda(t) = \frac{\beta}{\theta} \left(\frac{t}{\theta}\right)^{\beta-1}, \quad t > 0 \quad (13)$$

that is, the intensity function for the power law process. If $\kappa = 1$, then the MPLP reduces to the power law process since a failure occurs at every shock. If $\beta = 1$, then the process of shocks is a homogeneous Poisson process with intensity $1/\theta$. In this case, the times between failures are sums of i.i.d. exponential random variables, which is a gamma random variable. Thus, $\beta = 1$, reduces the MPLP to the gamma renewal process. Of course if $\kappa = \beta = 1$, then the model reduces to the homogeneous Poisson process.

The MPLP is a compromise between the bad-as-old and good-as-new models (assuming $\kappa > 1$ and $\beta > 1$). A failed/repared unit is in better condition than just before the failure because the counter for the number of shocks is reset to zero, and the number of shocks must again total κ . Also, the system is still not good as new because the intensity of shocks is higher than for a new system, which means that the shocks will tend to arrive at a faster rate.

Black and Rigdon [6] studied inference for the MPLP, including **maximum-likelihood estimation** and **confidence intervals** for the parameters. Maximum likelihood is a bit unstable and several iterations of the Nelder and Meade simplex algorithm (see Buchanon and Turner [7]) are often needed before

starting with the Newton–Raphson method. Asymptotic confidence intervals based on the log of the maximum likelihood estimates (MLEs), obtained using the delta method, have coverage rates closer to the nominal than the asymptotic intervals based on the MLEs themselves.

Another class of imperfect repair models is the reduction-in-intensity model of Doyen and Gaudoin [8]. Their arithmetic reduction-in-intensity (ARI) model assumes

$$\lambda_{T_i^+} = \lambda_{T_i^-} - S(i, T_1, \dots, T_i) \quad (14)$$

where $\lambda_{T_i^+}$ and $\lambda_{T_i^-}$ are, respectively, the limits of the values of the intensity function from the right (just after the failure) and from the left (just before the failure), and S is some function, which in general can depend on the failure number i and all previous failures. This general model has a number of special cases, including the following which may be the simplest. They call this the ARI_∞ model and it assumes

$$\lambda_{T_i^+} = \lambda_{T_i^-} - \rho \lambda_{T_i^-} = (1 - \rho) \lambda_{T_i^-} \quad (15)$$

In other words, after a failure/repair, the intensity is reduced by a factor of $1 - \rho$. Special cases of the ARI_∞ model include the NHPP ($\rho = 0$) and the renewal process ($\rho = 1$). Once again, this model is a compromise between NHPP (bad as old) and renewal process (good as new).

Figure 1 illustrates the idea for a power law intensity with $\rho = \frac{1}{3}$. The dashed line indicates the intensity function if there were no reduction in the intensity function. There are discrete jumps, reductions, in the intensity function at the time of each failure.

Doyen and Gaudoin [8] presented methods for maximum likelihood for the ARI model. Pan and Rigdon [9] described Bayesian methods for the ARI model for repairable systems.

Summary

Any model for which the performance of a failed/rep-
aired unit is between good-as-new (optimistic) and
bad-as-old (pessimistic) can be called an *imperfect repair model*. We have discussed a number of
models for repairable systems that fall into this cat-
egory, including the NHPP (minimal repair), the
Brown–Proschan imperfect repair model, the Block,

Figure 1 Intensity function for ARI_∞ model

Borges, and Savits age-dependent minimal repair model, the inhomogeneous gamma process (and the special case, the MPLP), and finally the reduction-in-intensity model.

Reliability Allocation

Introduction

Many systems are implemented by using a set of interconnected subsystems. While the architecture of the overall system may often be fixed, individual subsystems may be implemented differently. A designer needs to either achieve the target reliability while minimizing the total cost, or maximize the reliability while using only the available budget. Intuitively, some of the lowest-reliability components may need special attention to raise the overall reliability level. Such an optimization problem may arise while designing a complex software or a computer system. Such problems also arise in mechanical or electrical systems. A number of studies since 1960 have examined such problems [1].

In a nonredundant system, all the subsystems are essential. Often, however, an individual subsystem can be made more reliable by using a more costly implementation. This additional cost may represent wider columns in a building or more thorough testing of software. In redundant implementations, higher reliability can sometimes be achieved by using several copies of a subsystem, such that the system forms a parallel or *k-out-of-n* configuration.

The next section considers the problem formulation, followed by approaches used for setting up an optimization problem. As an example, software reliability allocation is examined in detail with two numerical illustrations. The last section considers reliability allocation in complex systems.

Problem Formulation

We assume that a system has been designed at a higher level as an assembly of appropriately connected subsystems. In general, the functionality of each subsystem can be unique; however, there can be several choices for many of the subsystems providing the same functionality, but differently reliability levels.

Here we consider the problem formulation for a common and widely applicable case. Let there be n subsystems SS_i , $i = 1, \dots, n$, each with reliability R_i and cost C_i . Let the cost C_i be a function of the reliability given by $f_i(R_i)$, it is referred to as the *cost*

function below. Let C_s and R_s represent the total system cost and the overall reliability and R_{ST} be the specified target reliability. If all the subsystems are essential to the system and if their failures are statistically independent, the system can be modeled as a *series system*. The cost minimization problem can be stated as follows:

$$\text{Minimize } C_s = \sum_{i=1}^n C_i = \sum_{i=1}^n f_i(R_i) \quad (1)$$

Subject to

$$R_{ST} \leq R_s$$

$$\text{i.e. } R_{ST} \leq \prod_{i=1}^n R_i \text{ since } R_s = \prod_{i=1}^n R_i \quad (2)$$

Note that equation (1) assumes that the cost of interconnecting the subsystems is negligible. An alternative problem would be to maximize R_s while keeping C_s less than or equal to the allocated cost budget.

The i th subsystem SS_i may have several implementation choices with different reliability values:

1. By extending a continuous attribute (for example, diameter of a column in building or time spent for software testing) the subsystem can be made more reliable.
2. Different vendors may offer their own implementations of SS_i at different costs.
3. It may be possible to use multiple copies of SS_i (for example, double wheels of a truck) to achieve higher reliability. Often the number of copies is constrained between a minimum (often one) and a maximum number because of implementation issues.

Note that in the first case, both the cost and the reliability can be varied continuously, whereas in the other two cases, the choices are discrete. In the first case, we can define a continuous cost function. In the second case too, the market forces may impose a cost function. In the third case, the subsystem may be modeled as a *parallel* or *k-out-of-n system* for reliability evaluation, provided the failures are statistically independent. A number of publications on reliability allocation consider only the third case, where the optimization problem becomes an integer optimization problem. It becomes a 0–1 optimization problem

2 Reliability Allocation

when choices are discrete and a component from a given list of candidates is either used or not used [2].

Approaches for Problem Setup

It is reasonable to assume that the cost function f_i would satisfy the following three conditions [3]:

1. f_i is a positive function
2. f_i is nondecreasing
3. f_i increases at a higher rate for higher values of R_i .

The third condition suggests that it can be very expensive to achieve the reliability value of one. In fact, for software, it has to been shown that under some assumptions, it is infeasible to achieve ultrahigh reliability [4].

In some cases, the cost function can be derived from basic considerations, as we will do below for **software reliability**. In other cases, it may be derived empirically by compiling data for different choices. The cost function is often stated in terms of the reliability, for example, the cost function proposed by Mettas [3] is given by

$$C_i(R_i, p_i, R_{i,\min}, R_{i,\max}) = \exp\left((1 - p_i) \frac{R_i - R_{i,\min}}{R_{i,\max} - R_i}\right) \quad (3)$$

where $R_{i,\min}$ and $R_{i,\max}$ are the minimum and maximum values of R_i and p_i is parameter ranging between zero and one that represents the relative difficulty of increasing a component's reliability. The cost function can also be given in terms of the failure rate as illustrated below for software reliability allocation.

A useful transformation of equation (2) can be obtained by taking the logarithms of both sides of the equation [5–7].

$$\ln(R_{ST}) \leq \sum_{i=1}^n \ln(R_i) \quad (4)$$

The transformation in equation (4) can sometimes reduce the problem to a linear optimization problem. The term $\ln(R_i)$ can also have a well-defined physical significance, in some cases, as the failure rate. When the failure rate of a subsystem SS_i is constant, its

reliability is given by an exponential relationship $R_i(t) = \exp(-\lambda_i t)$, the system failure rate is given by the summation of the subsystem failure rates and hence equation (4) can be restated as

$$\lambda_{ST} \geq \sum_{i=1}^n \lambda_i \quad (5)$$

The failure rate itself is a major reliability attribute. In some cases, such as in software reliability engineering, it is the failure rate that is often specified [8, 9]. The cost function of a subsystem can also be given in terms of its failure rate. If the cost C_i is given by the function $f_i(\lambda_i)$, equation (1) can be restated as

$$\text{Minimize } C_S = \sum_{i=1}^n C_i = \sum_{i=1}^n f_i(\lambda_i) \quad (6)$$

For example, let us consider software reliability. When a software is tested, defects in it are found and removed by debugging. A program tested more thoroughly will have fewer bugs and hence higher reliability. Several models relating software **reliability growth**, with the time spent in testing, have been proposed and validated. These are termed *software reliability growth models* (SRGMs). For the popular *exponential software reliability growth model* [8–10], the failure rate as a function of testing time d is given by

$$\lambda_i(d) = \lambda_{0i} \exp(-\beta_i d) \quad (7)$$

where λ_0 and β_1 are the SRGM parameters. If we assume that the cost is dominated by the testing time, the cost is given by the following function, which satisfies the three conditions mentioned above.

$$d(\lambda_i) = \frac{1}{\beta_i} \ln\left(\frac{\lambda_{0i}}{\lambda_i}\right) \quad (8)$$

Reliability Allocation Approaches for Basic Series and Parallel Systems

The reliability allocation problem for two basic reliability structures *series* and *parallel* can be solved by linearizing the constraints [1, 2, 7]. In a *series* system, the constraint is given in equation (2) above, which can be linearized by rewriting it as

$$\ln(R_{ST}) \leq \sum_{i=1}^n \ln(R_i) \quad (9)$$

which may then be solved relatively easily. An example is given below for software reliability allocation.

In a *parallel system*, functionally identical subsystems are configured such that correct operation of at least one of them assures a correctly functioning system. It is assumed that any overhead in implementing such a system is negligible. In real systems, the overhead involved will result in a lower level of reliability. In a number of studies, the problem assumes that the reliability of a subsystem can be increased by using a functionally identical component in parallel [2, 7]. For **parallel systems**, the constraint is given by

$$R_{ST} \leq 1 - \prod_{i=1}^n (1 - R_i) \quad (10)$$

The constraint can be linearized by using logarithms of the complements of reliability. Therefore, equation (10) can be rewritten as

$$\ln(1 - R_{ST}) \geq \sum_{i=1}^n \ln(1 - R_i) \quad (11)$$

Elegbede *et al.* have recently shown [7] that if the cost function satisfies the three properties given above, the cost is optimal if all the parallel components have the same cost. For software, computer hardware, and mechanical systems, the number of discrete parallel component is likely to be very small.

Reliability Allocation for Software Systems

As a detailed example, we examine the problem of software reliability allocation [6]. Typically, a software consists of sequentially executed blocks, such that only one is under execution at a time. Each block can be independently tested and debugged to reduce the failure rate below a target value. In some cases, the reliability of a block can be further increased by replication. For replication to be effective, each replicated version must be developed independently such that the failures are relatively independent. The impact of replication can be evaluated by assuming statistical independence. However, it has been shown that sometimes the statistical **correlation** can be significant, requiring more complex analysis.

Here, in this example we consider the common case, a nonredundant implementation of software,

divided into n sequential blocks [6]. Let us assume that a block i is under execution for a fraction x_i of the time where $\sum x_i = 1$ [5]. Then the reliability allocation problem can be written as

$$\text{Minimize } C = \sum_{i=1}^n \frac{1}{\beta_i} \ln \left(\frac{\lambda_{0i}}{\lambda_i} \right) \quad (12)$$

$$\text{Subject to } \lambda_{ST} \leq \sum_{i=1}^n x_i \lambda_i \quad (13)$$

Solution: Let us solve the problem posed by equations (12) and (13) by using the Lagrange multiplier approach by finding the minimum of

$$F(\lambda_1, \dots, \lambda_n) = C + \theta(\lambda_1 + \dots + \lambda_n) - \lambda_{ST} \quad (14)$$

where θ is the Lagrange multiplier. The necessary conditions for the minimum to exist are (a) the partial derivatives of the function F are equal to zero, (b) $\theta > 0$, and (c) $x_1 \lambda_1 + x_2 \lambda_2 + \dots + x_n \lambda_n = \lambda_{ST}$ [6]. Equating the partial derivatives to zero and using the third condition, the solutions for the optimal failure rates are found as follows:

$$\lambda_1 = \frac{\frac{\lambda_{ST}}{x_1}}{\sum_{i=1}^n \frac{\beta_i}{x_i}} \quad \lambda_2 = \frac{\beta_1 x_1}{\beta_2 x_2} \lambda_1 \quad \dots \quad \lambda_n = \frac{\beta_1 x_1}{\beta_n x_n} \lambda_1 \quad (15)$$

The testing times of the individual modules are given by equation (12). The optimal values of d_1 and $d_i, i \neq 1$ are given by

$$d_1 = \frac{1}{\beta_1} \ln \left(\frac{\lambda_{10} x_1 \sum_{i=1}^n \frac{\beta_i}{x_i}}{\lambda_{ST}} \right) \quad \text{and} \quad d_i = \frac{1}{\beta_i} \ln \left(\frac{\lambda_{i0} \beta_i x_i}{\lambda_1 \beta_1 x_1} \right) \quad (16)$$

Note that d_i is positive if $\lambda_i \leq \lambda_{i0}$. The testing time for a block must be nonnegative. If any of the testing times in equation (16) is negative, the optimization problem must be solved iteratively [6].

In software reliability engineering, the assumptions involved in formulation of the exponential model imply that the parameter β_i is inversely proportional to the software size [8, 11], when measured in terms of the lines of code. The value of x_i can be

4 Reliability Allocation

Table 1 Input data and optimal values for Example 1

Block	B ₁	B ₂	B ₃	B ₄	B ₅
β_i	7×10^{-3}	3.5×10^{-3}	2.333×10^{-3}	7×10^{-4}	3.5×10^{-4}
λ_{i0}	0.14	0.14	0.14	0.175	0.21
x_i	0.028	0.056	0.083	0.278	0.556
Optimal λ_i	0.06	0.06	0.06	0.06	0.06
Optimal d_i	121.043	242.085	363.128	1.529×10^3	3.579×10^3

reasonably assumed to be proportional to the code size. The values of λ_i and λ_{i0} do not depend on size but depend on the initial defect densities [11]. Therefore, if the exponential model indeed holds, the equation (15) states that the optimal values of the post-test failure rates $\lambda_1, \dots, \lambda_n$ are equal. In addition, if all the initial defect densities are also equal for all the blocks, then the optimal test times for each module is proportional to its size.

Example 1 A software system uses five functional blocks B1–B5. We construct this example assuming sizes 1, 2, 3, 10, and 20 KLOC (thousand lines of code) respectively, and the initial defect densities of 20, 20, 20, 25, and 30 defects per KLOC respectively. Let us assume that measured parameter values are given in the top three rows, which are the inputs to the optimization problem. The solution obtained using equations (15) and (16) are given in the two bottom rows. Let us now minimize the test cost such that the overall failure rate is less than or equal to 0.06 per unit time. Here the time units can be hours of testing time or hours of CPU time used for testing. (See Table 1).

Note that the optimal values of λ_i for the five modules are equal, even though they start with different initial values. This requires a substantial part of the test effort allocated to largest blocks. The total cost in terms of testing is 5.835×10^3 h.

Example 2 This is identical to the previous example with one difference, the numbers in the second

row for λ_{i0} are obtained assuming all five modules have the same defect density value of 20 per KLOC. (See Table 2).

We note that for this example, the optimal testing time is exactly proportional to the software size, block B₅ is tested for 20 times the time used for B₁. The final failure rates are identical for the five blocks.

The above discussion suggests that some preliminary rules may be used for obtaining initial apportionments. Some apportionment rules have been suggested in the literature [5].

Equal reliability apportionment For example, one can test a set of software blocks, such that at the end they all individually have the failure rate equal to the target failure rate for the system.

Complexity-based apportionment For example, the software size itself is a complexity metric. Therefore, the available test time can be apportioned in proportion to the software size.

Impact-based apportionment A block that is executed more frequently, or is more critical in terms of failures, should be assigned more resources.

Reliability Allocation for Complex Systems

In practice, many cases can be complex and may require an iterative approach [1, 2, 7, 12]. Such an approach is also needed if the objective function has multiple objectives and includes both the total cost

Table 2 Input data and optimal values for Example 2

Block	B ₁	B ₂	B ₃	B ₄	B ₅
β_i	7×10^{-3}	3.5×10^{-3}	2.333×10^{-3}	7×10^{-4}	3.5×10^{-4}
λ_{i0}	0.14	0.14	0.14	0.14	0.14
x_i	0.028	0.056	0.083	0.278	0.556
Optimal λ_i	0.06	0.06	0.06	0.06	0.06
Optimal d_i	121.043	242.085	363.128	1.21×10^3	2.421×10^3

and the system reliability [1]. These steps are based on [12]:

1. Design the system using functional subsystems.
2. Perform an initial apportionment of cost or reliability attributes based on suitable apportionment rules or preliminary computation.
3. Predict system reliability.
4. Determine if reallocation is feasible and will enhance the objective function. If so, perform reallocation.
5. Repeat until optimality is achieved.
6. See if this meets the objectives. If not, consider returning to step 1 and revising the design.
7. Finalize the design with recommended reliability allocation and the cost projections.

The optimization methods used in steps 2–5 above can be classified into three approaches [1].

1. **Exact methods** When the problem is not large, exact methods can be desirable. In general, the problem can be a nonlinear optimization problem. In a few cases, the problem can be transformed into a linear problem, as shown in the example above.
2. **Heuristics-based methods** Several heuristics for reliability allocation have been developed. Many of them are based on identifying the variable to which the solution is most sensitive and incrementing its value.
3. **Metaheuristic algorithms** These algorithms are based on artificial reasoning. The best known of them are *genetic algorithms*, *simulated annealing*, and *tabu-search*. These algorithms can be useful when the search space is large and approximate results are sought.

Some general purpose [13] and special purpose [6] software tools have been developed that can simplify setting up and solving the optimal allocation problem. The reliability allocation problem can also be formulated to address other reliability attributes like availability [14] or maintainability.

Accelerated Life Tests: Classical Methods for Design and Analysis

Introduction

In today's marketplace, new high-technology components are often required to be very reliable. In addition, manufacturers are usually compelled to develop new products in record time, so that they do not lose market opportunities. For instance, items deployed in environments where replacement costs are prohibitive, such as undersea and space, have to be designed in order to operate without failure for years whereas time spent to develop new products cannot exceed half a dozen months.

Reliability of this kind of products is very important; it is vital for manufacturers to satisfy in full the requirements of the customers.

To assure achievement of the desired reliability levels, it is necessary to design for reliability since the earliest stage of the product development and complete at least the first reliability loop. In this loop, failure data collection and analysis play the essential role of feeding information back to designers.

Unfortunately, in the case of high-reliability products, the exiguous amount of failure time data that it is possible to collect carrying out tests at normal use conditions does not allow statistical analyses of practical utility. In the above cases, the only way to obtain the needed amount of data in time is to test the products in conditions more severe than normal, forcing the products to fail more quickly. Over the years, such kind of tests have been indicated as **accelerated life tests** (ALTs). The main purpose of such testing is to estimate product's reliability or long-term performances at normal use condition. This risky but unavoidable extrapolation has to be performed using appropriate statistical models and methods.

Methods for Accelerating Life Tests

There are fundamentally two different ways to compress the life of products:

- *Increasing the usage rate*: This approach can be adopted in the case of products as toasters, refrigerator pumps, rolling bearings, or automotives, whose duration is defined in terms of cycles, mileages, and so on. Time to failure can be compressed by running the product faster, as in the case of the rolling bearings, or reducing the off time, as in the case of refrigerator pumps and toasters;
- *Increasing the stress*: This approach can produce two main effects: increasing the aging rate and/or shortening product life. The first effect can be observed in the case of products and materials whose failure is due to a chemical or physical **degradation** process. The aging process can be accelerated by increasing the level of experimental factors such as temperature and humidity. The second effect can be observed in the case of materials and components that fail when their strength falls below a critical bound that increase with some experimental factors such as voltage or mechanical load. Thus, higher than normal levels of these experimental factors force these products to fail more quickly than they would under normal use conditions. For example [1, p. 479–480], certain types of insulation present a dielectric strength (i.e., breakdown voltage) that decreases with time due to a chemical degradation process. Failure occurs when breakdown voltage falls below a threshold that increases with the applied voltage level.

For many different products these strategies enable the collection of failure data in a very short time.

In the case of products whose life is compressed by increasing the usage rate, usually, the desired estimates are obtained by simply assuming that the number of cycles to failure at higher usage rate remains the same as at normal use conditions.

In the case of overstress testing, extrapolation is usually performed by adopting statistical models that can account for the effect of the stress level on the failure mechanism.

In this article, only fully parametric models for ALT data with a single constant stress are considered. Moreover, only classical **estimation** procedures are discussed. Step-stress testing and/or other estimation methods are described in **Accelerated Life Tests: Bayesian Design, Accelerated Life Tests: Stress**

Step (Classical Methods), Accelerated Life Tests: Designs Comparison within a Bayesian Framework, and Accelerated Life Tests: Nonparametric Approach.

Fully Parametric Models for ALT with a Single Constant Stress

Fully parametric ALT models are special regression models in which the failure time has a distribution that explicitly depends on the value of a vector of, possibly transformed, accelerating variables, $\mathbf{z}$, also called *covariates* or *regressors*.

Most of these models are obtained by combining a standard parametric lifetime model and a life–stress relationship. The first model describes the failure time distribution at each fixed stress level, $\mathbf{z}$, the second accounts for the effect of the **covariate** vector, $\mathbf{z}$, on the parameters of this distribution.

In statistics, regression models are well studied and have a long history; the ones used to model ALT data have the two following peculiarities:

- owing to the nonnegative nature of lifetime, ALT models are usually based on distributions such as exponential, Weibull, or lognormal, rather than on **normal distribution**;
- owing to the purpose of the analyses, these models are used to estimate the product response for values of the covariates that fall outside the test region.

The first characteristic has created the need for appropriate statistical procedures. The second one exposes to unavoidable risks of error, which can be mitigated only if sound physical or chemical justifications can be made about the adequacy of the assumed model at normal use conditions. Nevertheless, many empirical ALT models are successfully used in applications.

In this section, the most commonly used simple failure time regression models are presented, where “simple” is used to indicate that only one accelerating variable is considered. All the models presented in this paper usually apply to a single failure mode; they may be not appropriate for products that fail from more causes. Models for these products are discussed in **Accelerated Life Tests: Analysis with Competing Failure Modes**.

Simple Accelerated Failure Time Model

The accelerated failure time (AFT) model is a widely used regression model. It expresses the effect of the accelerating variable, z , on lifetime, X , as follows:

$$X_z = \frac{X_0}{\varphi(z)} \quad (1)$$

where $\varphi(z)$ is a positive function called *acceleration factor*, X_0 is the lifetime at condition z_0 for which $\varphi(z_0) = 1$, and X_z is the corresponding lifetime at z .

According to this model, the shape of the reliability function is the same at any given level of the accelerating variable, but products fail faster or slower according to the value of z . In particular, the dependence of the p th quantile of $\ln(X)$ on the stress level, z , can be expressed as:

$$\ln[x_p(z)] = \ln[x_p(0)] - \ln[\varphi(z)] \quad (2)$$

and the acceleration factor, $\varphi(z_u, z)$, between the use stress level, z_u , and a reference stress level, z , can be expressed as:

$$\varphi(z_u, z) = \frac{x_p(z_u)}{x_p(z)} = \frac{\varphi(z)}{\varphi(z_u)} \quad (3)$$

Finally, the reliability function of X_z , $R(x; z)$, and that of X_0 , $R_0(x)$, are related by the following equation:

$$R(x; z) = R_0[x \cdot \varphi(z)] \quad (4)$$

One of the most-used forms for the acceleration factor is the log-linear model:

$$\varphi(z) = \exp(-a \cdot z) \quad (5)$$

which includes, as special cases, many widely applied life–stress relationships, such as the Arrhenius, the inverse power law, and the exponential models that are presented and justified in the Appendix.

In the case of failure-causing chemical or physical reactions the AFT model can be considered adequate if the following assumptions are satisfied [1, pp. 476–477, 566; 2, p. 152]:

- there is a single rate-controlling step;
- specimens under study are degrading products that fail when degradation overcomes a critical threshold;

- both the initial degradation level and the degradation threshold for which failure occurs do not depend on stress;
- rate-acceleration parameters are *fixed-effect* parameters. For example, the use of the Arrhenius model suggests that the activation energy does not vary from unit to unit (see the section titled “Simple Log-Location Scale Regression Model with Nonconstant Spread”).

Simple Log-Location Scale Regression Model

The simple log-location scale (LLS) regression model is probably the most commonly used parametric lifetime regression model. It can be formulated as follows:

$$R(x; z) = 1 - \Phi \left[\frac{\ln x - \mu(z)}{\sigma} \right] \quad (6)$$

where $\Phi(\cdot)$ is a fully specified cumulative distribution function (**cdf**).

This model assumes that the scale parameter, σ , is the same at each stress level and that the location parameter $\mu(z)$ is a linear function of a, possibly transformed, accelerating variable:

$$\mu(z) = \gamma_0 + \gamma_1 \cdot z \quad (7)$$

where $\gamma_0 = \mu(0)$ is the location parameter at $z = 0$ and γ_1 is a constant that depends on product geometry, test method, and other factors.

The resulting model can be expressed as follows:

$$R(x; z) = 1 - \Phi \left[\frac{\ln x - (\gamma_0 + \gamma_1 \cdot z)}{\sigma} \right] \quad (8)$$

An alternative formulation of equation (8):

$$R(x; z) = 1 - \Phi_* \left[\left(\frac{x}{\exp(\gamma_0) \cdot \exp(\gamma_1 \cdot z)} \right)^\beta \right] \quad (9)$$

where $\beta = \sigma^{-1}$ and $\Phi_*(\cdot) = \Phi[\ln(\cdot)]$, shows that the LLS model is in the AFT class.

Under model (8) the p th quantile, $\ln[x_p(z)]$, of $\ln(X)$ at any given stress level z , can be obtained as:

$$\ln[x_p(z)] = \sigma \cdot \Phi^{-1}(p) + \gamma_0 + \gamma_1 \cdot z \quad (10)$$

and the acceleration factor (see equation (2)), results in the following log-linear model:

$$\varphi(z) = \exp(-\gamma_1 \cdot z) \quad (11)$$

To obtain a fully parametric model it is necessary to select the shape of $\Phi(\cdot)$, this determines the shape of the lifetime distribution at each given stress level.

The well-known Weibull and lognormal regression models are obtained by choosing a standardized smallest extreme value cdf, $\Phi_{\text{SEV}}(\cdot)$ and a standard normal cdf, $\Phi_{\text{N}}(\cdot)$, respectively:

$$\Phi_{\text{SEV}}(y) = 1 - \exp[-\exp(y)] \quad (12)$$

$$\Phi_{\text{N}}(y) = \frac{1}{\sqrt{2\pi}} \cdot \int_{-\infty}^y \exp[-(u^2/2)] \cdot du \quad (13)$$

The exponential regression model is obtained as a special case of the Weibull regression model for $\sigma = 1$. These regression models have been successfully used to fit data from single constant-stress ALTs in the case of a very broad variety of products [3, Section 2; 4; 5, p. 28; 6].

Simple Log-Location Scale Regression Model with Nonconstant Spread

The LLS regression model is not always adequate for applications. Theoretical and experimental studies have shown that the scale parameter of the log failure time often depends on stress [7, 8]. A simple model that can account for this kind of dependence is an LLS regression model in which both location and scale parameters depend on stress:

$$R(x; z) = 1 - \Phi \left[\frac{\ln x - \mu(z)}{\sigma(z)} \right] \quad (14)$$

where $\Phi[\cdot]$ is a fully specified cdf. Many authors assume for $\mu(z)$ and $\sigma(z)$ [3, p. 106; 7; 9] the simple forms:

$$\mu(z) = \gamma_0 + \gamma_1 \cdot z \quad (15)$$

$$\ln[\sigma(z)] = \nu_0 + \nu_1 \cdot z \quad (16)$$

A justification for both constant and nonconstant spread models is given in [10], where, assuming that log lifetime, $\ln X(z)$, scales according to the Arrhenius model (see Appendix):

$$\ln X(z) = \ln A + \frac{E_a}{k} \cdot z \quad (17)$$

$$z = \frac{1}{T} \quad (18)$$

it is remarked that:

- the constant spread model is obtained in the case in which A is a random variable (i.e. it varies among test units) and E_a is a constant;
- the nonconstant spread model is obtained in the case in which both A and E_a are random variables.

A potential pitfall of this model is discussed in [1, p. 442; 3, p. 107].

Simple Proportional Hazard Model

The simple proportional hazard (PH) model [11] is a very general regression model. It assumes that the effect of a possibly transformed accelerating variable, z , on the lifetime distribution can be expressed through the following product:

$$h(x; \mathbf{z}) = h_0(x) \cdot \psi(z) \quad (19)$$

where $h(x; z)$ is the hazard function for units tested at z and $h_0(x)$ is the function obtained at condition z_0 for which $\psi(z_0) = 1$.

Owing to this assumption, also called the *proportionality assumption*, the ratio of the hazard functions $h(x; z_1)$ and $h(x; z_2)$, obtained in correspondence of two different stress levels, z_1 and z_2 , respectively, are proportional to one another:

$$\frac{h(x; z_1)}{h(x; z_2)} = \frac{h_0(x) \cdot \psi(z_1)}{h_0(x) \cdot \psi(z_2)} = \frac{\psi(z_1)}{\psi(z_2)} \quad (20)$$

The reliability function at z can be obtained from the reliability function $R_0(t)$ as follows:

$$R(x; z) = R_0(x)^{\psi(z)} \quad (21)$$

where $R_0(t) = \exp\left[-\int_0^t h_0(u) \cdot du\right]$.

In the case of a fully parametric approach both $h_0(x)$ and $\psi(z)$ have to be considered specified function of unknown parameters. Most of the PH models used in ALT with a single constant stress are obtained by combining baseline hazard function of nonnegative random variables such as exponential, Weibull, or lognormal with the log-linear relation:

$$\psi(z) = \exp(b \cdot z) \quad (22)$$

Assumptions of the PH model are very different from those of the AFT model. In fact, the Weibull regression model is the only model in both classes. The PH model is largely applied in the

biomedical field [12, p. 276]. In ALTs physical and chemical considerations generally suggest the use of models such as (6) or (14) are usually adopted. Therefore the PH model, in reliability, has been prevalently adopted in the analysis of field data to model the effect of environmental factors and/or of other sources of nonhomogeneity [1, p. 458; 13, 14].

Estimation Procedures for the Simple Log-Location Scale Regression Model

ALT data usually consist of a certain number of, complete or right-censored observations, $n = \sum_{i=1}^m n_i$, taken at m different stress levels, $z_1, z_2, \dots, z_m$, with n_i observations at z_i .

These data constitute the basis for performing point and interval estimates and for checking validity of the selected regression model. Statistical procedures employed to make inference from ALT data are slightly different from those used in “classical” regression analysis for two main reasons:

- the residual distribution is nonnormal and
- observations are usually censored.

So, analysis of these data is usually performed by adopting a combination of graphical and analytical methods. Moreover the analytical approach is prevalently based on the maximum-likelihood (ML) method rather than on other classical approaches, such as least-square estimators, which in the case of ALT data are often unsatisfactory [1, p. 154; 3, pp. 240–241; 12, pp. 169, 299, 306].

Application of graphical, ML and least-square methods to models presented in the section titled “Fully Parametric Models for ALT with a Single Constant Stress” is largely discussed in literature [1, Chapters 17–19; 3, Sections 3–5; 7; 9; 12, Chapters 6, 7; 15, Chapter 9; 16, Chapter 5; 17, Chapter 7]. Herein, attention will be focused on the application of ML methods to the model (8).

Point Estimation

The likelihood function for n s -independent exact and right-censored ALT data, obtained at m different

stress levels, $z_1, z_2, \dots, z_m$, is

$$L(\gamma_0, \gamma_1, \sigma) = \prod_{i=1}^m \prod_{j=1}^{n_i} \left[\frac{1}{\sigma \cdot x_{i,j}} \phi \left(\frac{\ln x_{i,j} - \gamma_0 - \gamma_1 \cdot z_i}{\sigma} \right) \right]^{\delta_{i,j}} \times \left[1 - \Phi \left(\frac{\ln x_{i,j} - \gamma_0 - \gamma_1 \cdot z_i}{\sigma} \right) \right]^{1-\delta_{i,j}} \quad (23)$$

where $\phi(y) = \frac{d}{dy} \Phi(y)$, n_i is the number of units allocated at stress z_i , $x_{i,j}$ is the duration of the j th test run at stress z_i , and $\delta_{i,j}$ is an indicator that assumes the value 1 if the $x_{i,j}$ is uncensored and 0 if it is censored. Given the data, the maximum-likelihood estimates (MLEs) of γ_0 , γ_1 and σ are the values, $\hat{\gamma}_0$, $\hat{\gamma}_1$ and $\hat{\sigma}$, that maximize equation (23) or the corresponding log-likelihood, $l(\gamma_0, \gamma_1, \sigma)$:

$$l(\gamma_0, \gamma_1, \sigma) = \ln[L(\gamma_0, \gamma_1, \sigma)] \quad (24)$$

An alternative formulation for the likelihood function that uses the equation (9) is the following:

$$L(\gamma_0, \gamma_1, \beta) = \prod_{i=1}^m \prod_{j=1}^{n_i} \left\{ \frac{\beta \cdot x_{i,j}^{\beta-1}}{[\exp(\gamma_0 + \gamma_1 \cdot z_i)]^\beta} \times \phi_* \left[\left(\frac{x_{i,j}}{\exp(\gamma_0 + \gamma_1 \cdot z_i)} \right)^\beta \right] \right\}^{\delta_{i,j}} \times \left\{ 1 - \Phi_* \left[\left(\frac{x_{i,j}}{\exp(\gamma_0 + \gamma_1 \cdot z_i)} \right)^\beta \right] \right\}^{1-\delta_{i,j}} \quad (25)$$

where $\phi_*(y) = \frac{d}{dy} \Phi_*(y)$.

As a rule, to maximize the likelihood it is necessary to use numerical procedures. The Newton–Raphson method usually gives good results. Nevertheless, when censoring is heavy and/or the amount of data is very limited, this method often fails to converge unless the starting values are very close to the MLEs. Valid suggestions to implement solving algorithms are given in [18–20]. In [9] an efficient procedure is presented for computing the MLEs of the Weibull-generalized log-linear regression model (both with constant and nonconstant shape parameters).

It can be worth to remark that when $\Phi(\cdot) = \Phi_N(\cdot)$ and observations are all uncensored, closed-form MLEs can be readily obtained using simple linear regression theory.

Example 1 Fit the Weibull–Arrhenius regression model to the temperature ALT data displayed in Table 1 (data from [17, p. 270]) and estimate the Weibull scale parameter, α_u (i.e. the 63.2th quantile), at the use temperature of 308.15 K (35 °C).

Solution The Weibull–Arrhenius log-likelihood function for data in Table 1 can be rewritten as follows:

$$l(\gamma_0, \gamma_1, \beta) = \ln[L(\gamma_0, \gamma_1, \beta)] = r_T \cdot \ln(\beta) - r_T \cdot \beta \times \gamma_0 - \beta \cdot \gamma_1 \cdot \sum_{i=1}^m r_i \cdot z_i + (\beta - 1) \times \sum_{i=1}^m \sum_{j=1}^{r_i} \ln x_{i,j} - \exp(-\beta \cdot \gamma_0) \times \sum_{i=1}^m \exp(-\beta \cdot \gamma_1 \cdot z_i) \cdot \sum_{j=1}^{n_i} x_{i,j}^\beta \quad (26)$$

with

$$r_1 = 8, r_2 = 7, r_3 = 10, r_T = \sum_{i=1}^3 r_i = 25, n_1 = 12,$$

Table 1 Temperature-accelerated life test data of a certain type of electric module^(a)

	(5500)		2037
	(5500)		
	(5500)		

^(a)Parentheses indicate time-censored data

$$n_2 = 8, n_3 = 10, n_T = \sum_{i=1}^3 n_i = 30, m = 3,$$

$$z_1 = \frac{1}{373.15}, z_2 = \frac{1}{393.15}, \text{ and } z_3 = \frac{1}{423.15}$$

where r_i (n_i) indicates the number of modules failed (tested) at temperature T_i , z_i is the transformed stress, $x_{i,1}, x_{i,2}, \dots, x_{i,r_i}$ are failure times and $x_{i,r_i+1}, \dots, x_{i,n_i}$ are censored times.

To maximize the likelihood it is necessary to use numerical procedures. MLEs, $\hat{\gamma}_0$, $\hat{\gamma}_1$, and $\hat{\beta}$, can be obtained by directly maximizing the log-likelihood function (26).

This maximization can be simplified by adopting the following more effective approach [19]:

- obtain $\hat{\gamma}_1$ and $\hat{\beta}$ by maximizing the profile log-likelihood:

$$l^*(\gamma_1, \beta)$$

$$= -r_T \cdot \ln \left[\left(\sum_{i=1}^m \exp(-\beta \cdot \gamma_1 \cdot z_i) \cdot \sum_{j=1}^{n_i} x_{i,j}^\beta \right) / \beta \right]$$

$$- \beta \cdot \gamma_1 \cdot \sum_{i=1}^m r_i \cdot z_i + (\beta - 1) \cdot \sum_{i=1}^m \sum_{j=1}^{r_i} \ln x_{i,j}$$

$$+ r_T \cdot [\ln(r_T) - 1] \quad (27)$$

- calculate $\hat{\gamma}_0$ as

$$\hat{\gamma}_0 = \ln \left[\frac{1}{r_T} \sum_{i=1}^m \exp(-\hat{\beta} \cdot \hat{\gamma}_1 \cdot z_i) \sum_{j=1}^{n_i} x_{i,j}^{\hat{\beta}} \right]^{\frac{1}{\hat{\beta}}} \quad (28)$$

Resulting MLEs of γ_0 , γ_1 , and β are the following:

$$\hat{\gamma}_0 = -3.156, \hat{\gamma}_1 = 4930, \text{ and } \hat{\beta} = 2.27.$$

The MLE, $\hat{\alpha}_u$, of the Weibull scale parameter at 308.15 K, α_u , can be obtained as

$$\hat{\alpha}_u = \exp \left(\hat{\gamma}_0 + \hat{\gamma}_1 \cdot \frac{1}{308.15} \right) = 65532.97 \text{ h} \quad (29)$$

Normal Approximation Confidence Intervals

Approximate $(1 - \alpha)\%$ **confidence intervals** for the parameters γ_0 , γ_1 , and σ can be computed by

adopting the following relationships:

$$\left[\hat{\theta}_i + \Phi_N^{-1}(\alpha/2) \cdot \sqrt{\widehat{\text{Asvar}}(\hat{\theta}_i)}, \hat{\theta}_i + \Phi_N^{-1}(1 - \alpha/2) \right. \\ \left. \times \sqrt{\widehat{\text{Asvar}}(\hat{\theta}_i)} \right]; \quad \theta_1 = \gamma_0, \theta_2 = \gamma_1, \theta_3 = \sigma \quad (30)$$

that are based on the assumption that the quantities

$$\frac{\hat{\theta}_i - \theta_i}{\sqrt{\widehat{\text{Asvar}}(\hat{\theta}_i)}}; \quad \theta_1 = \gamma_0, \theta_2 = \gamma_1, \theta_3 = \sigma \quad (31)$$

can be approximated by standard normal, $N(0, 1)$, random variables.

These intervals make use of the elements of the local estimate, $\hat{\Sigma}_{\hat{\gamma}_0, \hat{\gamma}_1, \hat{\sigma}}$, of the asymptotic variance–**covariance** matrix, $\Sigma_{\hat{\gamma}_0, \hat{\gamma}_1, \hat{\sigma}}$, of $\hat{\gamma}_0$, $\hat{\gamma}_1$, and $\hat{\sigma}$:

$$\hat{\Sigma}_{\hat{\gamma}_0, \hat{\gamma}_1, \hat{\sigma}}$$

$$= \begin{bmatrix} \widehat{\text{Asvar}}(\hat{\gamma}_0) & \widehat{\text{Ascov}}(\hat{\gamma}_0, \hat{\gamma}_1) & \widehat{\text{Ascov}}(\hat{\gamma}_0, \hat{\sigma}) \\ \text{Symmetric} & \widehat{\text{Asvar}}(\hat{\gamma}_1) & \widehat{\text{Ascov}}(\hat{\gamma}_1, \hat{\sigma}) \\ & & \widehat{\text{Asvar}}(\hat{\sigma}) \end{bmatrix} = I_0^{-1}$$

$$= \begin{bmatrix} -\frac{\partial^2 \ln L}{\partial \gamma_0^2} & -\frac{\partial^2 \ln L}{\partial \gamma_0 \cdot \partial \gamma_1} & -\frac{\partial^2 \ln L}{\partial \gamma_0 \cdot \partial \sigma} \\ & -\frac{\partial^2 \ln L}{\partial \gamma_1^2} & -\frac{\partial^2 \ln L}{\partial \gamma_1 \cdot \partial \sigma} \\ \text{Symmetric} & & -\frac{\partial^2 \ln L}{\partial \sigma^2} \end{bmatrix}_{(\hat{\gamma}_0, \hat{\gamma}_1, \hat{\sigma})}^{-1} \quad (32)$$

where I_0 is the observed information matrix, evaluated at $(\hat{\gamma}_0, \hat{\gamma}_1, \hat{\sigma})$, and I_0^{-1} is its inverse.

A better estimate, $\hat{\Sigma}_{\hat{\gamma}_0, \hat{\gamma}_1, \hat{\sigma}}$ (i.e., the so-called **MLE**), of $\Sigma_{\hat{\gamma}_0, \hat{\gamma}_1, \hat{\sigma}}$ can be obtained evaluating at $(\hat{\gamma}_0, \hat{\gamma}_1, \hat{\sigma})$ the inverse of the information matrix I :

$$I =$$

$$\begin{bmatrix} -E \left(\frac{\partial^2 \ln L}{\partial \gamma_0^2} \right) & -E \left(\frac{\partial^2 \ln L}{\partial \gamma_0 \cdot \partial \gamma_1} \right) & -E \left(\frac{\partial^2 \ln L}{\partial \gamma_0 \cdot \partial \sigma} \right) \\ & -E \left(\frac{\partial^2 \ln L}{\partial \gamma_1^2} \right) & -E \left(\frac{\partial^2 \ln L}{\partial \gamma_1 \cdot \partial \sigma} \right) \\ \text{Symmetric} & & -E \left(\frac{\partial^2 \ln L}{\partial \sigma^2} \right) \end{bmatrix} \quad (33)$$

For most models $\hat{\Sigma}_{\hat{\gamma}_0, \hat{\gamma}_1, \hat{\sigma}}$ cannot be expressed in closed form. Moreover the use of $\hat{\Sigma}_{\hat{\gamma}_0, \hat{\gamma}_1, \hat{\sigma}}$ does not give clear theoretical advantages with respect to $\hat{\Sigma}_{\hat{\gamma}_0, \hat{\gamma}_1, \hat{\sigma}}$ [3, p. 369; 12, p. 301].

This normal approximation is usually poor for small samples. When θ is a non negative parameter a *positive* confidence interval can be obtained by adopting the following approximation [1, p. 163; 17, p. 277]:

$$\frac{\ln(\hat{\theta}) - \ln(\theta)}{\sqrt{\widehat{\text{Asvar}}[\ln(\hat{\theta})]}} \sim N(0, 1) \quad (34)$$

the resulting $(1 - \alpha)\%$ two-sided approximate confidence interval is:

$$\left\{ \hat{\theta} \cdot \exp \left[\Phi_N^{-1}(\alpha/2) \cdot \frac{\sqrt{\widehat{\text{Asvar}}(\hat{\theta})}}{\hat{\theta}} \right], \right. \\ \left. \times \hat{\theta} \cdot \exp \left[\Phi_N^{-1}(1 - \alpha/2) \cdot \frac{\sqrt{\widehat{\text{Asvar}}(\hat{\theta})}}{\hat{\theta}} \right] \right\}$$

where the approximate identity

$$\widehat{\text{Asvar}}[\ln(\hat{\theta})] = \frac{\widehat{\text{Asvar}}(\hat{\theta})}{\hat{\theta}^2} \quad (35)$$

has been obtained adopting the δ method [1, p. 619].

More accurate confidence intervals can be obtained by adopting the likelihood ratio or other nonstandard methods [1, p. 438; 3, Section 5.8; 12, Chapter 6; 21]. Exact confidence intervals have been developed in the case of singly failure censored data for the exponential [22] and the Weibull regression models [23].

Checking Model Assumptions Using Graphical Methods

Adequacy of the simple LLS model can be assessed by analyzing the standardized **residuals**. For the model (8) these can be expressed as follows [1, p. 443]:

$$\hat{e}_{i,j} = \exp \left[\frac{\ln x_{i,j} - (\hat{\gamma}_0 + \hat{\gamma}_1 \cdot z_i)}{\hat{\sigma}} \right] \\ = \left(\frac{x_{i,j}}{\exp(\hat{\gamma}_0) \cdot \exp(\hat{\gamma}_1 \cdot z_i)} \right)^{\hat{\beta}} \quad (36)$$

where $\hat{\gamma}_0$, $\hat{\gamma}_1$, $\hat{\sigma}$ and $\hat{\beta} = 1/\hat{\sigma}$ are MLEs. Residuals, $e_{i,j}$, is censored if corresponding observation, $x_{i,j}$, is censored. In the case of censored data, the single sample of residuals is usually multiply censored.

The overall adequacy of the fitted model can be tested making a **probability plot** of the residuals. For example, a Weibull probability chart can be used with $\Phi(\cdot) = \Phi_{\text{SEV}}(\cdot)$ and a lognormal probability chart can be used for $\Phi(\cdot) = \Phi_N(\cdot)$. If the departure from linearity is not “strong” the model can be considered adequate.

A valid alternative to use residuals (36) consists in plotting on a probability chart the following *translated* data [3, p. 251]:

$$\hat{y}_{i,j} = \frac{x_{i,j}}{\exp[\hat{\gamma}_1 \cdot (z_i - z_u)]}; \quad i = 1, 2, \dots, m; \\ j = 1, 2, \dots, n_i \quad (37)$$

which can be thought of as their *equivalent* at the use stress level z_u .

In this case, the ML fit of the cdf at use stress level z_u can be plotted on the probability chart along with the *equivalent* data $\hat{y}_{i,j}$, to investigate potential deficiency of the overall model. This plot can also be used to perform graphical estimates of characteristics of the lifetime distribution at use condition. Values, $\hat{y}_{i,j}$, corresponding to censored observations $x_{i,j}$ have to be considered censored. As in the case of residuals (36), in the presence of censoring, the simple sample of *equivalent* data is usually multiply censored.

Specific causes of departure from the fitted model can be identified by making a multiple probability plot of the data, $x_{i,j}$, obtained at each stress level. The fitted model can be considered adequate if:

- data obtained at different stress levels depict approximately parallel straight lines on a “proper” probability chart;
- estimates of the characteristic life (e.g. the scale parameter), obtained at different stress levels, z_i , depict a straight line (see equation (10)) on a paper which has a log scale for characteristic life and a linear scale for the, possibly transformed, stress, z , where, for example, it is $z = 1/T$ for the Arrhenius model and $z = \ln V$ for the inverse power law model (see Appendix).

Finally, the ML fits of the “individual” cdfs obtained at each of the stress levels, z_i , can be plotted on the probability chart, along with the data, $x_{i,j}$, to identify potential deficiencies of the overall model at specific stress levels. Details about the application of

8 Accelerated Life Tests: Classical Methods

graphical methods in ALT are given in [1, Chapters 18, 19; 3, Section 3].

Example 2 Check adequacy of the Weibull–Arrhenius regression model for data of Example 1.

Solution The overall adequacy of model can be checked by plotting on a Weibull probability chart the single sample of equivalent data displayed in Table 2.

Equivalent data have been calculated adopting equation (37) with:

$$z_1 = \frac{1}{373.15}, \quad z_2 = \frac{1}{393.15}, \quad z_3 = \frac{1}{423.15},$$

$$z_u = \frac{1}{308.15}, \quad \text{and } \hat{\gamma}_1 = 4930$$

where $\hat{\gamma}_1$ is the MLE of γ_1 (see Example 1).

The plotting position, F_i , for the i th-ordered failure has been obtained *via* the Herd–Johnson method [24, p. 149]:

$$F_i = \prod_{j=1}^i \left(\frac{r_j}{r_j + 1} \right)^{\delta_j} \quad (38)$$

where r_j (see Table 2) is the reverse rank of the j th ordered observation, and δ_j is an indicator that assumes the value 1 if the j th observation is uncensored and 0 if it is censored. Only failure data are plotted on the probability chart. The Weibull probability plot of the equivalent data along with the ML fit of the cdf (see Example 1) at use stress level, z_u , are displayed in Figure 1.

Table 2 Equivalent data at $T = 308.15 \text{ K}^{(a)}$

r_i	Time (h)	r_i	Time (h)	r_i	Time (h)	r_i	Time (h)	r_i	Time (h)
30	13610.96	24	33762.09	18	50679.73	12	61464.59	6	80347.05
29	20170.81	23	34039.35	17	52155.94	11	(65782.30)	5	80556.62
28	23251.05	22	34207.19	16	54028.95	10	(65782.30)	4	91056.79
28	24393.29	21	38823.52	15	55989.24	9	(65782.30)	3	93068.79
26	31216.73	20	40245.56	14	58796.32	8	(65782.30)	2	97828.42
25	33058.60	19	45485.47	13	60352.27	7	66611.69	1	(97921.34)

^(a)Parentheses indicate time-censored data

Figure 1 Weibull plot of equivalent data at use temperature, $T = 308.15 \text{ K}$

Figure 2 Weibull multiple probability plot with individual Weibull ML fits at each temperature

Departure from linearity in Figure 1 is not “strong”, so the model can be considered adequate.

Specific causes of departures from the fitted model can be investigated making a multiple probability plot of individual samples, $x_{i,j}$, obtained at each stress level.

The plotting position, $F_{i,j}$, for the j th-ordered failure at temperature T_i has been calculated as:

$$F_{i,j} = \frac{j - 0.5}{n} \quad (39)$$

Censored data are not reported on the plot. Figure 2 shows the multiple probability plot along with the individual ML fits of the Weibull cdf at each temperature.

Individual MLEs of $\hat{\alpha}_i$ and $\hat{\beta}_i$ at each temperature have been obtained by solving, *via* numerical methods, the following system of equations:

$$\frac{\sum_{j=1}^{n_i} x_{i,j}^{\hat{\beta}_i} \ln(x_{i,j})}{\sum_{j=1}^{n_i} x_{i,j}^{\hat{\beta}_i}} - \frac{1}{\hat{\beta}_i} - \frac{1}{r_i} \cdot \sum_{j=1}^{r_i} \ln(x_{i,j}) = 0 \quad (40)$$

$$\hat{\alpha}_i = \left[\frac{1}{r_i} \sum_{j=1}^{n_i} x_{i,j}^{\hat{\beta}_i} \right]^{1/\hat{\beta}_i} \quad (41)$$

The resulting MLEs are reported in Table 3.

Table 3 Individual ML estimates of the Weibull parameters at each temperature

Individual MLE	$T_1 = 373.15 \text{ K}$	$T_2 = 393.15 \text{ K}$	$T_3 = 423.15 \text{ K}$
$\hat{\alpha}_i$	5215.54	3326.84	1337.54
$\hat{\beta}_i$	2.05	2.41	2.45

Data relative to different stress levels depict approximately straight lines on the Weibull probability chart, hence the lifetime at each different stress level can be considered Weibull distributed. Moreover these straight lines are roughly parallel. So it is possible to assume that these Weibull models have the same shape parameter.

Figure 3 Arrhenius plot of individual MLE of α_i versus T_i

Figure 4 Weibull multiple probability plot with ML fits of Weibull–Arrhenius model at each temperature

Validity of the Arrhenius relationship can be assessed by plotting each individual MLE (see Table 3) of the scale parameter, α_i , against its temperature, T_i , on a paper that has a log scale for α_i and a reciprocal scale for T_i . The resulting plot is displayed in Figure 3. The straight line on this plot is fitted by eye. Departure from linearity is not strong, so the Arrhenius model can be considered adequate.

Finally, Figure 4 shows a multiple probability plot of original data along with ML fits at each temperature. This plot shows no strong evidence of **lack of fit** of the overall model at any stress level.

Planning Test for the Simple Log-Location Scale Regression Model

Planning ALTs for the model (8) consists in choosing: a set of constant values of the accelerating stress; the number of units to test at each stress level; an optimization criterion and a type of censoring, if any. The purpose of developing ALT plans is that of obtaining good estimates respecting cost and time constraints. Traditional test plans, such as those used for analysis of variance (ANOVA) and classical regression analysis, normally consider equal number of units at each stress level. Moreover test levels are usually equally spaced over the test region. These kind of plans that perform well when the aim is to estimate product response at levels that fall within the experimental

region are not appropriate for ALTs. In fact, estimates from ALT data are more accurate when more units are tested at low rather than at high stress levels [1, p. 537]. The most-used optimization criteria for developing an ALT plan is the minimization of the asymptotic variance of the estimator of a quantile of interest, $x_p(z_u)$, at normal use conditions, z_u . As an alternative, when the interest is less focused, a useful *general purpose* criterion is to minimize the determinant $|\Sigma_{\hat{\gamma}_0, \hat{\gamma}_1, \hat{\sigma}}|$ of the asymptotic variance–covariance matrix, $\Sigma_{\hat{\gamma}_0, \hat{\gamma}_1, \hat{\sigma}}$. Most plans consider type I censoring. Some consider complete samples and type II censoring. Test plans for complete samples are given in [3, Section 6.1]. In the next section the basic principles for developing optimum censored ALT plans for the simple LLS model are briefly described. Details about theory for optimum type I censored ALT plans are given in [25, 26]. The main problem with this kind of plan is that it uses only two stress levels. This does not allow the validity of the assumed life–stress relationship to be checked (see Example 2). Moreover, they do not allow estimation of the model parameters when there are no failures at one of these two stress levels. Hence, these plans are often not of practical utility. Nevertheless, optimum plans have minimum variance and can be used as a reference to evaluate performances of alternative solutions. To overcome limitations of optimum plans, various authors have developed *compromise* test plans that are robust and have good performances. Compromise plans and plans with more than one

accelerating variable may be found, for example, in [1, Chapter 20; 3, Section 6; 17, Chapter 7]. Plans for the simple LLS model with nonconstant spread are described in [7]. An updated bibliography of ALT plans is provided in [27, 28].

Theoretical Derivation of an Optimum ALT Plan

The optimum experimental plan considered in this section consists of

- two stress levels: the low level, z_1 , and the high level, z_2 , both higher than the normal one, z_u ;
- $n \cdot \pi_1$ units, randomly chosen among n , to test at level z_1 and the remaining $n \cdot \pi_2 = n \cdot (1 - \pi_1)$ to test at level z_2 ;
- a common censoring time, η .

It is assumed that

- censoring time and sample size are prefixed to respect cost and time constraints.
- the high stress level z_2 is given. The accuracy of estimates increases with z . Thus, in practice, z_2 is chosen to be the higher value of z under which the assumed stress–life relation holds.

The aim of the plan considered in this section is to determine the value of the design factors z_1 and π_1 that minimize the asymptotic variance, $\text{Asvar}[\ln(\widehat{x_p(z_u)})]$, of the MLE, $\ln(\widehat{x_p(z_u)})$, of the quantile $\ln(x_p(z_u))$.

We have:

$$\ln[\widehat{x_p(z_u)}] = \hat{\gamma}_0 + \hat{\sigma} \cdot \Phi^{-1}(p) + \hat{\gamma}_1 \cdot z_u \quad (42)$$

given the asymptotic variance–covariance matrix:

$$\begin{aligned} \sum_{\hat{\gamma}_0, \hat{\gamma}_1, \hat{\sigma}} &= \begin{bmatrix} \text{Asvar}(\hat{\gamma}_0) & \text{Ascov}(\hat{\gamma}_0, \hat{\gamma}_1) & \text{Ascov}(\hat{\gamma}_0, \hat{\sigma}) \\ & \text{Asvar}(\hat{\gamma}_1) & \text{Ascov}(\hat{\gamma}_1, \hat{\sigma}) \\ \text{Symmetric} & & \text{Asvar}(\hat{\sigma}) \end{bmatrix} \\ &= I^{-1} \end{aligned} \quad (43)$$

the following expression for the $\text{Asvar}[\ln(\widehat{x_p(z_u)})]$ is readily obtained:

$$\begin{aligned} \text{Asvar}[\ln(\widehat{x_p(z_u)})] &= \text{Asvar}(\hat{\gamma}_0) + [\Phi^{-1}(p)]^2 \\ &\quad \times \text{Asvar}(\hat{\sigma}) + z_u^2 \cdot \text{Asvar}(\hat{\gamma}_1) \\ &\quad + 2 \cdot \Phi^{-1}(p) \cdot \text{Ascov}(\hat{\gamma}_0, \hat{\sigma}) \\ &\quad + 2 \cdot z_u \cdot \text{Ascov}(\hat{\gamma}_0, \hat{\gamma}_1) + 2 \\ &\quad \times \Phi^{-1}(p) \cdot z_u \text{Ascov}(\hat{\gamma}_1, \hat{\sigma}) \end{aligned} \quad (44)$$

Given that $\sum_{\hat{\gamma}_0, \hat{\gamma}_1, \hat{\sigma}}$ cannot be obtained in closed form, the values of z_1 and π_1 that minimize the $\text{Asvar}[\ln(\widehat{x_p(z_u)})]$ must be obtained by adopting appropriate numerical procedures.

It is important to remark that in the case of censored data, $\text{Asvar}[\ln(\widehat{x_p(z_u)})]$ depends on the unknown parameters, γ_0 , γ_1 , and σ , that one wants to estimate [3, p. 331]. So, to calculate optimum plans one needs to use in their place values obtained from experience, or from preliminary tests. An optimum plan that uses tentative values is, in general, better than plans devised by other means. Nevertheless, it is only locally optimum, hence it is strongly recommended to test the robustness of the procedure by performing a sensitivity analysis over the region in which the true values plausibly fall.

Practical charts for calculating optimum plans are given in [29, 30]. These charts give the optima extrapolation factor, ξ^* , and proportion, π_1^* as a function of the standardized censoring time, a , and slope, b , where:

$$\xi^* = \frac{z_2 - z_u}{z_2 - z_1^*} \quad (45)$$

$$a = \frac{\eta - (\gamma_0 + \gamma_1 \cdot z_2)}{\sigma} \quad (46)$$

$$b = \frac{\gamma_1 \cdot (z_u - z_2)}{\sigma} \quad (47)$$

Calculation of a and b requires tentative values for γ_0 , γ_1 , and σ (censoring time η and high stress level z_2 are given). The optimum low level z_1^* can be calculated as follows:

$$z_1^* = z_2 - \xi^*(z_2 - z_u) \quad (48)$$

Concluding Remarks

Inference from ALT data involves extrapolation in stress. One of the key problems in ALTs is to determine whether the model that fits data obtained under accelerated experimental conditions is able to fit data under normal use condition or not. The use of models that have a sound physical or chemical justification can help to mitigate the risk of making dangerous errors. Nevertheless, many serious pitfalls (see [31] for an extensive analysis of this topic) can be caused by ALT.

The use of sensitive analysis can help to develop robust procedures and evaluate the consequences of model misspecifications. Nevertheless, not exaggerating the overstress level is always the best solution [32], even if this leads again to a reduction of failure data.

In particular, with regard to the models presented in this paper, it is important to remark that they are for single-failure modes and simple failure-causing processes. Thus, their use can be considered adequate, for the aforementioned extrapolation, only if overstress accelerates the mechanism of failure under study without altering its nature or inducing other failure modes.

Analyses of ALT data in presence of more, detected or undetected, causes of failure or failure masking, have to be faced by adopting specific methods and models (*see Accelerated Life Tests: Analysis with Competing Failure Modes; Masked Failure Data*).

Appendix

Life–Stress Relationships

The models presented in this appendix are three of the most widely used to express the dependence of lifetime on a single accelerating variable. They are for constant-stresses and single-failure modes.

Their adequacy has been empirically demonstrated for many products; nevertheless, their use can often be theoretically justified.

On the other hand, for the same theoretical arguments, they can be considered adequate for extrapolation only if the separation between test and use conditions is limited.

Arrhenius Model. The Arrhenius life–stress relationship is widely employed to model the effect of temperature on lifetime of degrading product that fail when degradation overcomes a critical threshold. It can be satisfactorily applied in the case of simple failure-causing chemical or physical reactions (i.e., a single rate-controlling step exists, and that step is either a diffusion or an n th order chemical reaction [33]). According to this model, the dependence between the product characteristic life, τ , (i.e. the median or a given quantile of the lifetime) and the test temperature, T (absolute kelvin), can be expressed as

follows:

$$\tau = A \cdot \exp\left(\frac{E_a}{k \cdot T}\right) \quad (\text{A1})$$

where E_a is the activation energy (eV), k is the Boltzmann's constant (eV K⁻¹), and A is a constant that depends on product geometry, test methods, and other factors.

The acceleration factor between life, τ_u , at use temperature, T_u , and life τ at a given reference temperature, T , can be expressed as:

$$\varphi(T_u, T) = \frac{\tau_u}{\tau} = \exp\left[\frac{E_a}{k} \left(\frac{1}{T_u} - \frac{1}{T}\right)\right] \quad (\text{A2})$$

Appropriateness of the model has been confirmed experimentally for many product and materials [3, p. 75].

Inverse Power Law Model. The inverse power law model is an empirical relationship that is widely used to model the life–stress relationship in many different ALTs. As an instance, it has been successfully applied in accelerated voltage tests of insulators, accelerated thermal fatigue tests of metals, and in accelerated mechanical load tests of rolling bearings [3, p. 85]. Other popular models such as the Coffin–Manson relationship and the Palmgren equation can be considered special characterization of inverse power law model.

This life–stress model expresses the dependence between the product characteristic life, τ , and the applied stress as follows:

$$\tau = A \cdot S^{-c} \quad (\text{A3})$$

where the parameters A and c (usually called the *power*) are constants whose values depend on product geometry, test methods, and other factors.

The acceleration factor between life τ_u , at normal use stress level S_u and life, τ , at reference stress S and can be expressed as:

$$\varphi(S_u, S) = \frac{\tau_u}{\tau} = \left(\frac{S}{S_u}\right)^c \quad (\text{A4})$$

A justification for this model in the case of voltage-stress acceleration of insulators is given in [1, p. 482].

Exponential Relationship. According to this model, the relationship between life and a possibly transformed stress, S , can be expressed as follows:

$$\tau = \exp(a_1 - a_2 \cdot S) \quad (\text{A5})$$

The acceleration factor between life, τ_u , at use stress, S_u , and life τ at a given reference stress, S , is:

$$\varphi(S_u, S) = \frac{\tau_u}{\tau} = \exp[a_2(S - S_u)] \quad (\text{A6})$$

The use of this model is considered adequate for many electronic components [3, p. 96].

Accelerated Life Tests: Bayesian Design

Introduction and Overview

Accelerated life tests (ALTs) involve testing systems in an environment that is more severe than the use environment and using the data collected in the accelerated environment for inferring failure behavior in the use environment. The design problem in accelerated life testing is concerned with specification of the number and magnitude of the accelerated stress levels, and the number of items to be tested at these stress levels.

Most of the Bayesian literature in ALTs have focused on developing inference methods; see for example, Mazzuchi and Soyer [1], van Dorp *et al.* [2], Mazzuchi *et al.* [3], and van Dorp and Mazzuchi [4, 5]. The majority of the work published on design of ALTs relied on sample theoretic methods; see for example, the text by Nelson [6] and the recent bibliography of accelerated testing plans by Nelson [7, 8]. Exceptions to these are the earlier Bayesian papers by Martz and Waterman [9], DeGroot and Goel [10], and more recent Bayesian approaches by Menzefricke [11], Chaloner and Larntz [12], Polson [13], Verdinelli *et al.* [14], Soyer and Vopatek [15], Erkanli and Soyer [16], and Zhang and Meeker [17].

Most of these Bayesian approaches are based on the theory of optimal Bayesian designs for linear models as in Chaloner [18]. Thus, the results are applicable to ALT designs when the **life model** is normal or lognormal. For example, Chaloner and Larntz [12] consider Bayesian designs for type I censored tests when there is uncertainty about whether the underlying life model is lognormal or Weibull, and several fractiles of the life length distribution at the use stress are of interest. The optimality criterion considered by authors is proportional to the expected asymptotic variance of the fractiles of interest. Designs satisfying this criterion are identified using numerical methods. This approach can be considered as a Bayesian version of the sample theoretic methods considered in Nelson [6]. Menzefricke [11] formulates a Bayesian approach to the **optimal design** of type II censored ALTs for use when the life length model is lognormal. Verdinelli *et al.* [14] identify a design for a complete ALT

that maximizes utility, as represented by Shannon information, given the usual linear model assumptions. More recent work by Zhang and Meeker [17] also considers some large sample results for Bayesian ALT designs as well as simulation-based methods.

As noted by Vopatek [19] and Soyer and Vopatek [15], if the underlying life models are exponential or Weibull, nonlinearities arise in the analysis, and then optimal designs can be obtained by use of either numerical methods or special techniques such as linear Bayesian methods. Recent advances in statistical computing, nonparametric surface estimation, and implementation of **Markov chain Monte Carlo** (MCMC) methods have contributed to the development of computationally efficient methods for optimal designs. For example, recent simulation-based approach of Muller and Parmigiani [20] and its extensions presented by Muller [21] have been considered in ALT designs. Erkanli and Soyer [16] have used this approach for fixed (nonsequential) designs and developed an extension to sequential designs.

In this article, we some recent Bayesian approaches in ALT Designs are reviewed. By doing so, the Bayesian decision theoretic setup for the optimal ALT design problem following Polson [13] and Erkanli and Soyer [16] is presented. This setup is adopted to a single-point design problem and difficulties involved in evaluation of preposterior losses in the implementation of the Bayesian paradigm are illustrated. Linear Bayesian methods and Monte Carlo-based approaches to alleviate some of these difficulties are presented. Finally the implementation of a simulation-based design algorithm using the approach of Muller and Parmigiani [20] is dealt with.

Bayesian Decision Theoretic Setup for the Optimal Design Problem

In Bayesian paradigm, the optimal design problem can be viewed as a decision problem in the sense of Lindley [22]. Thus, the optimal designs are chosen by maximizing expected utility. As noted by Polson [13], this provides a formal approach to the design of experiments. A comprehensive review of Bayesian experimental design can be found in Chaloner and Verdinelli [23].

Erkanli and Soyer [16] point out that the Bayesian approach to the optimal design problem requires specification of three components:

2 Accelerated Life Tests: Bayesian Design

1. a utility (loss) function that reflects the consequences of selecting a specific design;
2. a probability model;
3. a prior distribution reflecting designer's *a priori* beliefs about all unknown quantities.

Let d denote a specific design, that is, the decision variable, λ_u , the failure characteristic of interest (such as the use environment failure rate) and, a , an action based on data (for example, a prediction for λ_u). We denote the utility function as $U(\lambda_u, d, a)$ and the probability model as $p(D|\lambda_u, d)$ where D is the data observed from experiment d . Prior beliefs about λ_u are described by the prior distribution $p(\lambda_u)$. It is possible that λ_u may be a vector or a function of several parameters. Once the design d is specified and the ALT is performed, data D is observed and uncertainty about λ_u is revised according to the laws of probability. Then, the optimal action a is chosen on the basis of the data. This process can be depicted by the decision tree in Figure 1.

In Figure 1, the decision node D_2 represents selection of the Bayes rule a given data. For the case of squared error loss $L(\lambda_u, d, a)$, the utility function is $U(\lambda_u, d, a) = -(\lambda_u - a)^2$ and the optimal Bayes rule a^* is the posterior mean. Then the last two nodes can be replaced by $U(\lambda_u, d, a^*) = -V(\lambda_u|D, d)$, which is the posterior variance of λ_u and the optimal design is chosen by minimizing the preposterior variance

$$E_{D|d}[V(\lambda_u|D, d)] = \int V(\lambda_u|D, d) p(D|\lambda_u, d) \times p(\lambda_u) d\lambda_u dD \quad (1)$$

In other words, the optimal design is given by $d^* = \operatorname{argmin}\{E_{D|d}[V(\lambda_u|D, d)]\}$.

As pointed out by Erkanli and Soyer [16], this solution is obtained as a result of “folding back” the decision tree through taking expectations at random nodes and maximizing the expected utility at the decision nodes of Figure 1. The above setup can be adopted for any form of the utility function

Figure 1 Decision tree for the design problem

$U(\lambda_u, d, a)$. For example, Verdinelli *et al.* [14] used the Shannon's information as the utility function. Thus, in general the optimal design is obtained as

$$d^* = \operatorname{argmax}_d \{E_{D|d}[U(\lambda_u, d, a^*)|D, d]\} \quad (2)$$

where $a^* = \operatorname{argmax}\{E_{\lambda_u|D, d}[U(\lambda_u, d, a)|D, d]\}$. In what follows, an example of the decision theoretic setup assuming exponential lifetimes is presented.

Example: Single Stress ALT Designs

An important component of the ALTs is the time transformation function (or the acceleration function) that describes the relationship between the failure characteristic of interest and the applied level of the stress variable.

Let λ_i denote the failure rate at the accelerated stress environment S_i , assuming that life length X_i is exponential with λ_i and the time transformation function is given by the power law model

$$\lambda_i = \alpha S_i^\beta \quad (3)$$

Let us consider the design of an ALT where n items will be tested until failure at a single accelerated stress environment S_i with the purpose of making inference about $\lambda_u = \alpha S_u^\beta$, the failure rate at the use stress environment. Such Single-point designs have been considered by Martz and Waterman [9].

In the above case, the design problem is to find the stress level S_i minimizing the preposterior variance of λ_u . In other words, in our setup, we assume that the design variable $d = S_i$ and the loss function is given by $L(\lambda_u, d, a) = (\lambda_u - a)^2$. Thus, the design problem requires computation of

$$S_i^* = d^* = \operatorname{argmin}\{E_{D|d}[V(\lambda_u|D, d)]\} \quad (4)$$

In other words, our decision problem in Figure 1 reduces to a single-stage problem. For illustrative purposes, we assume that β is known and we specify a gamma prior distribution for α with shape parameter a and scale b . Given n failures $D = (x_1, x_2, \dots, x_n)$ the posterior distribution of α is given by a gamma density denoted as $[G(a + n), (b + S_i^\beta T_i)]$, where T_i is the **total time on test** at stress environment S_i . Using the power law model,

the posterior variance of λ_u is

$$V(\lambda_u|D, S_i) = V(\alpha S_u^\beta|D, S_i) = \frac{(a+n)(S_u/S_i)^{2\beta}}{\left(T_i + \frac{b}{S_i^\beta}\right)^2} \quad (5)$$

It can be shown that the preposterior variance $E_{D|d}[V(\lambda_u|D, S_i)]$ is given by

$$V(\lambda_u|S_i) = \frac{a(a+1)S_u^{2\beta}}{(a+n+1)b^2} \quad (6)$$

where the expectation is with respect to the predictive distribution of T_i given S_i (Erkanli and Soyer 16). Since equation (6) is not a function of the stress S_i , it does not matter at what stress level the items are tested. This is due to the fact that β is assumed to be known in the power law model. This result was also noted by Vopatek [19] and Verdinelli *et al.* [14] for the special case of the power law with $\beta = 1$.

In general, except in a few special cases, the optimal designs in equations (1) and (2) cannot be obtained analytically. In ALT models where the underlying failure distribution is exponential or Weibull, posterior and/or predictive inferences are not in closed form. Thus, an evaluation of the designs in equations (1) and (2) requires use of either approximation techniques such as linear Bayesian methods as in Soyer and Vopatek [15] or Monte Carlo methods as in Erkanli and Soyer [16] and Zhang and Meeker [17].

Linear Bayesian Designs for ALTs

In the power law model example in the section titled “Example: Single Stress ALT Designs”, if the coefficient β is unknown, then the posterior variance $V(\lambda_u|D, S_i)$ cannot be obtained in closed form for any prior specification for β in the case of exponential lifetimes. One way to deal with this problem is to consider approximate Bayesian designs using linear Bayesian methods.

Soyer and Vopatek [15] consider the power law model in equation (3) with exponential lifetimes where both α and β are treated as unknown. The authors describe their uncertainty about these unknown quantities partially by specifying only the first- and second-order **moments**. More specifically,

they consider the log transformation of the power law model as

$$\eta_i = \log \lambda_i = \log \alpha + \beta \log S_i = \mathbf{F}_i' \boldsymbol{\theta} \quad (7)$$

where $\mathbf{F}_i' = (1 \log S_i)$ and $\boldsymbol{\theta} = (\log \alpha \beta)$. Prior to testing at S_i distribution of $\boldsymbol{\theta}$ is partially specified as $\boldsymbol{\theta} \sim (\mathbf{m}_0, \mathbf{C}_0)$. Following Mazzuchi and Soyer [1], the prior moments can be used in equation (7) to specify a log-gamma distribution as the prior for η_i with parameters a_i and b_i selected such that

$$\Psi(a_i) - \log b_i = \mathbf{F}_i' \mathbf{m}_0 \text{ and } \Psi'(a_i) = \mathbf{F}_i' \mathbf{C}_0 \mathbf{F}_i \quad (8)$$

where $\Psi(\bullet)$ and $\Psi'(\bullet)$ are the digamma and trigamma functions, respectively. Note that complete specification of the prior for η_i (and thus for λ_i) enables us to obtain the posterior distribution for η_i after testing at S_i . Under the assumption of no censoring, standard Bayesian conjugate analysis shows that the posterior distribution of η_i is a log-gamma density with parameters $(a_i + n)$ and $(b_i + T_i)$, where n is the total number of items tested under environment S_i and T_i is the total time on test.

To obtain the posterior variance $V(\eta_u|D, S_i)$ or $V(\lambda_u|D, S_i)$, it is necessary to update $\boldsymbol{\theta} = (\log \alpha \beta)$. Since prior distribution of $\boldsymbol{\theta}$ is only partially specified through moments, one can only update the moments given the data. This updating is done *via* using the linear Bayesian methods. Soyer and Vopatek [15] show that the posterior moments of $\boldsymbol{\theta}$ are given by

$$\mathbf{m}_i = \mathbf{m}_0 + \mathbf{h}_i \frac{E(\eta_i|D) - E(\eta_i)}{V(\eta_i|D)} \quad (9)$$

$$\mathbf{C}_i = \mathbf{C}_0 - \mathbf{h}_i \mathbf{h}_i' \frac{1 - V(\eta_i|D)/V(\eta_i)}{V(\eta_i|D)} \quad (10)$$

where $\mathbf{h}_i = \mathbf{C}_0 \mathbf{F}_i$. Thus, the posterior distribution of $\boldsymbol{\theta}$ is partially specified by the two moments as $(\boldsymbol{\theta}|D) \sim (\mathbf{m}_i, \mathbf{C}_i)$.

Once such posterior specification is available, we can use the fact that at the use stress we have $\eta_u = \mathbf{F}_u' \boldsymbol{\theta}$, where $\mathbf{F}_u' = (1 \log S_u)$ and obtain the posterior variance of η_u . We can show that $V(\eta_u|D, S_i)$ is given by

$$\mathbf{F}_u' \mathbf{C}_0 \mathbf{F}_u - (\mathbf{F}_u' \mathbf{C}_0 \mathbf{F}_i)^2 \left[\frac{1 - \Psi'(a_i + n)/\mathbf{F}_i' \mathbf{C}_0 \mathbf{F}_i}{\mathbf{F}_i' \mathbf{C}_0 \mathbf{F}_i} \right] \quad (11)$$

which implies that as n increases the posterior variance decreases for any level of S_i as expected. We

note that the posterior variance is not a function of the prior mean $\mathbf{m}_0$ but it depends on prior **covariance** matrix $\mathbf{C}_0$. Furthermore, the above is not a function of the total time on test T_i . As a result of this, the posterior variance is the same as the preposterior variance, that is, $V(\eta_u|D, S_i) = V(\eta_u|S_i)$. In other words, one can find the single-point optimal design by simply minimizing equation (11) with respect to S_i .

Different forms of the prior covariance matrix $\mathbf{C}_0$ were considered by Soyer and Vopatek [24] and the corresponding optimal designs were presented. For example, in the special case of the power law model where α is known, say $\alpha = 1$, it can be shown that the optimal design is to test all the items at the highest possible stress level S_H , that is, $S_i^* = S_H$. It was shown by Vopatek [19] that if $\log \alpha$ and β are assumed to be independent *a priori*, that is, if $\mathbf{C}_0$ is a diagonal matrix, then for large n an optimal design can be obtained as

$$S_i^* = S_u^{[1+1/[nV(\log \alpha)]]} \quad (12)$$

This implies that as the number of items to be tested is large, the optimal stress is closer to the use stress S_u . Similarly, as prior uncertainty about $\log \alpha$ increases, the optimal stress level moves closer to S_u .

If the loss function is specified in terms of the posterior variance of λ_u rather than of η_u then it can be shown that $V(\lambda_u|D, S_i)$ is a function of the total time on test. More Specifically, in order to obtain $V(\lambda_u|D, S_i)$, it is necessary to have a distributional form for η_u and thus for λ_u . This is done after updating by specifying a log-gamma distribution for η_u with parameters a_u and b_u selected such that

$$\Psi(a_u) - \log b_u = \mathbf{F}'_u \mathbf{m}_i \text{ and } \Psi'(a_u) = \mathbf{F}'_u \mathbf{C}_i \mathbf{F}_u \quad (13)$$

The above implies a gamma posterior for λ_u , implying that $V(\lambda_u|D, S_i) = a_u/(b_u)^2$. Using this form, Vopatek [19] obtained the preposterior variance $V(\lambda_u|S_i)$.

The linear Bayesian setup can be generalized to multiple point ALT designs in which one considers m different stress levels where $n_1, n_2, \dots, n_m$ are tested at stress environments $S_1, S_2, \dots, S_m$. This can be done either in an adaptive manner by solving m sequential one-point design problems or solving a fixed design problem. Some of these extensions as well as design of censored tests are considered in Vopatek [19] using linear Bayesian methods.

Simulation Methods for Bayesian Designs

In the power law model of the section titled “Example: Single Stress ALT Designs”, if β is unknown, then the preposterior variance of λ_u cannot be obtained in closed form. One way to compute the posterior variance is to use a MCMC method such as the Gibbs sampler; see Gilks *et al.* [24] for an excellent introduction to MCMC methods.

The Gibbs sampler requires the full conditional distributions $p(\alpha|\beta, D)$ and $p(\beta|\alpha, D)$. Using a gamma prior for α as before, the full conditional of α is given by the gamma distribution $\Gamma[(a+n), (b+S_i^\beta T_i)]$. On the other hand, any prior distribution on β does not yield a standard form for the full conditional $p(\beta|\alpha, D)$, which is given by

$$p(\beta|\alpha, D) \propto S_i^{\beta n} \exp(-\alpha S_i^\beta T_i) p(\beta) \quad (14)$$

Thus, a method such as the rejection sampling needs to be used to draw samples from $p(\beta|\alpha, D)$. In this particular case, the standard rejection sampling can be easily implemented since the maximum of the conditional likelihood $\mathcal{L}(\beta; \alpha, D)$ is analytically available. We can show that the maximum of the conditional likelihood is given by

$$\hat{\beta} = \frac{\log(n) - \log(\alpha T_i)}{\log(S_i)} \quad (15)$$

where $\log(n) - \log(\alpha T_i) > 0$. Thus, we can design a rejection sampling algorithm to generate from $p(\beta|\alpha, D)$ by using the prior $p(\beta)$ as the importance function as in Smith and Gelfand [25]. In other words, we can draw β from the prior and accept it with probability

$$\frac{\mathcal{L}(\beta; \alpha, D)}{\mathcal{L}(\hat{\beta}; \alpha, D)}$$

Once a sample is obtained from the joint posterior $p(\alpha, \beta|D)$, the posterior distribution $p(\lambda_u|D, S_i)$ and the variance $V(\lambda_u|D, S_i)$ can be computed from this sample. In finding the optimal design, we need to obtain the preposterior variance

$$E_D[V(\lambda_u|D, S_i)] = \int V(\lambda_u|D, S_i) p(D|S_i) dD \quad (16)$$

which can be written as

$$\begin{aligned} E_D[V(\lambda_u|D, S_i)] &= \iint V(\lambda_u|D, S_i) \\ &\times p(D|\lambda_u, S_i) \\ &\times p(\lambda_u) d\lambda_u dD \end{aligned} \quad (17)$$

We note that in the above $V(\lambda_u|D, S_i) = V(\lambda_u|T_i, S_i)$ is evaluated *via* the Gibbs sampler for a given design $d = S_i$. Since the integral in equation (17) is not available in closed form, we can use a Monte Carlo average to evaluate it. More specifically, for each generated value of (α_r, β_r) , $r = 1, \dots, R$, from the prior we can generate λ_i and T_i . On the basis of each generated value of T_i , using the Gibbs sampler we can obtain the posterior variance $V[\lambda_u|T_i^r, S_i]$ and compute preposterior variance for S_i using the Monte Carlo average

$$\frac{1}{R} \sum_{r=1}^R V[\lambda_u|T_i^r, S_i] \quad (18)$$

Note that an optimal one-point design can be obtained by minimizing equation (18) with respect to S_i . This Monte Carlo setup can be modified for the general ALT design problem as discussed next.

Standard Monte Carlo Approach for Bayesian ALT Designs

Erkanli and Soyer [16] consider a general fixed design for ALTs, where m distinct stress levels are used and n_i items are tested at the stress level S_i such that $n = \sum_{i=1}^m n_i$ is a predetermined number. The design problem is then to select

- $m \leq n$, the number of distinct stress levels
- the accelerated stress levels S_i , $i = 1, \dots, m$; and
- the number of items tested at each stress level, n_i , $i = 1, \dots, m$

in such a way that the expected utility is maximized. In the above, a specific design is given by $d = \{m, S_i, n_i, i = 1, \dots, m\}$. As in the section titled “Example: Single Stress ALT Designs”, the authors consider the power law model where one is interested in making inference about λ_u , the failure rate at the use stress environment.

As before, we assume that there is no censoring in the ALT and we choose the design minimizing the preposterior variance of λ_u . In other words, the evaluation of the optimal design requires the computation of posterior variance $V(\lambda_u|D, d)$, where $D = \{T_1, \dots, T_m\}$ and $T_i = \sum_{j=1}^{n_i} x_j$ is the total time on test at stress environment S_i . As in the previous case, evaluation of $V(\lambda_u|D, d)$ requires use of MCMC methods.

The following algorithm has been suggested by Erkanli and Soyer [16] for standard Monte Carlo evaluation of the preposterior variance $E_D[V(\lambda_u|D, d)]$:

- Step 1. Choose $d = \{m, S_i, n_i, i = 1, \dots, m\}$.
- Step 2. Generate (α_r, β_r) from the prior $p(\alpha, \beta)$, $r = 1, \dots, R$.
- Step 3. For $i = 1, \dots, m$, generate T_{ir} from $p(T_i|\lambda_i)$ using the power law.
- Step 4. For each $D_r = \{T_{1r}, \dots, T_{mr}\}$ evaluate $V[\lambda_u|D_r, d]$ using MCMC.
- Step 5. Compute preposterior variance for d using Monte Carlo average

$$\frac{1}{R} \sum_{r=1}^R V[\lambda_u|D_r, d] \quad (19)$$

- Step 6. Go to step 1 and repeat the steps 2–5 for a different design d .

The optimal design is selected as the d with the minimum value of equation (19).

A Surface Fitting Algorithm for Bayesian ALT Designs

As noted by Erkanli and Soyer [16], the implementation of the above Monte Carlo approach is not computationally efficient. The approach requires, for each level of the design variable, R draws from the statistical model and, for each draw, evaluation of the posterior variance using MCMC methods that typically requires large number of iterations. Thus, the approximation in equation (19) may require a large-scale computational effort. Especially, this will be inefficient for the case of multiple stress designs where we need to specify m optimal stress environments. To avoid the potential computational burden, the authors suggested a curve fitting approach proposed by Muller and Parmigiani [20] for finding optimal ALT designs. This approach facilitates preposterior analysis by replacing the expectation step with a smoothing step. The posterior variance is evaluated as $v_r = V(\lambda_{ur}|D_r, d_r)$ for each simulated experiment $\{d_r, \alpha_r, \beta_r, D_r\}$ and a smooth surface $L(d)$ is fitted to the points (d_r, v_r) and the optimal design is found by minimizing the fitted surface $L(d)$.

The proposed approach by Erkanli and Soyer [16] for the ALT design problem with $d = \{m, S_i, n_i, i = 1, \dots, m\}$ and $\theta = (\alpha, \beta)$ is as follows:

- Step 1. Select designs $d_r, r = 1, \dots, R$.
- Step 2. Draw R points (D_r, θ_r) from the density $p(D, \theta|d_r)$. This is done by independently generating $(T_{1r}, T_{2r}, \dots, T_{mr})$ from $p(T_i | \lambda_i, d_r)$ for $i = 1, \dots, m$. Use MCMC to evaluate $v_r = V(\lambda_{ur} | D_r, d_r)$ and record sample points (d_r, D_r, v_r) .
- Step 3. Fit a surface $L(d)$ to the points (d_r, v_r) .
- Step 4. Find the minimum over d of $L(d)$.

The above setup assumes that a total number of n items will be tested in an ALT. It is important to note that d consists of both discrete and continuous components. Given n , the discrete components of d , $\{m, n_i, i = 1, \dots, m\}$ are constrained as $n = \sum_{i=1}^m n_i$ and $m \leq n$. Erkanli and Soyer [16] considered the case of $m = 2$ point designs which are shown to be optimal for relationships such as power law model with two parameters (see for example, Chaloner and Larntz [12]).

For the case of two-point designs, an alternate design strategy is to consider a sequential design. The general m -stage sequential design problem for ALT is shown in Figure 2. The surface-fitting approach conceptually can be adopted to the sequential problem, but as the number of stages increases, the dimension of the surfaces that we fit at each stage also increases and this makes the implementation quite difficult. Thus, the proposed approach was extended in Erkanli and Soyer [16] for only two-stage design problems using a setup similar to what is considered in Erkanli *et al.* [26] for prevalence estimation.

An Illustration of the Curve Fitting Method

In this section, we will illustrate the implementation of the curve fitting algorithm introduced in the last section to a one-point design problem using exponential lifetimes and a power law model. In the illustration, the local regression model, Loess, of Chambers and Hastie [27] has been used in

step 3. Any one-dimensional smoothing method such as splines can be used for this purpose.

For illustrative purposes, we will assume independent gamma priors for α and β such that $\alpha \sim \Gamma(20, 1000)$ and $\beta \sim \Gamma(3, 1)$. We will assume that at the optimal stress level, $n = 2$ items will be tested and the design space consists of the stress range $S \in (1.05, 11)$ where $S_u = 1.05$ is the use stress. As previously discussed, our goal is to find the optimal stress level S_i in such a way that the preposterior variance of λ_u is minimized. In what follows, as an alternative, we are interested in finding the optimal stress level minimizing the preposterior variance of $\eta_u = \log \lambda_u$ so that our results are comparable to those of Soyer and Vopatek [15] where linear Bayesian designs are obtained.

We note that under the specified form of priors, we still need to use the Gibbs-rejection algorithm to evaluate the posterior variance $V(\eta_u | T_{ir}, d_r)$ in step 2 of the curve fitting algorithm for each design point $d_r = S_i, r = 1, \dots, R$. To find the optimal stress level, we choose $R = 1000$ design points in the range $(1.05, 11)$ in step 1 of the algorithm. The next 1000 random vectors $(\alpha_r, \beta_r, T_{ir})$ are simulated using the joint distribution $p(\alpha, \beta) p(T_{ir} | \alpha, \beta)$, where $(T_{ir} | \alpha, \beta) \sim \Gamma(n, \lambda_{ir})$ and $\lambda_{ir} = \alpha S_i^\beta$. After implementing the Gibbs sampler for each generated data point and evaluating the posterior variance $V(\eta_u | T_{ir}, d_r)$ for $r = 1, \dots, 1000$, we can fit a nonparametric regression curve to the points $(d_r = S_i, v_r = V(\eta_u | T_{ir}, d_r))$. As discussed before, this is equivalent to taking the expectation of the posterior variance with respect to T_{ir} . In Figure 3 we have the nonparametric approximation to preposterior variance of η_u , that is, $V(\eta_u | S_i)$. As can be seen from the figure the minimum of the curve is around 2.4–2.5. We note the fitted curve is flat around the minimum. This is owing to the fact that the loss function does not consider any costs associated with testing. Also, we note the variation in the preposterior variance, which is due to the large variance of β . These results are very similar to the

Figure 2 Decision tree for the m -stage design problem

Figure 3 Nonparametric approximation to $V(\eta_u|S_i)$ with $n = 2$

findings of Vopatek [19], which are based on linear Bayesian methods. The results are also pretty robust to the choice of R as long as $R > 500$.

Concluding Remarks

In this article, some of the recent results in the Bayesian design of ALTs have been reviewed. Following Polson [13] and Erkanli and Soyer [16], the design problem has been presented as a decision problem in the sense of Lindley [22] and some of the difficulties that arise in the development of Bayesian designs have been discussed. There is an illustration of how linear Bayesian methods and Monte Carlo based approaches can be used in alleviating some of these difficulties. Some of the author's experiences in using the simulation-based design algorithm of Muller and Parmigiani [20] have been presented. These findings suggest that this approach can be successfully implemented to fixed design problems of moderate dimensions. However, extension of the approach to more general ALT designs and sequential problems of more than two stages requires more experience.

Accelerated Life Tests: Stress Step (Classical Methods)

Introduction to Accelerated Life Testing

The failure time data are used for product reliability estimation. Failures of highly reliable units are rare and information other than traditional censored failure time data should be used. One way of obtaining this complementary reliability information is to apply the methods of the so-called accelerated life testing (ALT) for improvements in reliability life testing, to obtain the desired reliability results for the products more quickly than under normal operating conditions, given in terms of step stresses. Step-stress ALT provides an interesting approach to study the possibility to take into account the cumulative effect of the applied stresses on aging, fatigue, and **degradation** of testing items, systems, and so on. The idea of using step stresses in ALT was proposed at first by Miner [1], Pieruschka [2], Sedyakin [3], and Singpurwalla [4]. Later this idea was actively developed in publications of many statisticians, see, for example [5–28], and so on, where one can find a list of references on applications and estimation in ALT.

In ALT any *accelerated life model* is defined on a set $E = \{x(\cdot)\}$ of all possible or admissible stresses for considered problem, where any stress (explanatory variable) $x(\cdot) \in E$ is a deterministic (or random) time function:

$$x(\cdot) = (x_1(\cdot), \dots, x_m(\cdot))^T : [0, \infty) \rightarrow \mathbf{R}^m \quad (1)$$

$x_i(\cdot)$ is univariate explanatory variable. If $x(\cdot)$ is constant in time, $x(\cdot) \equiv x = \text{const}$, we shall write x instead of $x(\cdot)$ in all formulas.

Let E_1 denote a set of constant-in-time stresses, $E_1 \subset E$. Using a set E_1 one may construct a set $E_2, E_2 \subset E$ of step stresses of the form

$$x(u) = \begin{cases} x_1, & 0 \leq u < t_1 \\ x_2, & u \geq t_1 \end{cases} \quad (2)$$

for any $t_1 > 0$, where $x_1, x_2 \in E_1$. Similarly for any $k, k = 2, 3, \dots$ one may consider a class $E_k, E_k \subset E$,

of step stresses of the form

$$x(u) = \begin{cases} x_1, & 0 \leq u < t_1 \\ x_2, & t_1 \leq u < t_2 \\ \dots & \dots \\ x_k, & t_{k-1} \leq u < t_k \leq \infty \end{cases} \quad (3)$$

where $x_1, \dots, x_k$ are constant-in-time stresses from E_1 . It is clear that $E_1 \subset E_2 \subset \dots \subset E_k \subset E$, where E is a set of all admissible stresses.

The most-used stresses in ALT are step stresses from the classes E_2, E_3 , or E_4 , and so on, which we have just defined. The units are placed on test at an initial low constant stress x_1 and if they do not fail in a predetermined time t_1 , the stress is increased. If they do not fail in a predetermined time $t_2 > t_1$, the constant stress x_2 is increased once more, and so on.

Let $T_{x(\cdot)}$ be the failure time under $x(\cdot) \in E$. Then the cumulative distribution function, the hazard rate function, and the cumulative hazard function given $x(\cdot) \in E$ are as follows:

$$\begin{aligned} F_{x(\cdot)}(t) &= \mathbf{P}\{T_{x(\cdot)} \leq t \mid x(s) : 0 \leq s \leq t\}, \\ \lambda_{x(\cdot)}(t) &= \frac{F'_{x(\cdot)}(t)}{1 - F_{x(\cdot)}(t)}, \quad \Lambda_{x(\cdot)}(t) = \int_0^t \lambda_{x(\cdot)}(s) ds \end{aligned} \quad (4)$$

from which one can see their dependence on the *life history up to time t*. Denote by $\lambda_0(t)$ a *baseline rate function*. It corresponds to the failure rate of given items when hypothetically all of them are testing in the same “standard”, “normal”, or “usual” conditions, given by a stress $x_0(\cdot), x_0(\cdot) \in E$.

The two most-known *general* models of ALT with time-varying stresses are the *accelerated failure time* (AFT) model and the *proportional hazards* (PH) or **Cox model**.

The *AFT model* on E is

$$F_{x(\cdot)}(t) = F_0 \left(\int_0^t r[x(\tau)] d\tau \right), \quad x(\cdot) \in E \quad (5)$$

where $r(\cdot)$ is a positive function on E .

In practice, often a baseline cumulative distribution function F_0 is taken from some class of simple parametric distributions, such as Weibull, lognormal, log-logistic, and so on, and in this case we obtain the parametric AFT model. We have an interesting family when F_0 belongs to the power generalized Weibull (PGW) family of distributions (see [21]). In terms of

2 Accelerated Life Tests: Stress Step

the cumulative distribution functions the PGW family is given by the next formula:

$$F(t, \sigma, \nu, \gamma) = 1 - \exp \left\{ 1 - \left[1 + \left(\frac{t}{\sigma} \right)^\nu \right]^{\frac{1}{\gamma}} \right\},$$

$$t > 0, \gamma > 0, \nu > 0, \sigma > 0 \quad (6)$$

If $\gamma = 1$ we have the Weibull family of distributions. If $\gamma = 1$ and $\nu = 1$, we have the exponential family of distributions. The PGW family of distributions has very nice probability properties. All **moments** of this distribution are finite. Depending on the parameter values the hazard rate can be *constant*, *monotone* (increasing or decreasing), *unimodal* or $\cap$ shaped, and bathtub or $\cup$ shaped. Another interesting family, the *exponentiated Weibull family* of distributions, was proposed in [29].

The PH model on E is

$$\lambda_{x(\cdot)}(t) = r[x(t)]\lambda_0(t), \quad x(\cdot) \in E \quad (7)$$

The function r in the AFT model (as in the PH model) can be parameterized in the following way:

$$r[x(\tau)] = e^{\beta\varphi(x(\tau))} \quad (8)$$

where φ is some known function of the stress. For example, if $\varphi(x) = x, \ln x, 1/x$, we have generalizations of the log-linear, power rule, and Arrhenius models, respectively (see [9, 15]).

The AFT and PH models are rather restrictive. In the case of the AFT model, the stress changes locally only the scale. Suppose that the PH model holds on E , x_0 is a *design stress*, x_1 is an *accelerated stress* with respect to the stress x_0 , $x_0, x_1 \in E_1$, so that $F_{x_0}(t) \leq F_{x_1}(t)$ for all $t \geq 0$, and let

$$x(t) = \begin{cases} x_1, & 0 \leq t < t_1 \\ x_0, & t \geq t_1 \end{cases} \quad (9)$$

be a step stress. Then in the case of the PH model, $\lambda_{x(\cdot)}(t) = \lambda_{x_0}(t)$ for all $t > t_1$. So if one group of items is tested under the design stress x_0 and the second group is tested at first under an accelerated stress x_1 until the moment t_1 and after this moment is tested under the design stress x_0 , so that both groups are observed under the same design stress x_0 after the moment t_1 , the failure rate after the moment t_1 is the same for both groups. If items are aging, it is not natural to apply the PH model.

AFT and PH Models for Constant and Step Stresses

In terms of the cumulative distribution function, the PH model (7) is written as

$$F_{x(\cdot)}(t) = 1 - \exp \left\{ - \int_0^t r[x(\tau)] d\Lambda_0(\tau) \right\},$$

$$x(\cdot) \in E \quad (10)$$

In the particular case of constant-in-time stress x_j and the step stress (3), the AFT model (5) implies

$$F_{x_j}(t) = F_0(r_j t) \quad (11)$$

and for $t \in [t_{i-1}, t_i)$, ($i = 1, 2, \dots, k$)

$$F_{x(\cdot)}(t) = F_0 \left(\sum_{j=1}^{i-1} r_j \Delta t_j + r_i(t - t_{i-1}) \right) \quad (12)$$

In terms of F_{x_j} ,

$$F_{x(\cdot)}(t) = F_{x_i}(s_{i-1} + t - t_{i-1}) \quad (13)$$

where s_i can be determined recurrently from the equations

$$F_{x_{i+1}}(s_i) = F_{x_i}(s_{i-1} + t_i - t_{i-1}) \quad (14)$$

For the step stress (9) and $k = 2$ the PH model (10) implies

$$\lambda_{x(\cdot)}(\tau) = \begin{cases} \lambda_{x_1}(\tau), & 0 \leq \tau \leq t \\ \rho \lambda_{x_1}(\tau), & \tau > t \end{cases} \quad (15)$$

where $\rho = r(x_1)/r(x_0)$.

In this particular case of step stresses the Cox model is sometimes called the *tapered failure rate* (TFR) model, see [25]. If $k \geq 2$, equation (10) implies $F_{x_j}(t) = 1 - e^{-r_j \Lambda_0(t)}$ and for $t \in [t_{i-1}, t_i)$

$$F_{x(\cdot)}(t) = 1 - \exp \left\{ - \sum_{j=1}^{i-1} r_j (\Lambda_0(t_j) - \Lambda_0(t_{j-1})) \right. \\ \left. - r_i (\Lambda_0(t) - \Lambda_0(t_{i-1})) \right\} \quad (16)$$

In the case when the distribution under the design stress x_0 is Weibull:

$$F_{x_0}(t) = 1 - e^{-t^\delta/\alpha_0}, \quad \Lambda_0(t) = \frac{t^\delta}{r_0 \alpha_0} \quad (17)$$

we have

$$F_{x_i}(t) = 1 - e^{-t^\delta/\theta_i} \quad (18)$$

and for $t \in [t_{i-1}, t_i]$

$$F_{x(\cdot)}(t) = 1 - \exp \left\{ - \sum_{j=1}^{i-1} \frac{t_j^\delta - t_{j-1}^\delta}{\theta_j} - \frac{t^\delta - t_{i-1}^\delta}{\theta_i} \right\} \quad (19)$$

This particular case of the PH model was considered in [30].

Models with Finite Supports

Following [17], we consider generalization of both the AFT and the PH models: generalized proportional hazards (GPH) model. For this purpose we formulate these models in other terms. For any $x(\cdot)$ the random variable $R = \Lambda_{x(\cdot)}(T_{x(\cdot)})$ has the standard exponential distribution with the survival function $S_R(t) = e^{-t}$, $t \geq 0$, and is called the *exponential resource*, the number $\Lambda_{x(\cdot)}(t)$ being the *exponential resource used until the moment t under the stress $x(\cdot)$* . So the failure rate $\lambda_{x(\cdot)}(t)$ is the *rate of exponential resource usage*.

Under the PH model we have

$$\Lambda'_{x(\cdot)}(t) = r[x(t)]\lambda_0(t) \quad (20)$$

i.e., the rate of resource usage is proportional to some baseline rate and the constant of proportionality is a function of a stress.

Let us consider now the GPH model, proposed in [18]. GPH model holds on E if

$$\lambda_{x(\cdot)}(t) = r\{x(t)\}q\{\Lambda_{x(\cdot)}(t)\}\lambda_0(t), \quad x(\cdot) \in E \quad (21)$$

The rate of resource usage at the moment t depends not only on a stress applied at this moment but also on the resources used until t .

The PH model ($q(u) \equiv 1$) and the AFT model ($\lambda_0(t) \equiv \lambda_0 = \text{const}$) are particular cases of the GPH model.

Consider the case when the rate of exponential resource usage with respect to the baseline rate is proportional to a monotone function of the used resource. One of the most natural parameterizations of the function q in this case would be

$$q(u) = e^{\gamma u}, \quad \gamma \in R^1 \quad (22)$$

So we consider the so-called generalized linear proportional hazards (GLPH) model on E :

$$\lambda_{x(\cdot)}(t) = e^{\beta x(t) + \gamma \Lambda_{x(\cdot)}(t)} \lambda_0(t), \quad x(\cdot) \in E \quad (23)$$

This model implies, that if $\gamma \leq 0$, the support of the distribution is $[0, \infty)$, and if $\gamma > 0$, we have the model with *finite support* $[0, sp_{x(\cdot)})$, where $sp_{x(\cdot)}$ verifies the equation

$$\int_0^{sp_{x(\cdot)}} e^{\beta x(u)} d\Lambda_0(u) = 1 \quad (24)$$

In the particular cases of the step stress (equation 3) we have the equation (16) when $\gamma = 0$. In the case $\gamma \neq 0$ and $x(\cdot) \in E_k$, we have for all $t \in [t_{i-1}, t_i]$

$$F_{x(\cdot)}(t) = 1 - \left\{ 1 - \gamma \sum_{j=1}^{i-1} e^{\beta x_j} (\Lambda_0(t_j) - \Lambda_0(t_{j-1})) - \gamma e^{\beta x_i} (\Lambda_0(t) - \Lambda_0(t_{i-1})) \right\}^{1/\gamma} \quad (25)$$

and for the constant stress x_j

$$F_{x_j}(t) = 1 - \{1 - \gamma e^{\beta x_j} \Lambda_0(t)\}^{1/\gamma} \quad (26)$$

If the distribution of time to failure under the design stress x_0 is Weibull, i.e.

$$F_{x_0}(t) = 1 - e^{-t^\delta/\alpha_0}, \quad \lambda_0(t) = \frac{1}{\gamma} e^{-\beta x_0} \left(1 - e^{-\frac{\gamma}{\alpha_0} + \delta} \right) \quad (27)$$

then under the GLPH model (23) and the step stress (equation 3),

$$F_{x(\cdot)}(t) = 1 - \left\{ 1 + \sum_{j=1}^{i-1} e^{\beta(x_j - x_0)} [e^{-\gamma t_j^\delta/\alpha_0} - e^{-\gamma t_{j-1}^\delta/\alpha_0}] + e^{\beta(x_i - x_0)} [e^{-\gamma t^\delta/\alpha_0} - e^{-\gamma t_{i-1}^\delta/\alpha_0}] \right\}^{1/\gamma} \quad (28)$$

Note that if the rate of resource usage depends on used resource (i.e. $\gamma \neq 0$), the distribution of the time to failure under constant-in-time stresses $x_j \neq x_0$ is not Weibull:

$$F_{x_j}(t) = 1 - \{1 - e^{\beta(x_j - x_0)} [1 - e^{-\gamma t^\delta/\alpha_0}]\}^{1/\gamma} \quad (29)$$

Under the GLPH model, distributions of times to failure under constant-in-time stresses are from the same interesting family of distributions if we take

4 Accelerated Life Tests: Stress Step

one of the following two families of distributions K_1 and K_2 . The family K_1 :

$$F_{x_0}(t) = 1 - (1 + \alpha_0 t^\delta)^{1/\gamma}, \quad t \geq 0, \\ (\alpha_0 > 0, \delta > 0, \gamma < 0) \quad (30)$$

If $0 < \delta \leq 1$, the failure rate $\lambda_{x_0}(t)$ is *decreasing*. If $\delta > 1$, then the failure rate is increasing until the moment $t = \left(\frac{\delta-1}{\alpha_0}\right)^{1/\delta}$ and decreasing after this moment, i.e. it has the $\cap$ shape.

The family K_2 :

$$F_{x_0}(t) = 1 - (1 + \alpha_0 t^\delta)^{1/\gamma}, \quad t \in \left[0, \left(-\frac{1}{\alpha_0}\right)^{1/\delta}\right), \\ (\alpha_0 < 0, \delta > 0, \gamma > 0) \quad (31)$$

If $0 < \delta < 1$, the hazard rate is decreasing in the interval $\left[0, \left(\frac{\delta-1}{\alpha_0}\right)^{1/\delta}\right)$ and increasing in the interval $\left(\left(\frac{\delta-1}{\alpha_0}\right)^{1/\delta}, \left(-\frac{1}{\alpha_0}\right)^{1/\delta}\right)$. The hazard rate has the $\cup$ shape. Therefore this family is very appealing. If $\delta > 1$, the hazard rate is *increasing* on $\left(0, \left(-\frac{1}{\alpha_0}\right)^{1/\delta}\right)$.

Suppose that the time-to-failure distribution is from one of these families. If $F_{x_0}(t) \in K_i (i = 1, 2)$ and the GLPH model holds, then

$$\Lambda_0(t) = -\frac{\alpha_0}{\gamma} e^{-\beta x_0} t^\delta \quad \text{and} \\ F_{x_j}(t) = 1 - (1 + \alpha_j t^\delta)^{1/\gamma} \quad (32)$$

where $\alpha_j = \alpha_0 e^{\beta(x_j - x_0)}$. If $F_{x_0} \in K_2$, the support of the distribution is finite: $\left[0, \left(-\frac{1}{\alpha_j}\right)^{1/\delta}\right)$.

If $x(\cdot)$ is a step stress of the form (3) then

$$F_{x(\cdot)}(t) = 1 - \{1 + \alpha_0 \varphi(t, \beta, \delta)\}^{1/\gamma}, \\ 0 < t < sp_{x(\cdot)} \quad (33)$$

where

$$\varphi(t, \beta, \delta) = \begin{cases} \sum_{j=1}^{k^*-1} e^{\beta(x_j - x_0)} (t_j^\delta - t_{j-1}^\delta) + e^{\beta(x_{k^*} - x_0)} (t^\delta - t_{k^*-1}^\delta), & k^* > 1 \\ e^{\beta(x_1 - x_0)} t^\delta, & k^* = 1 \end{cases} \quad (34)$$

where

$$k^* = \left\{ k : \sum_{j=1}^{k-1} e^{\beta(x_j - x_0)} (t_j^\delta - t_{j-1}^\delta) \leq -\frac{1}{\alpha_0}, \right. \\ \left. \sum_{j=1}^k e^{\beta(x_j - x_0)} (t_j^\delta - t_{j-1}^\delta) > -\frac{1}{\alpha_0} \right\} \quad (35)$$

If $\alpha_0 > 0, \gamma < 0$, then $sp_{x(\cdot)} = +\infty$. If $\alpha_0 < 0, \gamma > 0$, the right limit of the support $(0, sp_{x(\cdot)})$ verifies the equation $\varphi(sp_{x(\cdot)}, \beta, \delta) = -1/\alpha_0$, i.e.

$$sp_{x(\cdot)} = \left\{ t_{k^*-1}^\delta - e^{-\beta(x_{k^*} - x_0)} \left[\frac{1}{\alpha_0} + \sum_{j=1}^{k^*-1} e^{\beta(x_j - x_0)} (t_j^\delta - t_{j-1}^\delta) \right] \right\}^{1/\delta} \quad (36)$$

and the failure rate

$$\lambda_{x(\cdot)}(t) = -\alpha_0 \frac{\delta}{\gamma} e^{\beta(x_{k^*} - x_0)} \frac{t^{\delta-1}}{(1 + \alpha_0 \varphi(t, \beta, \delta))}, \\ 0 < t < sp_{x(\cdot)} \quad (37)$$

has the same shape as in the case of constant-in-time stresses (decreasing or $\cap$ shape for the family K_1 , increasing or $\cup$ shape for the family K_2).

Remarks on Estimation

Suppose that all units are tested under stresses from E_k , i.e. they are initially placed on test at x_1 and run until t_1 when the stress is changed to $x_2 > x_1$. At x_2 , testing continues until t_2 when stress is changed to $x_3 > x_2$, and so on, until x_k . Under x_k , testing continues until all remaining units fail or until t_f , whichever comes first.

Denote by D the number of failures during the experiment, $T_{(1)} \leq \dots \leq T_{(D)}$ the observed moments of failures. In the case of a finite support, the following reparameterization can be introduced: $\sigma = sp_{x(\cdot)}, \beta, \gamma, \delta$. Then $\alpha_0 = -1/\varphi(\sigma, \beta, \delta)$. The likelihood function for the family K_1 is given by

the formula

$$L(\alpha_0, \beta, \gamma, \delta) = \left(-\alpha_0 \frac{\delta}{\gamma}\right)^D e^{\beta \sum_{i=1}^D (x_{k(T_{(i)})} - x_0)} \times \prod_{i=1}^D T_{(i)}^{\delta-1} \{1 + \alpha_0 \varphi(T_{(i)}; \beta, \delta)\}^{\frac{1}{\gamma}-1} \times \{1 + \alpha_0 \varphi(t_f; \beta, \delta)\}^{\frac{n-D}{\gamma}} \quad (38)$$

and for the family K_2 by the next one

$$L(\sigma, \beta, \gamma, \delta) = \left(\frac{\delta}{\gamma}\right)^D e^{\beta \sum_{i=1}^D (x_{k(T_{(i)})} - x_0)} \left(\frac{1}{\varphi(\sigma, \beta, \delta)}\right)^D \times \prod_{i=1}^n T_{(i)}^{\delta-1} \left(1 - \frac{\varphi(T_{(i)}, \beta, \delta)}{\varphi(\sigma, \beta, \delta)}\right)^{\frac{1}{\gamma}-1} \times \left(1 - \frac{\varphi(t_f, \beta, \delta)}{\varphi(\sigma, \beta, \delta)}\right)^{\frac{n-D}{\gamma}} \mathbf{1}_{\{T_{(D)} < \sigma\}} \quad (39)$$

The estimator for the cumulative distribution function $F_{x_0}(t)$ is

$$\hat{F}_{x_0}(t) = 1 - (1 + \hat{\alpha}_0 t^{\hat{\delta}})^{\frac{1}{\hat{\gamma}}} \quad (40)$$

In the case of the class K_1 , approximate **confidence intervals** for $F_{x_0}(t)$ and other reliability characteristics under the design stress x_0 are obtained by standard ML (maximum-likelihood) methods using the estimated Fisher information matrix. In the case of the class K_2 when the support is finite, rigorous asymptotic theory is to be established. If the time to failure under the design stress x_0 has the Weibull (or another) distribution, then estimation under the GLPH model can be done similarly taking equation (28) (or equation (25) with respective Λ_0) for $F_{x(\cdot)}$ instead of equation (33) in all equations.

Accelerated Life Tests: Designs Comparison within a Bayesian Framework

Introduction

Accelerated life tests (ALT) are used to reduce the time needed to obtain information related to life characteristics of an item, material, or part of interest. In such tests, some characteristics of the use environment (e.g., temperature, voltage, vibration, etc.) are selected and applied to the items at higher (accelerated) levels with the intent of inducing failures in a more rapid fashion. The two main avenues of research in ALT are (a) the **optimal design** of the test and (b) the statistical inference from the failure data obtained. The importance of the design of these tests is paramount to the process of obtaining meaningful inferences about the life of the items in their use environment. Statistical inference is based on one of two paradigms, classical or Bayesian, and often makes use of a time transformation function, which relates failure times at accelerated stress levels to failure times at use stress levels through the scale parameter of the lifetime distribution. Examples of such functions are the power law model, the Eyring model, and the Arrhenius model (see for example Mann *et al.* [1]).

Although there is a host of literature on ALT design, there has been a significant increase in the topic of step-stress accelerated life tests (SSALT) and their comparison to regular ALTs from a classical viewpoint (see for example, Miller and Nelson [2] and more recently Bai and Chung [3], Khamis and Higgins [4], and Khamis [5]). Bayesian approaches to ALT design have been considered in DeGroot and Goel [6], who investigated the optimal design of a partially accelerated life test (PALT), and Erkanli and Soyer [7] who developed a Bayesian decision theoretic method for selecting optimal fixed stress ALTs based on minimization of the expected predictive variance of the parameter of interest. To the best of our knowledge Miller and Nelson [2] were among the earliest to claim similarity of asymptotic estimator variance when comparing step-stress testing ALT with fixed stress ALT. To date, however, no one has considered a comparison of SSALTs and constant

stress ALTs using a Bayesian approach. This is necessary, because in ALT the number of data items available is often not large, bringing into question the use of asymptotic values for comparison (which are the basis for most of the classical design comparisons). This notion is illustrated clearly in McSorley *et al.* [8].

In this article we consider a comparison of ALT designs using the Bayesian inference model developed by van Dorp and Mazzuchi [9]. The model assumes that the life length of the test item at any stress is exponentially distributed and that the failure rates of the life lengths are ordered with respect to the severity of the environment. This restricted ordering of the prior and posterior failure rate estimates acts as a nonparametric time transformation function. Two optimality criteria shall be used for ALT design comparisons: the usual preposterior variance and a measure that takes into account both preposterior mean and preposterior variance.

A general likelihood for the ALT design problem is presented in the section titled “A General Likelihood Function for Accelerated Life Tests”. In the section titled “Prior Distribution”, the joint prior distribution of the parameters is introduced and in the section titled “Posterior Moments after a Single Test Item” expressions for posterior characteristics are developed. An example analysis is presented in the section titled “A Comparison of ALT Step Patterns”. In the last section we provide some concluding remarks.

A General Likelihood Function for Accelerated Life Tests

Any statistical inference procedure involves developing a likelihood. The likelihood model developed in this section allows for a comprehensive representation of regular fixed-stress, progressive step-stress, regressive step-stress, and profile step-stress life testing (see for example, Figure 1).

Following the setup of van Dorp *et al.* [10], typically in ALT, an environment can be described by a collection of stress variables and their levels. In this model, it is assumed that a total of K environments $E_1, \dots, E_K$ are preselected as candidate test environments within minimum and maximum design ranges of stresses to ensure that the predominant failure modes at use environments and accelerated environments are the same. It will be

2 ALT: Designs Comparison within a Bayesian Framework

Figure 1 Different ALT scenarios

assumed that these candidate test environments may be rank ordered with respect to severity using engineering knowledge, i.e., E_1 (E_K) coincides with the least (most) severe environment.

The lifetime distribution in a constant stress environment E_e will be modeled as an exponential lifetime distribution with failure rate λ_e , $e = 1, \dots, K$. The ordering of the test environments in terms of severity induces the same ordering in the associated failure rates, i.e.,

$$0 \equiv \lambda_0 < \lambda_1 < \dots < \lambda_K < \lambda_{K+1} \equiv \infty \quad (1)$$

We shall consider a single test item subjected to an ALT with m test intervals $[t_{i-1}, t_i)$, $i = 1, \dots, m$, with $t_0 \equiv 0$, $t_{m+1} \equiv \infty$. If the item has not failed by time t_m , it is removed (censored) from testing. As testing may proceed in a variety of step patterns, the actual test environment in $[t_{i-1}, t_i)$ will be denoted by E_{a_i} , $a_i \in \{1, \dots, K\}$. With the above setup, we have for the ALT reliability function during the test at time $t \in [t_{i-1}, t_i)$ equation (2) and for the ALT failure density or likelihood of a failure at time t during the test equation (3).

$$R(t|\lambda_1, \dots, \lambda_K) = \begin{cases} \exp\{-\lambda_{a_1} t\} & t \in [0, t_1) \\ \exp\left\{-\sum_{j=1}^{i-1} \lambda_{a_j} (t_j - t_{j-1}) - \lambda_{a_i} (t - t_{i-1})\right\} & t \in [t_{i-1}, t_i), \\ \exp\left\{-\sum_{j=1}^m \lambda_{a_j} (t_j - t_{j-1})\right\} & t > t_m \end{cases} \quad (2)$$

Figure 2 presents a comparison of the ALT reliability and density functions for a fixed stress and profile ALT test. The solid lines in Figure 2(a) and (b) (denoted 213) display the ALT reliability and density functions for a profile ALT test as defined by equation (4).

$$\begin{aligned} f(t|\lambda_1, \dots, \lambda_K) &= -\frac{d}{dt} R(t|\lambda_1, \dots, \lambda_K) \\ &= \begin{cases} \lambda_{a_1} R(t|\lambda_1, \dots, \lambda_K) & t \in [0, t_1) \\ \lambda_{a_i} R(t|\lambda_1, \dots, \lambda_K) & t \in [t_{i-1}, t_i), i = 2, \dots, m \\ 0 & t > t_m \end{cases} \end{aligned} \quad (3)$$

$$a_1 = 2, a_2 = 1, a_3 = 3$$

$$t_1 = 1, t_2 = 2, t_3 = 3$$

$$\lambda_1 = \frac{1}{2}, \lambda_2 = 1, \lambda_3 = \frac{1}{2} \quad (4)$$

Note that the equation (4) coincides with a profile ALT test since the environment in the first step is 2, in the second step it equals 1, and finally in the third step it equals 3. The solid line ALT reliability function in Figure 2(a) is continuous but not differentiable at the endpoint of each test interval. The solid line ALT density in Figure 2(b) is discontinuous and exhibits here jumps up and down. The dashed line in Figure 2(a) and (b) (indicated as 222) depict the ALT reliability and density functions of a fixed stress ALT with $a_i = 2$, $i = 1, \dots, 3$ and thus $\lambda_{a_i} = 1$, $i = 1, \dots, 3$.

Figure 2 ALT reliability function and ALT density function for a profile ALT test defined by equation (4) as a function of time t .

From equation (2) and the unit step lengths we obtain for the reliability at the end of the ALT test (i.e., the survival probability) for both ALT setups in Figure 2:

$$R(3) = \exp\left(-\sum_{i=1}^3 \lambda_{a_i}\right) = \exp(-3) \approx 0.05 \quad (5)$$

Hence, both ALT setups in Figure 2 are comparable from this vantage point. The immediate question that arises is whether there is any benefit with profile stepping (or step-stress testing in general) compared to a fixed stress ALT setup. In this article we shall compare different ALT step patterns by sampling different values of λ_i , $i = 1, \dots, 3$ from a prior distribution to be defined in the next section. For consistency in comparison, we shall evaluate posterior use stress statistics keeping the

ALT survival probability constant under different values of λ_i . This is achieved by “stretching” or “shrinking” the total test time t_m keeping the length of each test interval equidistant. Introducing the transformation

$$\lambda_e = -\text{Ln}(u_e) \iff u_e = \exp(-\lambda_e) \quad (6)$$

equations (2) and (3) may be expressed in terms of u_e for mathematical convenience (see section titled “Prior Distribution”). Quantities u_e may be interpreted as the reliability after one time unit of exposure to environment e and will henceforth be referred to as *unit reliabilities in the different testing environments*. Substituting equation (6) into equation (2) (and equation (3)), links the reliability of the test item at time t (the likelihood of failure at time t) to the unit reliabilities u_e , $e = 1, \dots, K$, we have, respectively:

$$R(t|u_1, \dots, u_K) = \begin{cases} (u_{a_1})^t & t \in [0, t_1) \\ \left\{ \prod_{j=1}^{i-1} (u_{a_j})^{t_j - t_{j-1}} \right\} (u_{a_i})^{t - t_{i-1}} & t \in [t_{i-1}, t_i), \\ & i = 2, \dots, m \\ \prod_{j=1}^m (u_{a_j})^{t_j - t_{j-1}} & t > t_m \end{cases} \quad (7)$$

$$f(t|u_1, \dots, u_K) = \begin{cases} -\text{Ln}(u_{a_i}) R(t|u_1, \dots, u_K) & t \in [t_{i-1}, t_i), \\ & i = 1, \dots, m \\ 0 & t > t_m \end{cases} \quad (8)$$

The mathematical forms of expressions (7) and (8) are more conducive to posterior updating as compared to expressions (2) and (3) utilizing the prior distribution to be defined in the next section.

Prior Distribution

Denoting Λ_e to be the random variable associated with failure rate realization λ_e and using equations (6) and (1) it follows that

$$0 \equiv u_{K+1} < U_K < \dots < U_1 < u_0 \equiv 1 \quad (9)$$

Rather than defining a prior distribution for $\underline{\Lambda} = (\Lambda_1, \dots, \Lambda_K)$ exhibiting property (equation (1)) for all realizations $\underline{\lambda} = (\lambda_1, \dots, \lambda_K)$, one may equivalently define a prior for $\underline{U} = (U_1, \dots, U_K)$ exhibiting property (equation (9)). Concentrating on $\underline{U} = (U_1, \dots, U_K)$, a prior distribution that is (a) mathematically tractable, (b) defined over the region specified in equation (9), and (c) imposes no other restrictions on u , is the multivariate ordered Dirichlet distribution,

$$\Pi\{\underline{u}|\underline{\eta}, \underline{v}\} = \frac{\prod_{e=1}^{K+1} (u_{e-1} - u_e)^{\eta \cdot v_e - 1}}{\mathbb{D}(\underline{\eta}, \underline{v})} \quad (10)$$

where, $\eta > 0$, $v_e > 0$, $e = 1, \dots, K + 1$, $\sum_{i=1}^{K+1} v_i = 1$,

$$\mathbb{D}(\underline{\eta}, \underline{v}) = \frac{\left\{ \prod_{e=1}^{K+1} \Gamma(\eta v_e) \right\}}{\Gamma(\underline{\eta})} \quad (11)$$

and $\Gamma(\cdot)$ is the gamma function satisfying $\Gamma(n + 1) = n\Gamma(n)$.

Using the transformation given by the rhs of equation (6) allows one to take full advantage of the mathematical properties of the ordered Dirichlet Distribution. For a detailed discussion of these properties see van Dorp and Mazzuchi [9]. The joint moment expression for $\underline{U} \sim \Pi\{\underline{u}|\underline{\eta}, \underline{v}\}$ defined by equation (10) follows as

$$E_{\underline{U}} \left[\prod_{e=1}^K (U_e)^{k_e} \middle| \underline{\eta}, \underline{v} \right] = \frac{\Gamma(\underline{\eta})}{\Gamma(\eta v_{K+1})} \times \prod_{e=1}^K \frac{\Gamma(\eta v_{\geq e+1} + k_{\geq e})}{\Gamma(\eta v_{\geq e} + k_{\geq e})} \quad (12)$$

where

$$v_{\geq e+1} = \sum_{i=e+1}^{K+1} v_i \text{ and } k_{\geq e} = \sum_{i=e}^K k_i \quad (13)$$

We have added the subscript $\underline{U} = (U_1, \dots, U_K)$ to emphasize that the expectation in equation (12) is taken with respect to the prior distribution (10).

Posterior Moments after a Single Test item

In this section we shall derive a closed form expression for posterior use stress moments of order k , for $k \geq 1$, given the failure or survival of the ALT test item up to time t . These derivations employ (a) the joint moments expressions (12), (b) the mathematical form of $R(t|u_1, \dots, u_K)$ defined by equation (7), (c) the fact that

$$\begin{aligned} & \int_0^1 \int_0^{u_1} \dots \int_0^{u_{K-1}} u_1^m f(t|u_1, \dots, u_K) \\ & \times \Pi\{\underline{u}|\underline{\eta}, \underline{v}\} du_K \dots du_1 \\ & = -\frac{d}{dt} \int_0^1 \int_0^{u_1} \dots \int_0^{u_{K-1}} u_1^m R(t|u_1, \dots, u_K) \\ & \times \Pi\{\underline{u}|\underline{\eta}, \underline{v}\} du_K \dots du_1 \end{aligned} \quad (14)$$

and (d) that for $W(t) = \prod_{e=1}^K \{g_e(t)/h_e(t)\}$ we have

$$\frac{d}{dt} W(t) = W(t) \times \sum_{e=1}^K \left[\frac{\frac{d}{dt} g_e(t)}{g_e(t)} - \frac{\frac{d}{dt} h_e(t)}{h_e(t)} \right] \quad (15)$$

Posterior Moments after Test a Item Survived up to Time t

Applying Bayes theorem allows for derivation of closed form posterior moments of the unit reliability in the use stress failure rate environment, i.e., u_1 . We have

$$\begin{aligned} E_{\underline{U}}[U_1^m | \underline{\eta}, \underline{v}, t] &= \\ & \frac{\int_0^1 \int_0^{u_1} \dots \int_0^{u_{K-1}} u_1^m \Pi\{\underline{u}|t, \underline{\eta}, \underline{v}\} du_K \dots du_1}{\int_0^1 \int_0^{u_1} \dots \int_0^{u_{K-1}} R(t|u_1, \dots, u_K) \Pi\{\underline{u}|\underline{\eta}, \underline{v}\} du_K \dots du_1} \end{aligned} \quad (16)$$

Denoting the amount of time that the test item has been exposed to environment E_e prior to t with $\tau_e(t)$,

one obtains

$$\begin{aligned} \tau_e(t) = & \sum_{j=1}^m (t_j - t_{j-1}) 1_{a_j}(e) \times 1_{[0,t)}(t_j) \\ & + \sum_{j=1}^m (t - t_{j-1}) 1_{a_j}(e) \times 1_{[t_{j-1}, t_j)}(t) \end{aligned} \quad (17)$$

where

$$1_{a_j}(e) = \begin{cases} 1 & \text{if in test interval } j \text{ the test} \\ & \text{environment } a_j \text{ is } e \\ 0 & \text{else} \end{cases} \quad (18)$$

and

$$1_{[0,t)}(t_j) = \begin{cases} 1 & t_j \in [0, t) \\ 0 & \text{else} \end{cases} \quad (19)$$

Employing the mathematical definition of $R(t|u_1, \dots, u_K)$ equation (7) it follows that we may rewrite

$$\begin{aligned} & \int_0^1 \int_0^{u_1} \dots \int_0^{u_{K-1}} u_1^m R(t|u_1, \dots, u_K) \\ & \quad \times \Pi\{\underline{u}|\eta, \underline{v}\} du_K \dots du_1 \\ & = E_U \left[\prod_{e=1}^K (U_e)^{k_e(m,t)} \right] \end{aligned} \quad (20)$$

where

$$k_e(m, t) = \begin{cases} \tau_e(t) + m & e = 1 \\ \tau_e(t) & e > 1 \end{cases} \quad (21)$$

Substitution of equation (20) into equation (16) yields

$$E_U[U_1^m|\eta, \underline{v}, t] = \frac{E_U \left[\prod_{e=1}^K (U_e)^{k_e(m,t)} \middle| \eta, \underline{v} \right]}{E_U \left[\prod_{e=1}^K (U_e)^{k_e(0,t)} \middle| \eta, \underline{v} \right]} \quad (22)$$

where $k_e(m, t)$ is defined by equation (21), $\tau_e(t)$ by equation (17) and the prior joint moments are defined by equation (12).

Posterior Moments after a Test Item Failed at Time t

Analogous to equation (16) and employing equations (14) and (20) it immediately follows that

$$\begin{aligned} E_U[U_1^m|\eta, \underline{v}, t] = & \frac{\int_0^1 \dots \int_0^{u_{K-1}} u_1^m f(t|u_1, \dots, u_K) \Pi\{\underline{u}|\eta, \underline{v}\} du_K \dots du_1}{\int_0^1 \dots \int_0^{u_{K-1}} f(t|u_1, \dots, u_K) \Pi\{\underline{u}|\eta, \underline{v}\} du_K \dots du_1} = \\ & \frac{\frac{d}{dt} \int_0^1 \dots \int_0^{u_{K-1}} u_1^m R(t|u_1, \dots, u_K) \Pi\{\underline{u}|\eta, \underline{v}\} du_K \dots du_1}{\frac{d}{dt} \int_0^1 \dots \int_0^{u_{K-1}} R(t|u_1, \dots, u_K) \Pi\{\underline{u}|\eta, \underline{v}\} du_K \dots du_1} \\ & = \frac{\frac{d}{dt} E_U \left[\prod_{e=1}^K (U_e)^{k_e(m,t)} \middle| \eta, \underline{v} \right]}{\frac{d}{dt} E_U \left[\prod_{e=1}^K (U_e)^{k_e(0,t)} \middle| \eta, \underline{v} \right]} \end{aligned} \quad (23)$$

where $k_e(m, t)$ is defined by equation (21) and $\tau_e(t)$ by equation (17). Utilizing equation (15) we immediately obtain

$$\begin{aligned} & \frac{d}{dt} E_U \left[\prod_{e=1}^K (U_e)^{k_e(m,t)} \middle| \eta, \underline{v} \right] \\ & = E_U \left[\prod_{e=1}^K (U_e)^{k_e(m,t)} \middle| \eta, \underline{v} \right] \\ & \quad \times \sum_{e=1}^K \left[\frac{\frac{d}{dt} \Gamma\{\beta v_{\geq e+1} + k_{\geq e}(m, t)\}}{\Gamma\{\beta v_{\geq e+1} + k_{\geq e}(m, t)\}} \right. \\ & \quad \left. - \frac{\frac{d}{dt} \Gamma\{\beta v_{\geq e} + k_{\geq e}(m, t)\}}{\Gamma\{\beta v_{\geq e} + k_{\geq e}(m, t)\}} \right] \end{aligned} \quad (24)$$

$$k_{\geq e}(m, t) = \sum_{i=e}^K k_i(m, t) \quad (25)$$

To further reduce equation (24), we note that $\frac{d}{dt} \Gamma(t)/\Gamma(t)$ may be recognized as the psi or

digamma function $\psi(\cdot)$ and thus

$$\frac{\frac{d}{dt} \Gamma\{\beta v_{\geq e+1} + k_{\geq e}(m, t)\}}{\Gamma\{\beta v_{\geq e+1} + k_{\geq e}(m, t)\}} = \psi\{\beta v_{\geq e+1} + k_{\geq e}(m, t)\} \sum_{i=e}^K 1_{a_j(i)} \times 1_{[t_{i-1}, t_i)}(t) \quad (26)$$

since

$$\frac{d}{dt} \{\beta v_{\geq e+1} + k_{\geq e}(m, t)\} = \sum_{i=e}^K \frac{d}{dt} k_i(m, t) \quad (27)$$

and finally

$$\frac{d}{dt} k_i(m, t) = \frac{d}{dt} \tau_i(t) = 1_{a_j(i)} \times 1_{[t_{j-1}, t_j)}(t) \quad (28)$$

Example

Let us consider the prior distribution on the unit reliabilities $\underline{U}$ with prior parameters

$$\begin{aligned} \eta &= 5, v_1 = 0.39347, v_2 = 0.23865 \\ v_3 &= 0.14475, v_4 = 0.22313 \end{aligned} \quad (29)$$

These prior parameters settings are chosen for illustration purposes such that:

$$\begin{aligned} E_{\underline{U}}[U_e | \eta, v_{\geq e+1}] &= \exp(-\lambda_e) \\ \text{where } \lambda_1 &= \frac{1}{2}, \lambda_2 = 1, \lambda_3 = 1\frac{1}{2} \end{aligned} \quad (30)$$

These values coincide with the ALT setup in Figure 2. Figure 3 depicts the behavior of $E_{\underline{U}}[U_1 | \eta, \underline{v}, t]$ given by equation (23) for $t < 3$ (i.e., the test item failed before the end of the ALT test) and $E_{\underline{U}}[U_1 | \eta, \underline{v}, t]$ given by equation (22) for $t > 3$ (i.e., the test item survived the ALT test) for both the profile 213 ALT setup and the fixed stress ALT setup such that $\lambda_{a_i} = 2, i = 1, 2, 3$ (indicated by 222 in Figure 3).

Note that the up and down jumps of the solid line in Figure 3 mimic those of the ALT density function $f(t | \lambda_1, \dots, \lambda_3) \equiv f(t | u_1, \dots, u_3)$ in Figure 2(b). Hence, a test item exposed to the ALT 213 setup will have a higher posterior unit reliability at use stress when it fails shortly before $t = 1$ rather than

Figure 3 Posterior expected use stress reliability as a function of test failure time and total test time 3 for prior parameter setting equation (29) and the ALT density functions in Figure 2(b)

failing shortly after $t = 1$ due to the jump down in likelihood of failure at $t = 1$ of the ALT 213 density. A reverse behavior can be observed at $t = 2$. On the other hand, the posterior unit reliability always increases smoothly in the case of the fixed stress ALT setup indicated by the line with wide dashes in Figure 3. The horizontal line with dashes depicts the average value of the prior use stress unit reliability i.e.,

$$E_{\underline{U}}[U_1 | \eta, v_{\geq 2}] = \exp(-\lambda_1) = \exp\left(-\frac{1}{2}\right) \approx 0.6065 \quad (31)$$

A Comparison of ALT Step Patterns

In this section we shall first set the stage for what is called a *preposterior analysis* of ALT step patterns in the section titled “A Comparison Analysis of Step Patterns in ALT”, by providing a preliminary comparison of the ALT profile and ALT fixed stress test presented in Figure 2 in the section titled “A Preliminary Comparison of the ALT Setups in Figure 2” We utilize this example to motivate a single measure to compare different step patterns that rewards both calibration and precision.

A Preliminary Comparison of the ALT Setups in Figure 2

Owing to equation (30), via which the prior parameters equation (29) are chosen, it seems intuitive to

expect that given a random failure time T_{λ^*} , where T_{λ^*} follows either of the ALT step patterns 213 and 222 defined in Figure 2(b) with $\lambda^* = (\frac{1}{2}, 1, 1\frac{1}{2})$, average posterior unit reliability should be equal or close to prior unit reliability, i.e.,

$$E_{T_{\lambda^*}}[E_U[U_1|\eta, \underline{v}, T_{\lambda^*}]] \approx E_U[U_1|\eta, v_{\geq 2}] \quad (32)$$

where the value of $E_U[U_1|\eta, v_{\geq 2}]$ is given by equation (31). (It is important here to emphasize the distinction between $E_U[U_1|\eta, \underline{v}, T_{\lambda^*}]$ —which is a posterior mean—and $E_U[U_1, T_{\lambda^*}|\eta, \underline{v}]$ —which is a joint mean. If we were to substitute $E_U[U_1, T_{\lambda^*}|\eta, \underline{v}]$ for $E_U[U_1|\eta, \underline{v}, T_{\lambda^*}]$ in equation (31), equality would hold owing to the law of total probability.) An additional measure to monitor agreement between the prior and the posterior distribution is the posterior variance. An increase in posterior variance compared to prior variance is typically associated, in a Bayesian analysis, with a disagreement between prior information and the observed data. To test the above assertion and observe prior–posterior disagreement, we generate samples $t_i^\circ, i = 1, \dots, 5000$ from both ALT density functions in Figure 2(b) and evaluate:

$$\hat{E}_{T_{\lambda^*}}[E_U[U_1|\eta, \underline{v}, T_{\lambda^*}]] = \frac{1}{5000} \sum_{i=1}^{5000} E_U[U_1|\eta, \underline{v}, t_i^\circ] \quad (33)$$

$$\begin{aligned} & \hat{E}_{T_{\lambda^*}}[\text{Var}_U[U_1|\eta, \underline{v}, T_{\lambda^*}]] \\ &= \frac{1}{4999} \sum_{i=1}^{5000} \text{Var}_U[U_1|\eta, \underline{v}, t_i^\circ] \end{aligned} \quad (34)$$

The results as well as the prior mean and variance $E_U[U_1|\eta, v_{\geq 2}]$, $\text{Var}_U[U_1|\eta, v_{\geq 2}]$ of use stress unit reliability are presented in Table 1. Note that the results for the ALT 213 profile stress test indicate slightly better calibration (since its values in the second row are closer to those in the first row compared to the ALT 222 setup) and higher precision (since the variance in its third row is less than that of the ALT 222 setup). Both ALT scenarios indicate agreement between prior distribution and observed data (on average) since the fourth row entries are reduced by more than 50% of the third row entries.

Table 1 A preliminary comparison of the ALT step patterns in Figure 2 utilizing prior parameter values $\eta, \underline{v}$ provided in equation (29)

	ALT 213	ALT 222
$E_U[U_1 \eta, v_{\geq 2}]$	0.6065	0.6065
$\hat{E}_{T_{\lambda^*}}[E_U[u_1 \eta, \underline{v}, T_{\lambda^*}]]$	0.6025	0.6024
$\text{Var}_U[U_1 \eta, v_{\geq 2}]$	0.0795	0.0795
$\hat{E}_{T_{\lambda^*}}[\text{Var}_U[u_1 \eta, \underline{v}, T_{\lambda^*}]]$	0.0354	0.0364

A test evaluation measure that rewards both calibration and precision may be defined to be

$$\begin{aligned} \mathcal{S}(T_{\lambda^*}, \eta, \underline{v}) = & \left[\left\{ \hat{E}_{T_{\lambda^*}}[E_U[U_1|\eta, \underline{v}, T_{\lambda^*}]] \right. \right. \\ & \left. \left. - E_U[U_1|\eta, v_{\geq 2}] \right\}^2 + \hat{E}_{T_{\lambda^*}}[\text{Var}_U[U_1|\eta, \underline{v}, T_{\lambda^*}]] \right]^{-\frac{1}{2}} \end{aligned} \quad (35)$$

The second term (first term) in equation (34) addresses precision (calibration). Recalling that precision is defined as the *reciprocal of the variance* it follows that higher values of $\mathcal{S}(T_{\lambda^*}, \eta, \underline{v})$ are preferred over lower values. For the results in Table 1, we have

$$\mathcal{S}_{213}(T_{\lambda^*}, \eta, \underline{v}) \approx 5.31 \text{ and } \mathcal{S}_{222}(T_{\lambda^*}, \eta, \underline{v}) \approx 5.28 \quad (36)$$

and on the basis of the evaluation measure defined by equation (36) we prefer the profile step-stress over the fixed stress one.

However, the comparison in equation (36) can only be considered a preliminary one (and not a meaningful one from Bayesian perspective) since it assumed perfect knowledge about failure rates $\lambda^* = (\frac{1}{2}, 1, 1\frac{1}{2})$ (and thus indirectly also about unit reliabilities u). This allowed to sample from the random variable T_{λ^*} and subsequently compare the known value of use stress unit reliability $u_1 = \exp(-\lambda_1) = \exp(-\frac{1}{2}) \approx 0.6065$ (with a value here equal to $E_U[U_1|\eta, v_{\geq 2}]$ in equation (31) due to the choice of prior parameters equation (29)) to posterior estimates $E_U[u_1|\eta, \underline{v}, T_{\lambda^*}]$.

A comparison Analysis of Step Patterns in ALT

Instead of assuming a fixed value $\lambda^* = (\frac{1}{2}, 1, 1\frac{1}{2})$ we shall sample failure rate vectors $\lambda^i, i = 1, \dots, 1000$

indirectly, by sampling vectors of unit reliabilities $\underline{u}^i, i = 1, \dots, 1000$ from the prior distribution equation (10) with the same prior parameters equation (29) and utilizing the transformations equation (6). For each realization $\underline{\lambda}^i$, we “stretch” the length of time t_m of the ALT test, to ensure the same ALT survival probability of ≈ 0.05 (see equation (5)) of the ALT densities in Figure 2 (which terminate at $t_m = 3$). Next, we sample a 1000 failure times of the random variable $T_{\underline{\lambda}^i}$ with a predefined ALT step pattern and evaluate one realization of the performance measures

$$\hat{E}_{T_{\underline{\lambda}^i}}[E_U[U_1 | \eta, \underline{v}, T_{\underline{\lambda}^i}]], \hat{E}_{T_{\underline{\lambda}^i}}[\text{Var}_U[U_1 | \eta, \underline{v}, T_{\underline{\lambda}^i}]] \text{ and } S(T_{\underline{\lambda}^i}, \eta, \underline{v}) \quad (37)$$

defined by equations (33–35). (We reduce the sample size from $T_{\underline{\lambda}^i}$ from 5000 to 1000 to reduce calculation time.) Summarizing, we shall obtain a sample of 1000 values of the statistics indicated by equation (37) associated with a predefined step pattern. Figure 4 summarizes the algorithm to generate these observations.

Figure 5 summarizes the analysis results for two fixed stress ALTs (indicated by 111 and 222), a progressive ALT (indicated by 123), and a profile ALT indicated by 213). The horizontal lines on each subplot indicate the prior values of each performance measure, whereas the values indicate the average value for the iteration series plotted in each subfigure. By comparing Figures A:111 and A:222, we immediately observe a larger sensitivity in the iteration series $i = 1, \dots, 1000$ to failure time data obtained in the use stress environment 1 as compared to the accelerated environment 3.

This larger sensitivity can be explained immediately by the correlations ϱ_{ef} between unit reliabilities U_e and U_f defined by equation (12). We obtain from the prior parameters equation (29) that

$$\varrho_{12} \approx 0.61; \varrho_{13} \approx 0.43; \varrho_{23} \approx 0.70 \quad (38)$$

The **correlation** $\varrho_{12} \approx 0.61$ in equation (38) thus acts as a “dampening” effect of data observed in the environment 2 on posterior updating of use stress unit reliability in environment 1. As a result, the numbers indicated in Figures A:111 and A:222 indicated higher calibration for the higher stress (environment 3) with prior use stress unit reliability ≈ 0.6065 (see equation (31)). This observation is amplified

Figure 4 Preposterior analysis algorithm to obtain 1000 values of the test statistics defined by equation (37)

when comparing the Figures B:222 and B:111. A lesser departure from prior variance 0.0795 (see Table 1) is observed in Figure B:222, whereas in Figure B:111 this value is reduced on average by more than 50%. This reduction implies a larger agreement between prior information and observed data in Figure B:111 than in Figure B:222. Both comparisons are combined in Figures C:111 and C:222, where the higher evaluation score 4.207 shows a preference for obtaining data in the use stress environment than in the higher stress environment 2. (Again, this also follows immediately from the correlation coefficient $\varrho_{13} \approx 0.61$ in equation (38).) Keeping ALT survivability constant, however, implies excessive test time at the use stress levels, which is

Figure 5 Preposterior analysis of different ALT test patterns

why ALT is being considered in the first place. On the other hand, while testing in a higher stress environment reduces test time, more test results may be needed to confirm or contest specified prior parameters. Differences observed above are similar but

exacerbated for a fixed stress ALT at environment 3 (but are not displayed) owing to the lower correlation $\varrho_{13} \approx 0.43$.

Comparing the progressive step-stress results in Figures A:123, B:123, and C:123 with those in their

“111 and 222” counterparts, it is interesting to note a lesser sensitivity in prior updating than observed in the “111” figures, but a slightly larger one than observed in the “222” figures. In Figure B:123 we still observe a relative large reduction in posterior variance on average (from 0.795 to 0.50) and an average evaluation score of value 4.061 in Figure C:123 (close to the value of use stress testing in Figure C:111). Similar comparisons of the figures associated with the profile ALT setup 213 reveal an improvement of results when compared to fixed stress testing at environment 2 except for the value 0.069 in Figure B:222, but less favorable results when compared to the progressive ALT 123 setup. (Results associated with other profiles are not displayed here, but are worse than the “213” ones and are available upon request.)

Summarizing our results seem to confirm within a Bayesian paradigm a favorable conclusion earlier made by Miller and Nelson [2] in a classical paradigm towards progressive ALT step-stress testing compared to fixed stress ALT. Moreover, our results seem to indicate a preference from an inference point of view toward progressive step-stress testing when compared to any other profile or regressive step patterns.

A Concluding Remark

It is important to recall here that comparisons in the section titled “A Comparison of ALT Step Patterns” are conducted in a context where the ALT survival probability is fixed at approximately 5% regardless of the step patterns and values of the sample failure rates λ^i (which requires “stretching” or “shrinking” the total test time). The conclusion of comparison between fixed stress testing at use stress and at a higher stress level may thus be considered “kicking in an open door”. Of course, we would prefer to test in use stress than in a higher stress from an inference point of view if we had the time to do so. The important observation is, however, that the larger the difference between the higher stress environment and the use stress environment, the larger the “dampening effect” of high-stress environment data on use stress updating (due to an ever smaller correlation between the two). Consequently, a larger amount of data at higher stress levels may be needed to observe similar departures from specified prior use stress information when compared to use stress testing. In

our judgment, this dampening effect is intuitive and realistic.

Such a dampening effect is not present when one utilizes a one-to-one transformation function (such as, for example, the power law) between a higher stress environment failure rate and that of use stress. Essentially, the one-to-one time transformation function “translates” a failure in a high-stress environment to that of use stress (and thus assumes no loss of information by testing at a higher stress level). “Correctness” of any statistical inference procedure that utilizes such a one-to-one time transformation function therefore “stands and falls” with the correctness of the time transformation function used. We are of the opinion that neither the functional form of the transformation function nor its parameters can be known exactly (especially when more than one stress parameter is varied at one time), which is why we propose instead the use of a relaxed ranking assumption of environments in terms of failure rates (see equation (1)) and a subsequent Bayesian analysis as presented in this article.

Accelerated Life Tests: Nonparametric Approach

Introduction

Accelerated life testing (ALT) is a method that exposes items to higher stress levels than they expect to receive during a normal use to induce early failures. Typical accelerating stresses include temperature, humidity, voltage, and pressure. These reduced times to failure are beneficial in many situations. For example, to test an item with a mean failure time that is measured in decades, such as a turbine rotor in a hydroelectric dam, under normal conditions would require waiting many years to determine whether the item is sufficiently reliable to be utilized. Even for an item with a much shorter failure time, sometimes it is necessary to accelerate life by testing at stress levels that are higher than normal. For example, for a computer memory chip, the changes in current technologies can be such that it may become obsolete before it is proved reliable. Thus, ALT is now increasingly used in manufacturing industries to reduce the test time and costs. The objective of ALT is either for reliability prediction or to compare one design with another. It is also used to generate failures for failure-mode analysis. Nelson [1] and Bagdonavicius and Nikulin [2] provide a comprehensive review of the theory and practice of ALT.

Parametric models have been introduced to describe the relationship between the distribution functions of lifetimes for different stress levels. The parametric models assume a particular form of the distribution functions at each stress level, and the relationship between them. Nonparametric models for ALT assume a physically reasonable functional relationship between the life distribution functions at the accelerated and nonaccelerated stress levels. However, there are no assumptions on the life distribution function. Parameter transformations are then used to obtain the lifetime distribution under normal stress level. Here, our focus is strictly on nonparametric models. For more see also Basu and Ebrahimi [3], Devarajan and Ebrahimi [4], Jin *et al.* [5], Park and Wei [6], Liero and Liero [7], and references cited there.

Nonparametric Approach to ALT under Multiple Stress Variables

In this section we describe methods for obtaining estimate of life distribution function under normal stress level. Consider a k -dimensional stress vector $\mathbf{S} = (V_1, \dots, V_k)$ applied to an item. Let $F(t|\mathbf{S}_i)$ and $F(t|\mathbf{S}_0)$ be the distribution functions at the stress level $\mathbf{S}_i$ and at normal stress level $\mathbf{S}_0$, respectively. Here $\mathbf{S}_j = (V_{1j}, \dots, V_{kj})$. Our objective is to estimate $F(t|\mathbf{S}_0)$ using observations from accelerated stress levels alone.

Suppose that the relationship between $F(t|\mathbf{S})$ and $F(t|\mathbf{S}_0)$ is

$$F(t|\mathbf{S}) = F(g_{\mathbf{S}_0, \mathbf{S}}(t)|\mathbf{S}_0), \text{ for all } t \geq 0 \quad (1)$$

where $g_{\mathbf{S}_0, \mathbf{S}}(t)$ is called an *acceleration function* and $g_{\mathbf{S}_0, \mathbf{S}}(t) \geq t$ with $g_{\mathbf{S}_0, \mathbf{S}_0}(t) = t$. An acceleration function $g_{\mathbf{S}_0, \mathbf{S}}(t)$ is said to be linear if

$$g_{\mathbf{S}_0, \mathbf{S}}(t) = \alpha(\mathbf{S}_0, \mathbf{S})t, \text{ for all } t \geq 0 \quad (2)$$

In the equation (2), $\alpha(\mathbf{S}_0, \mathbf{S})$ is the acceleration coefficient between $\mathbf{S}$ and $\mathbf{S}_0$. It is important to note that using equations (1) and (2) the acceleration coefficient at the stress level $\mathbf{S}_0$ is 1, that is, $\alpha(\mathbf{S}_0, \mathbf{S}_0) = 1$.

If equation (2) holds, then it is clear that for any two acceleration levels $\mathbf{S}_i$ and $\mathbf{S}_j$ we have

$$F(t|\mathbf{S}_j) = F(\theta_{ij}t|\mathbf{S}_i), \text{ for all } t \geq 0 \quad (3)$$

where $\theta_{ij} = \alpha(\mathbf{S}_0, \mathbf{S}_j)/\alpha(\mathbf{S}_0, \mathbf{S}_i)$ is the relative acceleration coefficient.

In the light of equation (3) one can show that

$$F(t|\mathbf{S}_0) = F\left(\frac{t}{\alpha(\mathbf{S}_0, \mathbf{S})} \middle| \mathbf{S}\right) \quad (4)$$

Throughout this section $\mathbf{S}_1 < \mathbf{S}_2$ means that $\mathbf{S}_1$ is less severe than $\mathbf{S}_2$. That is, $F(t/\alpha(\mathbf{S}_0, \mathbf{S}_1)) \leq F(t/\alpha(\mathbf{S}_0, \mathbf{S}_2))$ for all $t \geq 0$. Also, in our discussion throughout for simplicity, we shall limit ourselves only to two-dimensional stress vectors $\mathbf{S} = (V_1, V_2)$.

We assume that the relation between $F(t|\mathbf{S}_i)$ and $F(t|\mathbf{S}_0)$ is given by the following acceleration function:

$$g_{\mathbf{S}_0, \mathbf{S}_i}(t) = \left(\frac{V_{1i}}{V_{10}}\right)^a \left(\frac{V_{2i}}{V_{20}}\right)^b t \quad (5)$$

2 Accelerated Life Tests: Nonparametric Approach

From the equation (3) the model is thus given by

$$F(t|S_i) = F\left(\left(\frac{V_{1i}}{V_{10}}\right)^a \left(\frac{V_{2i}}{V_{20}}\right)^b t | S_0\right) \quad (6)$$

One way to find a and b in the equation (6) is to generate a linear system of two equations by choosing two different levels (i, j) , (i, k) , $i \neq j \neq k$ and solve the system for a and b . From the equation (2), one can easily show that

$$\theta_{ij} = \frac{\alpha(S_0, S_j)}{\alpha(S_0, S_i)} = \left(\frac{V_{1j}}{V_{1i}}\right)^a \left(\frac{V_{2j}}{V_{2i}}\right)^b \quad (7)$$

and

$$\theta_{ik} = \frac{\alpha(S_0, S_k)}{\alpha(S_0, S_i)} = \left(\frac{V_{1k}}{V_{1i}}\right)^a \left(\frac{V_{2k}}{V_{2i}}\right)^b \quad (8)$$

Taking log on both sides, the two equations become

$$\log \theta_{ij} = a \log \frac{V_{1j}}{V_{1i}} + b \log \frac{V_{2j}}{V_{2i}} \quad (9)$$

$$\log \theta_{ik} = a \log \frac{V_{1k}}{V_{1i}} + b \log \frac{V_{2k}}{V_{2i}} \quad (10)$$

Estimation Procedure When Observations Are Not Censored

An ALT is conducted by selecting $S_1, \dots, S_\ell$. At S_j n_j items are put on test. For item p at the stress level S_j its failure time T_{jp} , $j = 1, \dots, \ell$, $p = 1, \dots, n_j$ is observed. Using this information the point estimates of θ_{ij} and θ_{ik} are

$$\hat{\theta}_{ij} = \frac{\bar{T}_i}{\bar{T}_j}, \quad i \neq j \quad (11)$$

$$\hat{\theta}_{ik} = \frac{\bar{T}_i}{\bar{T}_k}, \quad i \neq k \quad (12)$$

respectively, where $\bar{T}_i = \sum_{p=1}^{n_i} T_{ip}$. Now, using equations (12), we rewrite equations (10) as follows:

$$\log \left(\frac{\bar{T}_i}{\bar{T}_j} \right) = a \cdot \log \left(\frac{V_{1j}}{V_{1i}} \right) + b \cdot \log \left(\frac{V_{2j}}{V_{2i}} \right) \quad (13)$$

$$\log \left(\frac{\bar{T}_i}{\bar{T}_k} \right) = a \cdot \log \left(\frac{V_{1k}}{V_{1i}} \right) + b \cdot \log \left(\frac{V_{2k}}{V_{2i}} \right) \quad (14)$$

Solving the above system for a and b , we obtain

$$\hat{a}_{ijk} = \frac{\log \hat{\theta}_{ij} \cdot \log(V_{2k}/V_{2i}) - \log \hat{\theta}_{ik} \cdot \log(V_{2j}/V_{2i})}{\log(V_{1j}/V_{1i}) \cdot \log(V_{2k}/V_{2i}) - \log(V_{1k}/V_{1i}) \cdot \log(V_{2j}/V_{2i})} \quad (15)$$

$$\hat{b}_{ijk} = \frac{\log \hat{\theta}_{ik} \cdot \log(V_{1j}/V_{1i}) - \log \hat{\theta}_{ij} \cdot \log(V_{1k}/V_{1i})}{\log(V_{1j}/V_{1i}) \cdot \log(V_{2k}/V_{2i}) - \log(V_{1k}/V_{1i}) \cdot \log(V_{2j}/V_{2i})} \quad (16)$$

where $\hat{a}_{ijk}$ and $\hat{b}_{ijk}$, $i, j, k = 1, \dots, \ell$, are estimators of a and b .

These $\ell(\ell-1)(\ell-2)/6$ estimators of a and b from equations (16) are used to form a weighted average that gives the estimators $\hat{a}$ and $\hat{b}$ by

$$\hat{a} = \frac{\sum_{i=1}^{\ell} \sum_{j=i+1}^{\ell} \sum_{k=j+1}^{\ell} w_{ijk} \cdot \left[\log \hat{\theta}_{ij} \cdot \log(V_{2k}/V_{2i}) - \log \hat{\theta}_{ik} \cdot \log(V_{2j}/V_{2i}) \right]}{\sum_{i=1}^{\ell} \sum_{j=i+1}^{\ell} \sum_{k=j+1}^{\ell} w_{ijk}^2} \quad (17)$$

and

$$\hat{b} = \frac{\sum_{i=1}^{\ell} \sum_{j=i+1}^{\ell} \sum_{k=j+1}^{\ell} w_{ijk} \cdot \left[\log \hat{\theta}_{ik} \cdot \log(V_{1j}/V_{1i}) - \log \hat{\theta}_{ij} \cdot \log(V_{1k}/V_{1i}) \right]}{\sum_{i=1}^{\ell} \sum_{j=i+1}^{\ell} \sum_{k=j+1}^{\ell} w_{ijk}^2} \quad (18)$$

respectively, where $w_{ijk} = \log(V_{1j}/V_{1i}) \cdot \log(V_{2k}/V_{2i}) - \log(V_{1k}/V_{1i}) \cdot \log(V_{2j}/V_{2i})$. It is important to note that the set of weights used in equations (18) is one of many different ways that one can assign weights.

Using the estimates $\hat{a}$ and $\hat{b}$, we could transform the failure times from any level to failures at the normal stress level. Observing that T_{ip} under the stress level S_i is stochastically equivalent to observing $(V_{1i}/V_{10})^a \cdot (V_{2i}/V_{20})^b \times T_{ip}$ under the stress level S_0 for $i = 1, \dots, \ell$, we define

$$T'_{ip} = \left(\frac{V_{1i}}{V_{10}}\right)^{\hat{a}} \cdot \left(\frac{V_{2i}}{V_{20}}\right)^{\hat{b}} \cdot T_{ip} \quad (19)$$

Using equation (19) and the fact that $(V_{2i}/V_{20})^b \cdot (V_{1i}/V_{10})^a \times T_{ip}$ and $T - T$ is the lifetime of an item

at the normal stress level—have identical distribution, a consistent estimate of average lifetime at S_0 is given by

$$\begin{aligned}\hat{\mu}_0 &= \frac{1}{N} \sum_{i=1}^{\ell} \sum_{p=1}^{n_i} T'_{ip} \\ &= \frac{1}{N} \sum_{i=1}^{\ell} \sum_{p=1}^{n_i} \left(\frac{V_{1i}}{V_{10}} \right)^{\hat{a}} \cdot \left(\frac{V_{2i}}{V_{20}} \right)^{\hat{b}} \cdot T_{ip} \\ &= \frac{1}{N} \sum_{i=1}^{\ell} n_i \left(\frac{V_{1i}}{V_{10}} \right)^{\hat{a}} \cdot \left(\frac{V_{2i}}{V_{20}} \right)^{\hat{b}} \bar{T}_i\end{aligned}\quad (20)$$

Also a consistent estimate of the life distribution function at S_0 is given by

$$\hat{F}(t|S_0) = \frac{1}{N} \sum_{i=1}^{\ell} \sum_{p=1}^{n_i} I(T'_{ip} \leq t) \quad (21)$$

where

$$\begin{aligned}I(T'_{ip} \leq t) &= 1, \text{ if } T'_{ip} \leq t \\ &= 0, \text{ otherwise}\end{aligned}\quad (22)$$

It should be noted that $N = \sum_{i=1}^{\ell} n_i$.

Estimation Procedure When Observations are Censored

Suppose an ALT is conducted at $S_1, \dots, S_{\ell}$. However, at S_j instead of observing T_{jp} , $p = 1, \dots, n_j$ we observe

$$X_{jp} = \min(T_{jp}, T_{jp}^*) \text{ and } \delta_{jp} = \begin{cases} 1, & T_{jp} \leq T_{jp}^* \\ 0, & \text{otherwise} \end{cases} \quad (23)$$

$p = 1, \dots, n_j$, $j = 1, \dots, \ell$. The random variable T_{jp}^* is referred to as the *censoring time* of item p at S_j , $p = 1, \dots, n_j$, $j = 1, \dots, \ell$. Here T_{jp} and T_{jp}^* are assumed to be independent.

In developing the estimators of a and b , we consider the transformation $W_{jp} = \log X_{jp}$, $j = 1, \dots, \ell$, $p = 1, \dots, n_j$. Then the observations are (W_{jp}, δ_{jp}) , $j = 1, \dots, \ell$, $p = 1, \dots, n_j$. In the presence of the above information, an estimator of survival function of $\log T_j$ at S_j , $j = 1, \dots, \ell$, is given by the

Kaplan–Meier [8] and it is

$$\hat{S}_j^{(1)}(w) = \begin{cases} 1, & w \leq w_{j(1)} \\ 0, & w > w_{j(n_j)} \\ \prod_{p=1}^{c-1} \left(\frac{n_j - p}{j - p + 1} \right)^{\delta_{jp}}, & \text{otherwise,} \end{cases} \quad (24)$$

for $c = 2, \dots, n_j$

Following arguments similar to equations (16) and (18), Basu and Ebrahimi [3] and Klein and Moeschberger [9], one can estimate θ_{ij} and θ_{ik} by

$$\hat{\theta}_{ij}(C) = \exp(\eta_{ij}), \quad i \neq j \quad (25)$$

and

$$\hat{\theta}_{ik}(C) = \exp(\eta_{ik}), \quad i \neq k \quad (26)$$

where η_{ij} and η_{ik} are values of η which minimize

$$g_{ij}(\eta) = \min_{\eta} \int_0^{\infty} [\hat{S}_j^{(1)}(w - \eta) - \hat{S}_i^{(1)}(w)]^2 dw \quad (27)$$

and

$$g_{ik}(\eta) = \min_{\eta} \int_0^{\infty} [\hat{S}_k^{(1)}(w - \eta) - \hat{S}_i^{(1)}(w)]^2 dw \quad (28)$$

respectively. One can show that η_{ij} , which minimizes equation (27) is the median of a discrete random variable with **pdf**:

$$h_{n_i n_j}(v) = \begin{cases} a_c b_d, & v = w_{j(d)} - w_{i(c)}, \text{ for all } c, d \\ 0, & \text{otherwise,} \end{cases} \quad (29)$$

$$a_c \equiv \begin{cases} \hat{S}_i^{(1)}(w_{i(c)}) - \hat{S}_i^{(1)}(w_{i(c+1)}), \\ c = 1, \dots, n_i - 1 \\ \hat{S}_i^{(1)}(w_{i(n_i)}), & c = n_i \end{cases} \quad (30)$$

$$b_d \equiv \begin{cases} \hat{S}_j^{(1)}(w_{j(d)}) - \hat{S}_j^{(1)}(w_{j(d+1)}), \\ d = 1, \dots, n_j - 1 \\ \hat{S}_j^{(1)}(w_{j(n_j)}), & d = n_j \end{cases} \quad (31)$$

Now our estimators of $\hat{a}$ and $\hat{b}$ can be simply obtained by replacing $\hat{\theta}_{ij}$ and $\hat{\theta}_{ik}$ in equation (18) by $\hat{\theta}_{ij}(C)$ and $\hat{\theta}_{ik}(C)$. Here C stands for censored. η_{ik} can be defined similarly.

Now consider the transformation

$$Z_{jp} = \left(\frac{V_{1j}}{V_{10}} \right)^{\hat{a}} \left(\frac{V_{2j}}{V_{20}} \right)^{\hat{b}} X_{jp} \quad (32)$$

4 Accelerated Life Tests: Nonparametric Approach

Table 1 Stress–rupture data of Kevlar/epoxy strands at elevated levels of pressure and temperature

Stress level i	Pressure (psi) V_{1i}	Temperature (°C) V_{2i}	Average lifetime $\bar{T}_i$	Sample size n_i
1	80	100	0.6902	47
2	80	110	0.2537	39
3	85	100	0.1472	47
4	73	120	1.2824	52
5	80	120	0.1639	75
6	85	110	0.0909	84
7	85	120	0.0343	128
8	73	100	4.99	75
9	73	110	1.9800	78
10	67	100	49.8500	55
11	67	110	20.5500	53
12	67	120	7.1100	73

Then, the observations are (Z_{jp}, δ_{jp}) , $j = 1, \dots, \ell$, $p = 1, \dots, n_j$. To estimate distribution function at S_0 , combine all observations, i.e., $U_1 = Z_{11}, U_2 = Z_{12}, \dots, U_N = Z_{\ell n_\ell}$, $\gamma_1 = \delta_{11}, \dots, \gamma_N = \delta_{\ell n_\ell}$ and then use the Kaplan–Meier estimator:

$$\hat{F}(u|S_0) = \begin{cases} 0, & u \leq u(1) \\ 1 - \left[\prod_{j=1}^{m-1} \left(\frac{N-j}{N-j+1} \right)^{\gamma_j} \right], & u \in [u(m-1), u(m)], m = 2, \dots, N \\ 1, & u > u(N) \end{cases} \quad (33)$$

Also, a consistent estimate of the average lifetime at S_0 is $\hat{\mu}_0 = \int_0^\infty (1 - \hat{F}(u|S_0)) du$.

Example

In this section, we illustrate the nonparametric **estimation** described in the previous section using the dataset presented in Table 1.

For this data the normal condition stress level was assumed to be $S_0 = (V_{10}, V_{20}) = (35, 70)$. We use equation (18) to obtain $\hat{a} = 23.0999$ and $\hat{b} = 8.4737$ and then, using the complete dataset, the $N = 806$ rescaled variables T'_{ip} , $i = 1, \dots, 12$, $p = 1, \dots, n_i$, were obtained applying equation (19). A consistent estimate of the mean lifetime μ_0 at the normal stress level S_0 was then computed using equation (20). In this case, $\hat{\mu}_0 = 267.658$.

Accelerated Life Tests: Analysis with Competing Failure Modes

Introduction

Accelerated life tests (ALT) are applied on long-life components to obtain failure data in a reasonable time interval, and are performed at higher stress levels that exceed the normal use conditions. The goal is to make inference about the life distribution of the component under use conditions using failure data obtained under more severe environment. To be valid, an accelerated life test must not alter the basic modes and/or mechanism of failure or their relative prevalence. In real experiments, all these problems may occur if the stresses become too high. Many authors took into account the change in failure mechanism, and proposed distributional or Bayesian models that allow all data to be taken into account. However, when more failure modes are present, their relative prevalence, as the stress increases, has not been yet considered, even if this is indicated by accelerated life data.

Multiple failure modes or competing failure modes are often present in industrial accelerated life experiments. Classical and Bayesian models available in the literature usually assume independent failure modes. Little work has been done for dependent competing failure modes, and it resumes to multivariate models with positively correlated lives of failure modes, or to upper and lower bounds for the component life distribution. All these models do not take into account the change in the relative prevalence of the failure modes and the change in the dependence structure as the stress increases.

The purpose of this article is to study the influence of the dependence structure of competing failure modes, as their relative dominance changes with the increase of the applied stress. This is obtained by integrating the results of **competing risk** theory into the ALT procedure, and by using graphical techniques in model selection. Nelson's motorettes data [1] presents a strong change of the relative prevalence of competing failure modes and it will be used as a support application throughout the article.

The section titled "Overview of ALT and Competing Risks" presents several step-stress ALT models, with independent and dependent competing failure modes. Empirical distribution function based on competing risk data are used in the section titled "Graphical Competing Risks Analysis of Motorettes Data" to illustrate the change of the relative dominance of the competing failure modes, and to select the appropriate model to interpret ALT data. An ALT model with dependent failure modes is presented in the section titled "A Copula-Dependent ALT – Competing Risks Model". The dependence structure is modeled by a copula given the rank correlation coefficient, for each stress level. The impact of the independence assumption on the estimated lifetime of the component under use conditions is studied in the section titled "Data Application", with application to two ALT datasets.

Overview of ALT and Competing Risks

We consider an m -constant stress level ALT. At each stress level l , $l = 1, \dots, m$, a number of items are tested until a failure or a censored time occurs. The failure is assumed to occur owing to k competing failure modes, $X_1, X_2, \dots, X_k$. In a competing risks context, we observe the shortest of X_i , $i = 1, \dots, k$, and observe which failure mode it is. In many cases we can reduce the problem to the analysis of two competing risks classes, described by two random variables X_1 and X_2 , and we call X_2 the censoring variable. Competing risk data will only allow us to estimate the subsurvival functions,

$$S_{X_1}^*(t) = P(X_1 > t, X_1 < X_2) \quad (1)$$

and

$$S_{X_2}^*(t) = P(X_2 > t, X_2 < X_1) \quad (2)$$

but not the true survival functions of X_1 and X_2 . Hence, we are not able to estimate the underlying failure distributions without making additional model assumptions.

The conditional subsurvival function is the subsurvival function conditioned on the event that the failure mode in question is manifested. Assuming continuity of $S_{X_1}^*$ and $S_{X_2}^*$ at zero,

$$\begin{aligned} CS_{X_1}^*(t) &= P(X_1 > t, X_1 < X_2 | X_1 < X_2) \\ &= S_{X_1}^*(t) / S_{X_1}^*(0) \end{aligned} \quad (3)$$

2 ALT: Analysis with Competing Failure Modes

$$\begin{aligned} CS_{X_2}^*(t) &= P(X_2 > t, X_2 < X_1 | X_2 < X_1) \\ &= S_{X_2}^*(t)/S_{X_2}^*(0) \end{aligned} \quad (4)$$

Closely related to the notion of the subsurvival functions is the probability of censoring beyond time t ,

$$\begin{aligned} \phi(t) &= P(X_2 < X_1 | \min(X_1, X_2) > t) \\ &= S_{X_2}^*(t)/(S_{X_1}^*(t) + S_{X_2}^*(t)) \end{aligned} \quad (5)$$

This function seems to have some diagnostic value, enabling us to choose the competing risk model that fits the data.

ALT and Independent Competing Risks

The presence of independent competing risks in ALT has been widely studied in the literature. McCool [2] presented a technique for calculating estimate intervals for Weibull parameters of a primary failure mode when a secondary failure mode having the same (but unknown) Weibull shape parameter is acting. Klein and Basu [3, 4] presented the analysis of ALT when more than one failure mode is acting. Assuming independence among competing failure modes for each stress level, the authors obtained maximum likelihood estimators when the lifetimes are exponentially or Weibull – with common- or different-shape parameter – distributed.

Nelson [1] presented graphical and analytical (maximum likelihood) methods to analyze data on a failure mode, estimate a product life distribution when multiple failure modes act, and estimate a product life distribution with certain failure modes eliminated. Nelson indicated that complete datasets are usually analyzed with standard least-squares regression analysis. Such analysis may be misleading for data with competing failure modes. The analysis should consist in a separate Arrhenius model for each failure mode and a series-system model for the relationship between the failure times of each failure mode and the failure time of the component. Examples of products that have multiple causes of failure are given, including insulation systems, ball bearings, and industrial heaters.

A large sample data is considered by Nelson (p. 393), and is collected from a temperature-accelerated life test of motor insulation (the turn, phase, or ground insulation can fail). The experiment was conducted for observing a greater number of failures for each failure mode. When the specimen fails

by a specific failure mode, that insulation is isolated and the motorette is kept on test and runs to a second or third failure. In actual use, the first failure from any cause ends the life of the motor. This fact conducts to a pseudo-competing risk data.

Nelson analysis of motorettes data consists in a separate Arrhenius-lognormal model for each failure mode, and a competing risk (series system) model for the relationship between the failure times of different failure modes and the failure time of a specimen. The assumptions made in the Arrhenius-lognormal model are as follows:

- for temperature T , life has a lognormal distribution;
- the log standard deviation σ_k is constant for all stress levels;
- the mean log life as a function of $x = 1000/T$ is $\mu_k(x) = \alpha_k + \beta_k x$;

where α_k , β_k , and σ_k are the parameters characteristic for the failure mode k , product, and test method. For units run at stress l , the probability that failure mode k survives time t is

$$R_k(t) = \Phi(-(\log(t) - \mu_k(x))/\sigma_k) \quad (6)$$

where Φ is the normal function.

ALT and Dependent Competing Risks

Simple empirical upper and lower bounds of the system life distribution can be found, when the lives of competing failure modes are positively correlated. The lower limit corresponds to the most pessimistic case, when independent failure modes are considered. The upper limit is the lowest life distribution for a single failure mode. These bounds may give some insights with respect to the true distributional form, especially when these bounds are translated to time average failure rate bounds.

Other techniques in dealing with dependent failure modes in ALT are based on multivariate distributions. Multivariate exponential and Weibull distributions – dominant in literature – have properties not suited for all applications.

Klein and Basu [4] proposed a bivariate Weibull model. They considered two competing risks X_1 and X_2 , both Weibull distributed with shape parameter a and scale parameter $\lambda_i(T, \beta_i) + \lambda_{12}(T, \beta_{12})$, $i = 1, 2$, at each temperature (stress) level T ($\beta_1, \beta_2, \beta_{12}$ are

time transformation parameters). The joint survival function of (X_1, X_2) is given by

$$S(x_1, x_2) = \exp(-\lambda_1(T, \beta_1)x_1^a - \lambda_2(T, \beta_2)x_2^a - \lambda_{12}(T, \beta_{12})\max(x_1, x_2)^a) \quad (7)$$

To estimate the parameters of X_1 and X_2 at use conditions, classical methodology of ALT is applied. They illustrated this procedure on the motorette data. However, as shown in the section titled “Graphical Competing Risks Analysis of Motorettes Data”, simple plots of data will reject the applicability of exponential and Weibull multivariate models to this specific dataset.

More elaborate, dependent, competing risk models based on the use of copula have been presented by Hougaard [5] and Bunea and Bedford [6]. These models will be discussed in the section titled “A Copula-Dependent ALT–Competing Risks Model”.

Graphical Competing Risks Analysis of Motorettes Data

Cooke [7] presented several independent and dependent competing risks models. These models have been further investigated by Bedford and Cooke [8], Langseth and Lidqvist [9], and Bunea *et al.* [10]. Nevertheless, the choice of the most appropriate model to fit the competing risk data remains an open debate. All the above authors gave some guidelines for model selection. An important indicator for model selection is the probability of censoring after time t , $\phi(t)$, together with the conditional subsurvival functions $CS_{X_1}^*(t)$ and $CS_{X_2}^*(t)$ (see [10]). Note, that empirical version of these function can be directly obtained from a competing risk dataset.

The model selection guidelines for the most well known competing risk models – independent exponential model, random signs model, conditional independence model, mixture of exponentials model – are as follows:

- If the risks are exponential and independent, then the conditional subsurvival functions are equal and correspond to exponential distributions. Moreover, $\phi(t)$ is constant.
- Under random signs censoring, $\phi(0) > \phi(t)$ and $CS_{X_1}^*(t) > CS_{X_2}^*(t)$ for all $t > 0$.
- If the conditional independence model holds with exponential marginals, then the conditional subsurvival functions are equal and $\phi(t)$ is constant.

- If the mixture of exponentials model holds, then $\phi(t)$ is strictly increasing and $CS_{X_1}^*(t) < CS_{X_2}^*(t)$ for all $t > 0$.

In addition to the above statements, one can easily show that Klein and Basu’s multivariate exponential model requires equal conditional subsurvival function. Simple calculations give the subsurvival and conditional subsurvival functions:

$$S_{X_1}^*(t) = \frac{\lambda_1 + \lambda_{12}}{\lambda_1 + \lambda_2 + \lambda_{12}} \exp(-(\lambda_1 + \lambda_2 + \lambda_{12})t) \quad (8)$$

$$S_{X_2}^*(t) = \frac{\lambda_2 + \lambda_{12}}{\lambda_1 + \lambda_2 + \lambda_{12}} \exp(-(\lambda_1 + \lambda_2 + \lambda_{12})t) \quad (9)$$

$$CS_{X_1}^*(t) = CS_{X_2}^*(t) = \exp(-(\lambda_1 + \lambda_2 + \lambda_{12})t) \quad (10)$$

Note that the conditional subsurvival function should be equal at each stress level to have a valid ALT–competing risks model.

Figure 1 shows the empirical conditional subsurvival functions for motorettes data, with failure modes grouped in two competing risk classes: risk 1 – turn-failure modes and risk 2 – phase- and ground-failure modes. One can see a strong change in the failure mechanism as the stress level increases. At the first stress level the dominant failure mode is risk 2, with its conditional subsurvival function lying entirely above the conditional subsurvival function of risk 1. A mixture of exponentials model may be appropriate for this case. The conditional subsurvival functions are more or less equal for stress level 2 and 3, indicating that an independent exponential model may apply. Data obtained from stress level 4 indicates a dominant conditional subsurvival functions for risk 1, and thus a random signs model may be selected (risk 1 being censored).

The change in the relative prevalence of the failure modes does not allow a classical ALT–competing risk model to analyze data. Since the conditional subsurvival functions are not equal for each stress level, the assumption of independent exponential or Weibull with same shape parameter failure modes is clearly rejected by motor insulation data. On the basis of model selection criteria presented at the beginning of this section, the random signs model and the multivariate exponential (or Weibull with same shape parameter model) are also rejected. The next section will present a more complex dependent model and investigate the influence of the degree of dependence on the estimated distribution functions at use conditions.

Figure 1 Empirical conditional subsurvival functions for motorettes data, at each temperature (stress) level

A Copula-Dependent ALT–Competing Risks Model

Competing risks and copula

We assume that the dependence structure between X_1 and X_2 is given by a copula. The copula of two random variables X_1 and X_2 with distribution functions $F_{X_1}(X_1)$ and $F_{X_2}(X_2)$, is the distribution C on the unit square $[0, 1]^2$ of the pair $(F_{X_1}(X_1), F_{X_2}(X_2))$. The functional form of $C: [0, 1]^2 \rightarrow \mathbf{R}$ is $C(u, v) = H(F_{X_1}^{-1}(u), F_{X_2}^{-1}(v))$, where H is the joint distribution function of (X_1, X_2) and $F_{X_1}^{-1}$ and $F_{X_2}^{-1}$ are the right-continuous inverses of F_{X_1} and F_{X_2} . Under the assumption of independence of X_1 and X_2 , the marginal distribution functions of X_1 and X_2 are uniquely determined by data. Zheng and Klein [11] showed a more general result that, if the copula of (X_1, X_2) is known, then the marginal distributions functions of X_1 and X_2 are uniquely determined by the competing risk data. More precisely, the marginal distributions functions F_{X_1} and F_{X_2} are solutions

of the following system of ordinary differential equations:

$$\begin{cases} \{1 - C_u(F_{X_1}(t), F_{X_2}(t))\} F'_{X_1}(t) = F_{X_1}^{*'}(t) \\ \{1 - C_v(F_{X_1}(t), F_{X_2}(t))\} F'_{X_2}(t) = F_{X_2}^{*'}(t) \end{cases} \quad (11)$$

with initial conditions $F_{X_1}(0) = F_{X_2}(0) = 0$, where $C_u(F_{X_1}(t), F_{X_2}(t))$ and $C_v(F_{X_1}(t), F_{X_2}(t))$ denote the first order partial derivatives $\frac{\partial}{\partial u} C(u, v)$ and $\frac{\partial}{\partial v} C(u, v)$ calculated in $(F_{X_1}(t), F_{X_2}(t))$. $F_{X_1}^{*'}(t) = S_{X_1}^*(0) - S_{X_1}^*(t)$ and $F_{X_2}^{*'}(t) = S_{X_2}^*(0) - S_{X_2}^*(t)$ are the subdistribution functions of X_1 and X_2 (see [8]).

Measures of Association

Let X and Y be two random variables. There are many **measures of association** for the pair (X, Y) , which are symmetric in X and Y . The best-known measures of association are Kendall's τ and Spearman's ρ .

For the goal of this article, we will henceforth consider only Spearman's ρ . The Spearman's ρ is

defined as the product moment correlation of $F_X(X)$ and $F_Y(Y)$:

$$\begin{aligned}\rho_r(x, y) &= \rho(F_X(X), F_Y(Y)) \\ &= \frac{\text{Cov}(F_X(X), F_Y(Y))}{\sqrt{\text{Var}(F_X(X))\text{Var}(F_Y(Y))}}\end{aligned}\quad (12)$$

The simple formula relating Spearman's ρ to copula density is

$$\rho(X, Y) = 12 \int_0^1 \int_0^1 uv dC(u, v) - 3 \quad (13)$$

Since the measure of association is to be treated as a primary parameter, it is necessary to choose a family of copulae that model all possible measures of association in a simple way. Meeuwissen and Bedford [12] have proposed to use the unique copula with the given Spearman's ρ that has minimum information with respect to the independent distribution, and also they have given a method to calculate this copula numerically. Prior knowledge or subjective information to obtain values for the measure of association is needed. Expert judgment is used to model the uncertainty over the measure of association (see [6]).

Work of Zheng and Klein suggests that the important factor for an estimate of the marginal survival function is a reasonable guess at the strength of the association between competing risks and not the functional form of the copula. For this reason we will choose a class of copula that is easy to work with from the mathematical point of view. A class with such properties is the Archimedean copula.

Archimedean Copula

Let X_1 and X_2 be continuous random variables with joint distribution H and marginal distribution F_{X_1} and F_{X_2} . The Archimedean copula is defined as

$$\varphi(H(x_1, x_2)) = \varphi(F_{X_1}(x_1)) + \varphi(F_{X_2}(x_2)) \quad (14)$$

or in terms of copula

$$\varphi(C(u, v)) = \varphi(u) + \varphi(v) \quad (15)$$

The function φ is called an *additive generator of the copula*. If $\varphi(0) = 1$, φ is a strict generator and $C(u, v) = \varphi^{-1}(\varphi(u) + \varphi(v))$ is a strict Archimedean copula. For our goal we choose a one-parameter

family of copulae, which has a strict generator. The Gumbel family is defined as follows:

$$C_\alpha(u, v) = \exp(-((- \log u)^\alpha + (- \log v)^\alpha)^{1/\alpha}) \quad (16)$$

with parameter $\alpha \in [1, \infty)$. The generator is the function $\varphi_\alpha(t) = (- \log t)^\alpha$. Using the relation between Spearman's ρ and copula (equation (13)), we can obtain α as a function of Spearman's ρ . However, no analytical solution can be found and numerical calculations are needed.

Copula ALT-Competing Risks Model

Let U_1 and U_2 be two random variables associated with the conditional subsurvival functions of X_1 and X_2 . The ALT-competing risk model proposed has two steps: the first step consists of a separate Arrhenius-lognormal model for each random variable U_1 and U_2 ; the second step models the dependence structure of X_1 and X_2 at each stress level and at use conditions by a copula, with the rank correlation coefficient given as a primary parameter.

Graphical and analytical (maximum likelihood) analysis of the Arrhenius-lognormal model (see [1]), applied to the conditional subsurvival functions at each stress level, enables us to find the conditional subsurvival functions at use conditions, and to estimate the distributional parameters. Elicitation of the rank correlation coefficient at each stress level and at use conditions using experts' opinion allows us to fully specify the copula. Further, applying Zheng and Klein's result (equation (11)) one can obtain the distribution functions of X_1 and X_2 at each stress level and at use conditions.

Data Application

We will apply the copula ALT-competing risks model to Nelson's motorettes data. Table 1 presents the estimated parameters of the lognormal distribution (for U_1 and U_2) at each stress level and at use conditions. These distributions, together with the values in point zero of the subsurvival functions of X_1 and X_2 , and with the elicited rank correlation coefficients, constitute input factors in the system of equations (11).

Figure 2 shows the distribution functions of X_1 and X_2 at each stress level. One can see a shift to the left of the plots as the stress increases, indicating a shorter time to failure as the stress is higher.

Figure 2 Distribution functions for each failure mode, at each temperature (stress) level (motorettes data)

Table 1 Estimated parameters of the lognormal distribution (for U_1 and U_2) at each stress level and at use conditions (motorettes data)

Temperature (°C)	μ_{U_1}	σ_{U_1}	μ_{U_2}	σ_{U_2}
180	1.4061	0.0201	1.4660	0.0280
190	1.3683	0.0208	1.4165	0.0206
220	1.2453	0.0236	1.2506	0.0321
240	1.1540	0.0259	1.2243	0.1026
260	1.0535	0.0287	1.1508	0.1334

Figure 3 presents the distribution functions of X_1 and X_2 at use condition, for different degree of dependence between failure modes: from independence in the upper left corner to strong dependence in the lower right corner. Even if a logarithmic scale is used, one can see the difference that the degree of dependence makes in estimating the true distribution functions at use conditions.

A more clear visualization of the above results may be obtained by analyzing the industrial heaters data presented by Nelson (p. 420). This data is

Figure 3 Distribution functions for each failure mode, at use conditions (motorettes data); different degree of dependence are considered

collected from a temperature-accelerated life test of industrial heaters, which have two failure modes – open (breaking of the heating element wire) and short (breakdown of the electrical insulation). A Bayesian Arrhenius-exponential model for random variables U_1 and U_2 is used (see [13]), and the dependence structure is modeled by an Archimedean copula, given the rank correlation coefficient.

Table 2 Estimated failure rates of U_1 and U_2 at each stress level and at use conditions (industrial heaters data)

Temperature ($^\circ\text{F}$)	λ_{U_1}	λ_{U_2}
1150	4.1075E-04	6.0985E-05
1600	6.5287E-04	6.8595E-04
1675	8.0000E-04	7.4048E-04
1750	1.0865E-03	1.3333E-03
1820	3.9393E-03	4.0000E-03

Figure 4 Distribution functions for each failure mode, at use conditions (industrial heaters data); different degree of dependence are considered

Table 2 presents the estimated failure rates of U_1 and U_2 at each stress level and at use condition. Figure 4 shows the distribution functions at use conditions of X_1 and X_2 . The sensitivity of the estimated distributions with respect to the degree of dependence is more obvious in this case.

Conclusions

Several ALT-competing risks models have been presented in this article. Classical independent and

dependent models failed to suit all types of ALT data. Simple plots of experimental data have rejected the applicability of such models, especially when the relative dominance of competing failure modes changes as the applied stress increases. A new dependent ALT-competing risks model based on copula has been proposed. The results show a high sensitivity with respect to the degree of dependence between competing failure modes. Thus, the assumption of “independent failure modes” can lead to wrong results when the risks are actually highly correlated. The disadvantage of this method consists in the large

number of measures of association that need to be estimated by experts (one for each stress level and one for use conditions).

Prediction of Expected Fatigue Lives of Fiber Reinforced Plastic Joints

Introduction

Analysis of fatigue is typically based on the concept of a function D that represents the accumulated damage due to stresses and strains occurring at any given time. This function is presumed to increase monotonically, and failure is expected when the accumulated damage reaches some critical level. Usually the damage function is normalized so that it reaches unity at failure — $D = 1$ at the time of failure. This reasonable concept is very compatible with stochastic modeling, with $\{D\}$ becoming a stochastic process when stresses are stochastic. The problem of predicting time of failure then becomes one of studying the $\dot{D}$ rate of growth of $\{D\}$. The practical difficulty in implementing the accumulated **damage model** is that D is not observable by currently available means. D is known at only two points; it is presumed to be at least approximately zero for a specimen that has not yet been subjected to loads and it is unity when failure occurs [1].

Background

Current fatigue analysis methods are based on various approximations and assumptions about the function D . The goal in formulating such approximations is to achieve compatibility with the results of experiments. These experiments are sometimes performed with quite complicated time histories of loading, but more typically they involve simple periodic (possibly harmonic) loads in so-called *constant-amplitude tests*. It is presumed that each period of the motion contains only one peak and one valley. In this situation, the number of cycles until fatigue failure is usually found to depend primarily on the amplitude of the cycle, although this is usually characterized with the alternative nomenclature of *stress range*, which is essentially the double amplitude, being equal to a peak value minus a valley value. There is a secondary dependence on the mean stress level, which can be taken as the average of the peak and valley stresses [1].

Constant-Amplitude Fatigue

The notation S_r denotes the stress range of a cycle and N_f designate the number of cycles until failure in a constant-amplitude test. A typical experimental investigation of constant-amplitude fatigue for specimens of a given configuration and material involves performing a large number of tests including a number of values of S_r , and then plotting the (S_r, N_f) results. This is called an *S/N curve*, and it forms the basis for most information and assumptions about D . One can emphasize the dependence of fatigue life on stress range by writing $N_f(S_r)$ for the fatigue life observed for a given value of the stress range. In principle, the *S/N curve* of $N_f(S_r)$ versus S_r could be any nonincreasing curve, but experimental data commonly show that a large portion of that curve is well approximated by an equation of the form

$$N_f(S_r) = K S_r^{-m} \quad (1)$$

in which K and m are positive constants whose values depend on both the material and the geometry of the specimen. This *S/N curve* becomes a straight line on log–log paper. If S_r is given either by small or very large values, then the form of equation (1) will generally no longer be appropriate, but fatigue analysis usually consists of predicting failure due to moderately large loads, so equation (1) is often quite useful.

Because of the considerable scatter in *S/N data*, it is necessary to use a statistical procedure to account for specimen variability and choose the best $N_f(S_r)$ curve. For the common power-law form of equation (1), the value of K and m are usually found from linear regression, which minimizes the mean-squared error in fitting the data points. It should be noted that this linear regression of data does not involve the use of any probability model.

As noted, the fatigue life also has a secondary dependence on the mean stress. Although this effect is often neglected in fatigue prediction, there are simple empirical formulas that can be used to account for it in an approximate way. One such approach is called the *Goodman correction*, and it postulates that the damage done by a loading $x(t)$ with mean stress x_m and stress range S_r is the same as would be done by an “equivalent” mean-zero loading with an increased stress range of S_e , given by $S_e = S_r / (1 - x_m/x_u)$, in which x_u denotes the ultimate stress capacity of the material. The *Gerber correction* is similar, $S_e =$

2 Prediction of Expected Fatigue Lives of Fiber Reinforced Plastic Joints

$S_r/[1 - (x_m/x_u)^2]$, and has often been determined to be in better agreement with empirical data. Note that use of the Goodman or Gerber correction allows one to include both mean stress and stress range in fatigue prediction, while maintaining the simplicity of a one-dimensional S/N relationship [1].

Another power-law relationship established in metal fatigue is the Manson–Coffin relationship, usually expressed as [2]

$$\varepsilon_{ap} = \varepsilon_f(N)^c \quad (2)$$

in which ε_{ap} is the applied plastic strain amplitude, and ε_f and c are fatigue coefficients. The Manson–Coffin equation is usually employed in the context of local approaches to fatigue damage accumulation; only in such a situation can the plastic strain magnitude be quantified from local material response due to stress concentration and/or residual stresses.

Because it is difficult to define plastic strain for composite materials, the Manson–Coffin relation has not found any application. However, owing to its universality, the power-law S/N curve is often used to characterize fatigue failures, especially when little information on the fatigue behavior of a particular material exists. In composite fatigue, this relationship is usually associated with the names of Hahn and Kim [3] who preferred to express it as

$$sN^d = c \quad (3)$$

In this equation d and c are model (material) parameters, and s is the ratio of the applied stress, S , and the material's ultimate strength, S_{ult} , i.e.,

$$s = \frac{S}{S_{ult}} \quad (4)$$

This ratio is frequently applied as a measure of loading severity in fatigue studies.

Hahn and Kim also consider the semilogarithmic S/N curve model in which the applied stress level is related to $\log(N)$, expressing it as

$$s = k \log(N) + b \quad (5)$$

where k and b are material parameters and s is given by equation (4) [2].

Stochastic Fatigue

As previously noted, the fundamental problem in stochastic analysis of fatigue is to define a stochastic

process $\{D\}$ to model the accumulation of damage caused by a stochastic stress time history $\{X\}$. It seems that most predictions of fatigue life in practical problems are based on simpler models in which information about the accumulated damage is obtained from the constant-amplitude S/N curve.

Hwang and Han [4] suggested that a composite material D can be most generally expressed as

$$D = D(D_0, n, S, f, T, M, \dots) \quad (6)$$

where D_0 is the initial damage existing prior to the application of the considered loading segment, n is the number of fatigue cycles, S is the applied stress level, f is the loading frequency, T is the temperature, and M is the moisture content. The effect of the last three parameters on fatigue damage will not be considered in this section.

The combined influence of the other three parameters, D_0 , n , and S , on the fatigue damage accumulation can be considered in the assumption that when damage is caused by a multilevel stress history, not only does the damage contribution from each loading cycle need to be added up, but the influence of the loading of each cycle on the damage caused by subsequent cycles needs to be identified. This is quite a complex situation that is rarely employed in practice. The first simplification is done by neglecting the effect of D_0 . That is, by assuming that damage caused by the sequence of n cycles with magnitude S is always the same regardless of where this sequence occurs in the loading history. Such damage accumulation rules have been considered in the context of fatigue of fiber reinforced plastic (FRP) laminates and are discussed below.

The simplest damage accumulation law, which is commonly known as *Palmgren–Miner's rule*, assumes that damage contribution from each cycle of the loading history is independent of the other cycles. Therefore, the damage inflicted by n stress cycles with magnitude S is simply

$$D = \frac{n}{N} \quad (7)$$

where N denotes the cycles to failure at S from the constant-amplitude S/N curve. For all stress levels this damage rule yields

$$D = \sum_{i=1}^m \frac{n_i}{N_i} \quad (8)$$

where n_i is the number of cycles having amplitude S_i and N_i is the cycles to failure at S_i .

In many situations, the rate of fatigue damage accumulation in composites may deviate significantly from that assumed in equation (7). For example, Howe and Owen [5] reported that

$$D = B \left(\frac{n}{N} \right) - C \left(\frac{n}{N} \right)^2 \quad B, C > 0 \quad (9)$$

fits much better with constant-amplitude data that they obtained from chopped strand mat (CSM) composites. Such an equation, however, has no particular benefit over the linear damage accumulation rule, equation (7). Making damage a function of the ratio of n/N only implies that it is always the same regardless of the cycle's position in the loading sequence. Therefore, there is always a measure of damage that accumulates linearly under constant-amplitude loadings.

In connection with equation (1), Palmgren–Miner's rule equation (8) is used almost exclusively in metal fatigue. By treating a multilevel stress time history as a random process, equations (1) and (8) sometimes allow quite a simple stochastic approach to be used to estimate cumulative damage. This approach is applicable when the loading can be described as a zero-mean, Gaussian, and narrowband stochastic process. In such a case, the amplitudes of the fatigue cycles possess a Rayleigh probability distribution, which can be expressed as

$$p_S(S) = \frac{S}{S_{\text{rms}}^2} \exp \left(-\frac{S^2}{2S_{\text{rms}}^2} \right) \quad (10)$$

In the above formula, S_{rms} denotes the root-mean-square (RMS) value of the stochastic stress history. By using the Palmgren–Miner hypothesis equation (7) and the power-law S/N curve equation (1), the expected fatigue damage $E[D]$ and the expected cycles to failure $E[N]$ are expressed as

$$\begin{aligned} E[D] &= \frac{1}{E[N]} = \frac{1}{K} E[S^m] \\ &= \frac{1}{K} \int_0^\infty \frac{S^{m+1}}{S_{\text{rms}}^2} \exp \left(-\frac{S^2}{2S_{\text{rms}}^2} \right) dS \end{aligned} \quad (11)$$

The integration of the above equation yields

$$E[D] = \frac{1}{E[N]} = \frac{1}{K} 2^{\frac{m}{2}} S_{\text{rms}}^m \Gamma \left(1 + \frac{m}{2} \right) \quad (12)$$

where $\Gamma(\cdot)$ is the gamma function. Equation (12) is known as the *Rayleigh approximation*.

An expression similar to equation (12) can be derived if the Palmgren–Miner rule is applied in conjunction with the semilogarithmic S/N curve model equation (5). To this end, assume first that the semilogarithmic model is expressed as

$$\log(N) = b - aS \quad (13)$$

in which b and a are the parameters of the model obtained from a linear regression of the experimental data. This equation can be further rearranged as

$$N = 10^{b-aS} = e^{\bar{b}-\bar{a}S} \quad (14)$$

where

$$\bar{b} = b \ln(10) \quad \bar{a} = a \ln(10) \quad (15)$$

The expected damage can then be expressed as

$$\begin{aligned} E[D] &= \frac{1}{E[N]} = e^{-\bar{b}} \int_0^\infty \frac{S}{S_{\text{rms}}^2} \\ &\quad \times \exp \left(-\frac{S^2}{2S_{\text{rms}}^2} + \bar{a}S \right) dS \end{aligned} \quad (16)$$

Performing the integration in equation (16) gives

$$\begin{aligned} E[D] &= \frac{1}{E[N]} = e^{-\bar{b}} \left[1 + \bar{a}S_{\text{rms}} \exp \left(\frac{\bar{a}^2 S_{\text{rms}}^2}{2} \right) \right. \\ &\quad \times \left. \Phi(\bar{a}S_{\text{rms}}) \sqrt{2\pi} \right] \end{aligned} \quad (17)$$

in which $\Phi(\cdot)$ denotes the Gaussian cumulative function [6].

Experimental Approach

The composite test program discussed in this paper was set up to provide a more realistic insight into the static and fatigue behavior and damage accumulation of FRP joints. To study the fatigue damage accumulation in FRP specimens, several different specimen configurations were designed and fabricated for characterization under constant- and variable-amplitude fatigue loadings.

The base laminate consisted of an alternating 0/90° stacking sequence of 30 plies made of 0.025 in.

4 Prediction of Expected Fatigue Lives of Fiber Reinforced Plastic Joints

thick Woven Roving (WR) glass fabric and 510-A vinyl ester resin. This layup was fabricated by Hardcore DuPont Composites, L.L.C., into several panels measuring 2 ft by 3 ft using the Seeman composite resin infusion molding process (SCRIMP) process. The postcure cycle for the panels was 2 h at 160 °F. The panels were then cut into specimens.

The behavior of composite joints under static, constant-amplitude, and variable-amplitude fatigue was studied. Each configuration was realized in a single geometry butt-strap joint. Specimens were made of the same laminate as previously discussed with the addition of 15 ply laminates of the same layup; joint adherents were oriented along the 0/90° material direction. Figure 1 shows the typical geometries of joint specimens [6].

Static Tests

The static tests consisted of ultimate tension and compression strength tests, which were designed to characterize the static behavior of the specimens and to aid in selecting the appropriate stress levels for the fatigue tests. In all configurations, some strain gages were mounted on the surface of the joints in order

to monitor the evolution of the state at the points of interest. All bonded specimens failed in an adhesive mode. The bolted joint exhibited a combination of cleavage-tension and shear-out failure and the bolted-bonded joint, after demonstrating first a bond failure, had finally failed in a shear-out mode. In the compressive regime, the bonded joint had delaminated in both laps and one of the adherents owing to the combined effect of contraction and buckling. Similarly, the bolted joint had shortened and buckled antisymmetrically (mode 2) and all joint components had delaminated as a consequence. The bonded-bolted joint showed an early bond failure and a final failure due to a symmetric buckling and a consequent delamination in all components. The bolted-bonded joint is the most advantageous configuration, as far as the tensile strength is concerned, since it has a higher initial stiffness, a higher failure load and a very good ductility compared to the others. On the other hand, in the compressive regime, although it has a higher initial stiffness, its strength and ductility are lower than those of the bolted configuration, which may be due to the difference in the buckling mode, since a mode 2 buckling requires a higher load to occur [6].

Fatigue Tests

The fatigue tests typically consisted of two to three specimens tested at each stress level, or RMS level for constant or variable amplitude, respectively. All tests were performed at constant frequency. The variable-amplitude loading represents a segment of a sinusoidal time history composed of 10 000 end points, which with the assumption of stationary and ergodicity can be shown to be a narrowband Gaussian process. This segment is repeated until failure of the specimen occurs [6].

Tables 1 and 2 show the constant-amplitude and variable-amplitude test results for different types of composite joints.

The failure of the bonded joints is an adhesive failure of the bond, while that of the bolted joints is a bearing failure followed by a partial shear-out failure. The failure of the bonded-bolted joints is a two-stage one. First, and very early, comes the adhesive failure of the bonds and then, typically after a long time, the bearing and partial shear-out failures of the bolts occurs.

The experimental fatigue lives from the constant-amplitude tests of all joint configurations are presented in Figure 2 on a log(S)–log(N) scale and in

Figure 3 on a S-log(N) scale. Both logarithmic and semilogarithmic S/N curve models were fit to these data by linear regression. The curves indicate a definite deviation from the logarithmic S/N curve model for all joint configurations. Neither S/N curve model appears to represent the data well.

Variable-Amplitude Fatigue Tests Analysis

Experimental variable-amplitude fatigue lives are obtained by applying the aforementioned time

history to the specimens at different RMSs; and the analytic random fatigue lives are calculated by following the fatigue damage accumulation models (equations (12) and (17)). Comparison between the variable-amplitude fatigue results and the Rayleigh approximation, based on both logarithmic and semilogarithmic S/N curve model is provided in Table 3. It can be seen that for the lower RMS levels considered, the classical Rayleigh approximation underestimates the actual fatigue life from 37 to 67%. The same trend is observed for Gaussian approximation method and the

expected fatigue lives are underestimated from 56 to 66%.

The fatigue lives at the higher RMS levels are significantly overestimated by using both Rayleigh and

Gaussian methods. For both bonded only and bolted only specimen types, the predictions at the higher RMS levels (1.75 ksi) are somewhat improved by the use of Rayleigh approximation method, but this

Figure 3 S/N curves of FRP joints (semi-log curve fit)

Table 3 Comparison of Rayleigh and Gaussian fatigue lives with test results

Joint type	RMS level (ksi)	Experimental (geometrical mean)	Rayleigh approximation	Gaussian method
Bonded only	1.25	2 855 600	925 300	979 200
	1.75	33 500	113 600	148 300
Bolted only	1.25	354 600	225 500	129 800
	1.75	8340	22 100	26 100
Bonded and bolted	1.75	8 600 700	3 510 200	3 789 200
	2.25	161 100	275 400	234 500

improvement is quite marginal. At the same time, Rayleigh approximation leads to further deviation from the experimental mean for the two lower stress RMS levels of bonded only and bonded and bolted specimens (1.25 and 1.75, respectively). These large deviations mainly come from the basic assumptions built in the Rayleigh approximation.

As pointed out in the previous section, the classical Rayleigh and Gaussian approximation formulas (12) and (17) is based on both equation (1) and on the Palmgren–Miner damage accumulation rule equation (8). Therefore, misrepresentation of the actual stress-life relationship caused by a poor S/N curve

function or insufficient S/N data, or disregarding the sequence effects by using the Miner rule, are main reasons for the shortcomings of the Rayleigh approximation in estimating the random fatigue lives.

Conclusion

Fatigue damage in FRP laminates occurs in the form of diffuse zones containing microcracks in the matrix, fiber–matrix debonding sites, ply delamination, and broken fibers. This damage leads to **degradation** of the elastic moduli of the laminate, and is therefore

best modeled by stiffness degradation approaches. Various S/N curve models for constant-amplitude fatigue damage characterization can be described in terms of the fatigue modulus concept of Hwang and Han. In contrast, fatigue damage accumulation techniques constitute a much less investigated area; most data available deal with two-stage loading cases only [6]. The constant- and variable-amplitude fatigue studies on the laminate joints tested show a definite trend toward deviation from the power-law S/N curve model. Variable-amplitude fatigue tests with narrowband stress histories demonstrate significant deviation of the observed fatigue lives from those predicted with the Rayleigh approximation and Gaussian cumulative function. Such a deviation can be attributed to the inadequacy of the Palmgren–Miner’s damage accumulation rule for composite materials and to poor representation or insufficiency of the constant-amplitude data as well as load frequency and sequence effects, which have not yet been quantified and incorporated into a fatigue damage accumulation model.

Design for Reliability

Introduction

To ensure product reliability, an organization must follow certain practices during the product development process. These practices impact reliability through the selection of materials, product design, manufacturing, assembly, shipping and handling, operation, and maintenance and repair. These practices are listed below and briefly described in this chapter.

- Define realistic product requirements determined by factors including the life-cycle application profiles, required operating and storage life, performance expectations, size, weight, and cost. The product requirements should be based on both the customer's needs and the manufacturer's capability to meet those needs.
- Define the product life-cycle conditions by specifying all relevant manufacturing, assembly, storage, handling, shipping, operating, and maintenance conditions.
- Ensure that the supply-chain participants have the capability to produce the parts (materials) or services to meet the final reliability objectives.
- Select the materials and parts that have sufficient quality, and are capable of delivering the expected performance and reliability in the application. The materials and parts must be characterized. Variabilities in material properties and manufacturing processes will impact the product's reliability.
- Identify the potential failure modes, failure sites, and failure mechanisms by which the product can be expected to fail.
- Design to the usage and process capability of the product (i.e., the quality level that can be controlled in manufacturing and assembly) considering the potential failure modes, failure sites, and failure mechanisms. The designed product must satisfy the manufacturability, quality, reliability, and budget requirements and constraints, and be available to the customers in a timely manner.
- Qualifications should be conducted to verify the reliability of the product in the expected life-cycle conditions. Qualification encompasses all activities that ensure that the nominal design and

manufacturing specifications will meet or exceed the reliability goals. The goal of this step is to provide a physics-of-failure basis for design decisions, with an assessment of all possible failure mechanisms for the anticipated product.

- All manufacturing and assembly processes must be capable of producing the product within the statistical process window required by the design. Therefore, characteristics of the process must be identified, measured, and monitored. Regardless of how well a product is designed, it cannot be reliable unless the variability in the manufacturing processes is controlled (not necessarily minimized). Each process may involve screens and tests to assess **statistical process control**.
- Manage the life-cycle usage of the product using closed-loop management procedures. This includes realistic inspection and maintenance procedures, and root-cause analysis.

Product Requirements and Constraints

A product's requirements and constraints are defined in terms of customer demands and the company's core competencies, culture, and goals. There are various reasons to justify the creation, modification, upgrade, or even discontinuation of a product. For example, a company may want to address a perceived market need or to open new markets. In some cases, a company may need to develop new products to remain competitive in a key market or to maintain market share and customer confidence. In other cases, a company may want to fill a need of specific strategic customers, or to demonstrate experience with a new technology or methodology, or to improve maintainability of an existing product. In addition, product updates are often developed to reduce the life-cycle costs of an existing product.

To make reliable products, there should be a joint effort between the supplier and the customer. According to IEEE 1332 [1], there are three reliability objectives to achieve in the stage of defining product requirements and constraints. First, the supplier, working with the customer, shall determine and understand the customer's requirements and product needs, so that a comprehensive design specification can be generated. Second, the supplier shall structure and follow a series of engineering activities so that the resulting product satisfies

2 Design for Reliability

the customer's requirements and product needs with regard to product reliability. Third, the supplier shall perform activities that assure the customer that the reliability requirements and product needs have been satisfied.

If the product is for direct sale to end users, marketing usually takes the lead in defining the product's requirements and constraints through interaction with the customer's marketplace, examination of product sales figures, and analysis of the competition. Alternatively, if the product is a subsystem that fits within a larger product, the requirements and constraints may be determined by the customer's requirements for the larger product into which the subsystem fits. The product definition process involves multiple influences and considerations. Figure 1 shows a diagram of constraints in the product definition process.

Two prevalent risks in defining the requirements and constraints are the inclusion of irrelevant requirements and the omission of relevant requirements. The inclusion of irrelevant requirements can involve unnecessary design and testing time as well as money. Irrelevant or erroneous requirements generally result from two sources: requirements created by persons who do not understand the constraints and opportunities implicit in the product definition, and inclusion of requirements for historical reasons. The omission

of critical requirements can significantly reduce the effectiveness of the product.

The initial requirements are formulated into a requirements document, where they are prioritized. The requirements document should be approved by the engineers, the management, the customers, and other involved parties. Usually, the specific people involved in the approval will vary with the organization and the product. For example, for human safety-critical products, legal representatives should attend the approval to identify legal considerations with respect to the implementation of the parts selection and management team's directives. The results of capturing product requirements and constraints allow the design team to choose parts and develop products that conform to company objectives.

Once a set of requirements has been completed, the product engineering function creates a response to the requirements in the form of a specification. The specification states the requirements that must be met; the schedule for meeting the requirements; the identification of those who will perform the work; and the identification of potential risks. Differences in the requirements document and the preliminary specification become the topic of trade-off analyses.

Once product requirements are defined and the design process begins, there should be an assessment

Figure 1 Constraints in the product definition process

of the product requirements against the actual product design. As the product's design becomes increasingly detailed, it becomes increasingly important to track the product's characteristics (size, weight, performance, functionality, reliability, and cost) in relation to the original product requirements. The rationale for making changes should be documented. The completeness with which the tracking of requirements is performed can significantly reduce future redesign costs of the product. Planned redesigns or design refreshes through technology monitoring and use of road maps ensure that a company is able to market new products or redesigned versions of old products in a timely, effective manner to retain their customer base and ensure continued profits.

Product Life-Cycle Conditions

The life-cycle conditions of the product play a significant role in determining the product requirements and guiding reliability assessments. It influences decisions regarding product design and development, materials and parts selection, qualification, product safety, warranty, and support.

The phases in a product's life cycle include manufacturing and assembly, testing, rework, storage, transportation and handling, operation^a (modes of operation, on-off cycles, etc.), repair and maintenance, and disposal. During each phase of its life cycle, the product experiences various external and internal environmental and usage loads. The life-cycle loads can be thermal (steady-state temperature, temperature ranges, temperature cycles, temperature gradients), mechanical (pressure levels, pressure gradients, vibrations, shock loads, acoustic levels), chemical (aggressive or inert environments, ozone, pollution and humidity levels, contamination, fuel spills), physical (radiation, electromagnetic interference, altitude), and/or electrical loading conditions (power, power surge, current, voltage, voltage spikes). These loads, either individually or in various combinations, may influence the reliability of the product. The extent and rate of product **degradation** depend upon the nature, magnitude, and duration of exposure to such loads.

Defining and characterizing the life-cycle loads is often the most uncertain element of the overall design for reliability process [2]. The challenge occurs because products can experience completely different

application conditions, depending on location and customer. The application conditions include the application duration, the number of applications, the product utilization or nonutilization profile, and maintenance or servicing conditions. For example, typically all desktop computers are designed for office environments. However, the operational profile of each unit may be completely different depending on user behavior. Some users may shut down the computer every time after it is used; others may shut down only once at the end of the day; still others may keep their computers powered on all the time. Thus, the temperature profile experienced by each product, and hence its degradation due to thermal loads, will be different. There are four methods used to estimate the life-cycle loads on a product: market studies and standards, field trial and service records, similarity analysis, and *in situ* monitoring. Each is discussed below.

Market surveys and standards^b provide a coarse estimate of the actual environmental loads expected in the field. The environmental profiles available from these sources are typically classified according to industry type, such as military, consumer, telecommunications, automotive, and commercial avionics. Often the data include the worst-case and typical-use conditions.

Field trial records provide estimates of the environmental profiles experienced by the product. The data depend on the durations and conditions of the trials, and can be extrapolated to get an estimate of actual environmental conditions. Service records provide information on the maintenance, replacement, or servicing performed. This data can give an idea of the life-cycle environmental and usage conditions that lead to servicing or failure.

Similarity analysis is a technique for estimating environmental loads when sufficient field histories for similar products are available. Before using data on existing products for proposed designs, the characteristic differences in design and application for the two products need to be reviewed. Changes and discrepancies in the conditions of the two products should be critically analyzed to ensure the applicability of available loading data for the new product. For example, electronics inside a washing machine in a commercial laundry are expected to experience a wider distribution of loads and use conditions (due to a large number of users), and higher usage rates compared with those in a domestic washing machine.

These differences should be considered during similarity analysis.

Environmental and usage conditions experienced by the product over its life cycle can be monitored *in situ*. This data is often collected using sensors, either mounted externally or integrated with the product and supported by telemetry systems. Load distributions should be developed from data obtained by monitoring products used by different customers, ideally from various geographical locations. The data should be collected over a sufficient period to provide an accurate estimate of the loads and their variation over time. *In situ* monitoring has the potential to provide the most accurate account of load history for use in health (condition) assessment and design of future products.

Reliability Capability

The selection of a supplier for electronic parts or services is often based on factors that do not explicitly address reliability, such as technical capabilities, production capacity, geographic location, support facilities, and financial and contractual factors. A selection process that takes into account the ability of suppliers to design for reliability and meet reliability objectives during manufacturing, testing, and support can improve reliability of the final product throughout its life cycle. This can provide valuable competitive advantage to an equipment manufacturer or system integrator.

Reliability capability is a measure of the practices within an organization that contribute to the reliability of the final product, and the effectiveness of these practices in meeting the reliability requirements of customers. The reliability capability of an organization is a combination of the reliability capabilities of constituent reliability activities. Reliability capability assessment is the act of quantifying the effectiveness of these activities, using a metric called the *reliability capability maturity*. From a reliability perspective, maturity indicates whether the key reliability practices within an organization are well understood, supported by documentation and training, applied to all products throughout the organization, and continually monitored and improved.

In the absence of systematic evaluation of these organizational traits, product testing and monitoring of field performance are often the primary means

for assessing reliability over time. Improvement in product reliability based on these metrics is generally limited to a single product family and is difficult to institutionalize over the long term and across product lines. Periodic assessment of organizational reliability capability offers a method for identifying practices in need of improvement and implementing required improvements on a continual basis across multiple product lines or departments.

Parts and Materials Selection

A parts selection and management methodology helps a company to make risk-informed decisions when purchasing and using parts and materials. The methodology shown in Figure 2 describes this approach to parts (materials) selection.

In the manufacturer assessment step, the part manufacturer's ability to produce parts with consistent quality is evaluated. This was already discussed in the section titled "Reliability Capability". Similarly the distributor assessment evaluates the distributor's ability to provide parts without affecting the initial quality and reliability, and to provide specific services, such as part problem and change notifications.

The goal-of-performance assessment is to evaluate the part's ability to meet the performance requirements (e.g., functional, mechanical, and electrical) of the product. There is often a minimum and a maximum limit beyond which the part will not function properly and, in general, these bounds are defined by the recommended operating conditions for the part.

Reliability assessment provides information about the ability of a part to meet the required performance specifications in its life-cycle application environment for a specified period of time. If the parametric and functional requirements of the product cannot be met within the required local environment, then the local environment may have to be modified, or a different part may have to be used. If part reliability is not ensured through the reliability assessment process, an alternate part or product redesign should be considered.

Reliability assessment is conducted through the use of reliability test data (conducted by the part manufacturer), virtual reliability assessment results, or accelerated test results. If the magnitude and duration of the life-cycle conditions are less severe than those of the reliability tests, and if the test sample

Figure 2 Parts selection and management methodology

size and results are acceptable, the part reliability is acceptable. Otherwise, a virtual reliability assessment should be considered. Virtual reliability is a simulation-based methodology used to identify the dominant failure mechanisms associated with the part under life-cycle conditions to determine the acceleration factor for a given set of accelerated test parameters, and to determine the times to failure corresponding to the identified failure mechanisms. If virtual reliability proves insufficient to validate part reliability, accelerated testing should be performed on representative part lots at conditions that represent the application condition to determine the part reliability. This decision process is illustrated in the diagram in Figure 3.

Failure Modes, Mechanisms, and Effects Analysis

A failure mode is the manner in which a failure can occur – that is, the ways in which the products fails to perform its intended design function, or performs the function but fails to meet its objectives [3, 4]. A failure mode can also be defined as any physically observable change caused by a failure mechanism. In an electrical system, failure mode can be the change of current, voltage, or electrical noise beyond some limiting values. Sometimes the failure modes are intentionally accentuated so that the user of a system is aware of the existence of a problem. The

Figure 3 Decision process for part reliability assessment

addition of a compound with a distinct smell to natural gas to indicate the existence of a leak is such an example. Another example is the grinding noise when the brake pads wear out in a car. Failure modes are closely related to the functional and performance requirements of the product. Failure mechanisms are the processes by which a specific combination of physical, electrical, chemical, and mechanical stresses induces failures. Each failure mechanism is a process but not a physical condition or failure site. For example, solder failure is not a failure mechanism, but that description does identify a failure site.

The **failure mode and effects analysis** (FMEA) methodology, which was developed in the 1950s and has since continuously evolved, is a procedure to recognize and evaluate the potential failure of a product and its effects, and to identify actions that could eliminate or reduce the likelihood of the potential failure to occur [5]. This methodology can also be referred to as *failure modes effects and criticality analysis* (FMECA), where the criticality of each failure mode is also estimated and reported.

A limitation of the FMEA procedure is that it does not identify the product failure mechanisms and models in the analysis and reporting process. Investigation of the possible failure modes and mechanisms of the product aids in developing reliable designs. A design team must be aware of the possible failure mechanisms to design hardware capable of withstanding loads without failing. Failure mechanisms and their related physical models are necessary for effective tests and screens to audit nominal design and manufacturing specifications, as well as the level of defects introduced by excessive variability in manufacturing and material parameters.

The purpose of failure modes, mechanisms, and effects analysis (FMMEA) is to identify potential failure mechanisms and models for all the potential failure modes, and to prioritize failure mechanisms. FMMEA is based on understanding the relationships between product requirements and the physical characteristics of the product (and their variation in the production process), the interactions of product materials with loads (stresses at application conditions), and their influence on the product's susceptibility to failure with respect to the use conditions. This involves finding the failure mechanisms and reliability models to quantitatively evaluate the susceptibility to failure. FMMEA uses life-cycle environmental and operating conditions and the duration of the intended

application with knowledge of the active stresses and potential failure mechanisms. The FMMEA process is summarized in Figure 4.

An essential input to an FMMEA is a well-developed life-cycle environmental profile (LCEP). Information on life-cycle conditions can be used to include or eliminate failure mechanisms that are active only under certain application conditions.

The product under investigation needs to be defined. The product is then divided into convenient and logical elements. This breakdown can be either functional (i.e., according to what the system elements "do") or architectural (i.e., according to where the system elements "are"), or both (i.e., functional within a location or *vice versa*). For example, in an automobile, a functional breakdown would include the cooling system, braking system, propulsion system, and so on. An architectural breakdown would involve the engine compartment, passenger compartment, and dashboard or control panel.

After this logical breakdown is performed, all possible failure modes for each identified element should be listed. Potential failure modes may be identified using numerical stress analysis, accelerated tests to failure (e.g., Highly Accelerated Life Tests (HALT)), past experience, and engineering judgment. The failure mode identification should not imply a cause or mechanism.

A failure cause is defined as the specific process, design, and/or environmental condition that initiates a failure and whose removal will eliminate the failure. Life-cycle environmental and operational conditions are used to determine the potential causes for the potential failure modes. Knowledge of potential failure causes can help identify the failure mechanisms that create the failure modes for a given element. This list of causes should be exhaustive and input should be taken from several functional groups.

Identification of the failure mechanisms should be performed with care so that they are not confused with sites, modes, or causes. While performing FMMEA for specific hardware, specialists for those products or subsystems should be included in the physical structure.

The failure models should show the times to failure as a function of product material, geometry, environmental, and application conditions. Failure models for well-known failure mechanisms can be obtained from the literature. This may be a difficult step to perform if the failure mechanisms are not

Figure 4 FMMEA methodology

clearly identified as a physical process. It may also be necessary to develop failure models or determine the values of constants associated with the models from prior failure data or from other test data. Organizations should assign resources to develop, maintain, and update failure model libraries for the failure mechanisms of concern.

Using the failure models in association with environmental conditions, product design and geometry, a process is followed to determine the highest-priority failure mechanisms. The goal then becomes to identify and eliminate or control the causes responsible for those mechanisms.

Design Techniques

Once the parts, materials, processes, and stress conditions are identified, the objective is to design a product using parts and materials that have been sufficiently characterized in terms of performance over time when subjected to the manufacturing and application profile conditions. Only through a methodical design approach, using physics-of-failure analysis, testing, and root-cause analysis can a reliable and cost-effective product be designed.

Design guidelines based on physics-of-failure models can also be used to develop tests, screens, and

derating^c factors. Tests based on physics-of-failure models can be designed to measure specific quantities, to detect the presence of unexpected flaws, and to detect manufacturing or maintenance problems. Screens can be designed to precipitate failures in the weak population while not cutting into the design life of the normal population. Derating or safety factors can be determined to lower the stresses for the dominant failure mechanisms.

The following sections describe approaches that can be employed in the design phase of electronic equipment to improve reliability.

Protective Architectures

The objective of protective architectures is to enable some form of action, after an initial failure or malfunction, to prevent additional or secondary failures. Protective techniques include the use of fuses and circuit breakers, self-sensing structures, and adjustment structures that correct for parametric shifts.

In designs where safety is an issue, it is generally desirable to incorporate some means for preventing a part, structure, or interconnection from failing or from causing further damage when it fails. Fuses and circuit breakers are examples of elements used in electronic products to sense excessive current

drain and disconnect power from the concerned part. Fuses within circuits can also safeguard parts against voltage transients or excessive power dissipation, and protect power supplies from shorted parts. Similarly, thermostats can be used to sense critical temperature limiting conditions, and to automatically disconnect the product or part of the system from the power circuit until the temperature returns to normal. Self-checking circuitry can also be incorporated to sense abnormal conditions and restore normal conditions, or to activate circuitry that will compensate for the malfunction.

In some instances, it may be desirable to permit partial operation of the product after a part failure, possibly with degraded performance, rather than completely disconnecting power supply to the product. For example, in shutting down a failed circuit whose function is to provide precise trimming adjustment within a deadband of another control product, acceptable performance may be achieved, under emergency conditions, with the deadband control product alone [6].

Sometimes, the physical removal of a part from a product can harm or cause failure in another part by removing load, drive, bias, or control. In such cases, an interlock mechanism may be implemented within the part that is to be removed to shut down or protect other parts.

By reducing the number of failures, protective techniques also affect product availability and effectiveness. In addition, protective architectures must be designed by considering the impacts of maintenance, repair, and part replacement. For example, if a fuse protecting a circuit is replaced, the following questions need to be answered: what is the impact when the product is reenergized? Which protective architectures are appropriate for post-repair operations? What maintenance guidance must be documented and followed when fail-safe protective architectures have or have not been included?

Stress Margins

A properly designed product should be capable of operating satisfactorily with parts that drift or change with time and with changes in operating conditions, such as temperature, humidity, pressure, and altitude, as long as the parameters remain within their rated tolerances.

Figure 5 Stress limits and margins

Figure 5 provides a schematic representation of the hierarchy of product stress limits and margins. The specified tolerance limit is set by the manufacturer to limit the conditions of customer use. The design margin corresponds to the stress value that the product is designed to survive without failure. The operating margin is the expected stress value that may lead to a recoverable failure. The destruct margin is the expected stress value that may lead to permanent (overstress) failure.

To prevent out-of-tolerance failures, a design team must consider the combined effects on stress levels of manufacturing tolerances, including those for parts used in future repair or maintenance operations; expected environmental conditions; and drifts due to aging over the period specified in the reliability requirement. Parts and structures should be designed to operate satisfactorily at the extremes of the parameter ranges, and allowable ranges must be included in the procurement or reprocurement specifications.

Statistical analysis and worst-case analysis can be used to assess the effects of part and structural parameter variations. In statistical analysis, a functional relationship is established between the output characteristics of the structure and the parameters of one or more of its parts. In worst-case analysis, the effect that a part has on the product output is evaluated on the basis of end-of-life performance values or out-of-specification replacement parts.

To ensure that the parts used in a system remain within the predetermined margins shown in Figure 5, derating can be used. Derating is the practice of limiting thermal, electrical, and mechanical stresses to levels below the manufacturer's specified ratings to improve reliability. Derating can provide added protection from system anomalies unforeseen by the designer (e.g., transient loads, electrical surges).

For example, manufacturers of electronic hardware often specify limits for supply voltage, output current, power dissipation, junction temperature, and frequency. The equipment design team may decide to select an alternative component or make a design change that ensures that the operational condition for a particular parameter, such as temperature, is always below the rated level. The stress reduction is expected to extend the useful operating life where the failure mechanisms under consideration are of the wear-out type. This practice is also expected to provide a safer operating condition by furnishing a margin of safety when the failure mechanisms are of the overstress type.

As inherently suggested by the term *derating*, the methodology involves a two-step process: a “rated” stress value is first determined from the part manufacturer’s data book, and a reduced value is then assigned. The margin of safety that the process of derating must provide is the difference between the maximum allowable actual applied stress and the demonstrated limits of the part capabilities. The part capabilities as given by manufacturer specifications are taken as the demonstrated limits. System design teams often choose to design a product based on conservative stress assumptions due to lack of knowledge of the life-cycle conditions, at the expense of overall productivity. There are reasons to believe that the part manufacturers already provide safety margin when choosing the operating limits. When these values are derated by the users, effectively a second level of safety margin is added.

In order to be effective, derating must target the appropriate, critical stress parameters based on models of the relevant failure mechanisms. Once the failure models for the critical failure mechanisms have been identified, using for example an FMMEA, the impact of derating on the effective reliability of the part for a given load can be determined. Instead of derating the stress rating values provided by the device manufacturers, the goal should be to determine the safe operating envelope for each part and subsystem and then operate within that envelope.

Redundancy

Redundancy exists when one or more of the parts of a system can fail and the system can still function with the parts that remain operational. A design team often finds that redundancy is the quickest way to

improve product reliability if there is insufficient time to explore alternatives, or if the part is already designed. It can be the most cost-effective solution, if the cost of redundancy is economical in comparison with the cost of redesign. It may even be the only solution if the reliability requirement is beyond the state of the art.

A redundant design may also exceed the limitations on size and weight, or power limitations. When not properly implemented, redundancy can also provide a false sense of security. If the cause can affect all the redundant elements of a product at the same time, then the benefits of redundancy will be lost. Also, the failure of sensing and switching circuitry or software can result in failure even in the presence of redundancy. Besides these possibilities, the design team may find that the disadvantages of redundancy may outweigh the benefits when the implementation of redundancy proves too expensive.

Integrated Diagnostics and Prognostics

Design guidelines and techniques should involve strategies to assess the reliability of the product in its life-cycle environment. A product’s health is the extent of deviation or degradation from its expected normal (in terms of physical condition and performance) operating condition. Knowledge of a product’s health can be used for the detection and isolation of faults or failures (diagnostics) and for the prediction of an impending failure based on the current conditions (prognostics). Thus, by determining the advent of failure, based on actual life-cycle conditions, procedures can be developed to mitigate and manage potential failures and maintain the product.

Diagnostics and prognostics can be integrated into a product by (a) installing built-in fuses and canary structures that will fail faster than the actual product when subjected to life-cycle conditions [7]; (b) sensing parameters that are precursors to failure, such as defects or performance degradation [8]; (c) sensing the life-cycle environmental and operational loads that influence the system’s health, and processing the measured data to estimate the life consumed [9, 10]. The life-cycle data measured by such integrated monitors can be extremely useful in future product design and end-of-life decisions [11]. An example of integrated prognostics in electronic products is the self-monitoring analysis and reporting

technology (SMART) currently employed for hard disk drives (HDD) in certain computing equipment [12]. HDD operating parameters, including flying height of the head, error counts, variations in spin time, temperature, and data transfer rates, are monitored to provide advance warning of failures. This is achieved through an interface between the computer's start-up program (BIOS) and the HDD.

Qualification

Qualification includes all activities that ensure that the nominal design and manufacturing specifications will meet the desired reliability targets. Qualification validates the ability of the nominal design and manufacturing specifications of the product to meet the customer's expectations, and assesses the probability of survival of the product over its complete life cycle. The purpose of qualification is to define the acceptable range of variability for all critical product parameters affected by design and manufacturing, such as geometric dimensions, material properties, and operating environmental limits. Product attributes that are outside the acceptable ranges are termed *defects*, since they have the potential to compromise product reliability [13].

Qualification tests should be performed during initial product development, and immediately after any design or manufacturing changes in an existing product. A well-designed qualification procedure provides economic savings and quick turnaround during development of new products or products subject to manufacturing and process changes.

Investigating failure mechanisms and assessing the reliability of products where longevity is required may be a challenge, since a very long test period under actual operating conditions is necessary to obtain sufficient data to determine actual failure characteristics. The results from FMMEA should be used to guide this process. One approach to the problem of obtaining meaningful qualification data for high-reliability devices in shorter time periods is using methods such as virtual qualification and accelerated testing to achieve test-time compression.

Virtual Qualification

Virtual qualification has the potential to significantly accelerate the qualification process of a part for

its life-cycle environment. Virtual qualification is based on computer-aided simulation, and can assist in identifying and ranking the dominant failure mechanisms associated with the part under life-cycle loads, determining the acceleration factor for a given set of accelerated test parameters, and determining the time to failure corresponding to the identified failure mechanisms.

Each failure model comprises a stress analysis model and a damage assessment model. The output is a ranking of different failure mechanisms, based on the time to failure. The stress model captures the product architecture, while the **damage model** depends on a material's response to the applied stress. Virtual qualification can be used to optimize the product design in such a way that the minimum time to failure of any part of the product is greater than its desired life. Although the data obtained from virtual qualification cannot fully replace those obtained from physical tests, they can increase the efficiency of physical tests by indicating the potential failure modes and mechanisms that can be expected.

Ideally, a virtual qualification process will involve identification of quality suppliers, quality parts, physics-of-failure qualification, and a risk assessment and mitigation program. The process allows qualification to be readily incorporated into the design phase of product development, since it allows design, manufacturing, and testing to be conducted promptly and cost effectively. It also allows consumers to qualify off-the-shelf components for use in specific environments without extensive physical tests. Since virtual qualification reduces emphasis on examining a physical sample, it is imperative that the manufacturing technology and quality assurance capability of the manufacturer be taken into account. If the data on which the virtual qualification is performed are inaccurate or unreliable, all results are suspect. In addition, if a reduced quantity of physical tests is performed in the interest of simply verifying virtual results, the operator needs to be confident that the group of parts selected is sufficient to represent the product. The effect of manufacturing variabilities can be parametrically assessed by simulation as part of the virtual qualification process. Further, it should be remembered that the accuracy of the results using virtual qualification depends on the accuracy of the inputs to the process – that is, the system geometry and material properties, the life-cycle loads, the failure models used (e.g., constants in the failure model),

the analysis domain, and discretization approach (spatial and temporal). Hence, to obtain a reliable prediction, the variability in the inputs should be specified using distribution functions, and the validity of the failure models should be tested by conducting accelerated tests.

Accelerated Testing

Accelerated testing is based on the concept that a product will exhibit the same failure mechanism and mode in a short time under high-stress conditions as it would exhibit in a longer time under actual life-cycle stress conditions. The purpose is to decrease the total time and cost required to obtain reliability information for the product under study. It is generally possible to quantitatively extrapolate from the accelerated environment to the usage environment with some reasonable degree of assurance.

Accelerated tests can be divided into two categories: qualitative tests and quantitative tests. Qualitative tests in the form of overstressing the products to obtain failure may be the oldest form of reliability testing. Such tests typically target a single load condition, such as shock, temperature extremes, or electrical overstress. Qualitative tests generally only yield failure mode information, and do not reveal the failure mechanism or time to failure. Quantitative tests target wear-out failure mechanisms, in which failures occur as a result of cumulative load conditions. Time to failure is the major outcome of quantitative accelerated tests.

The easiest and most common form of accelerated life testing is continuous-use acceleration. For example, a washing machine is used for 10 h per week on average. If it were continuously operated, the acceleration factor would be 16.8. However, this method is not applicable to high-usage products. Under such circumstances, accelerated testing is conducted to measure the performance of the test product at loads or stresses that are more severe than would normally be encountered, so as to enhance the damage accumulation rate within a reduced time period. The goal of such testing is to accelerate time-dependent failure mechanisms and the damage accumulation rate to reduce the time to failure. On the basis of the data from those accelerated tests, life in normal-use conditions can be extrapolated.

Accelerated testing begins by identifying all the possible overstress and wear-out failure mechanisms.

The load parameter that directly causes the time-dependent failure is selected as the acceleration parameter, and is commonly called the *accelerated load*. Common accelerated loads include thermal loads, such as temperature, temperature cycling, and rates of temperature change; chemical loads, such as humidity, corrosives, acids, solvents, and salts; electrical loads, such as voltage or power; and mechanical loads, such as vibration, mechanical load cycles, strain cycles, and shocks/impulses. The accelerated environment may include a combination of these loads. Interpretation of the results for combined loads requires a quantitative understanding of their relative interactions and the contribution of each load to the overall damage.

Failure due to a particular mechanism can be induced by several acceleration parameters. For example, corrosion can be accelerated by both temperature and humidity, and creep can be accelerated by both mechanical stress and temperature. Furthermore, a single accelerated stress can induce failure by several wear-out mechanisms simultaneously. For example, temperature can accelerate wear-out damage accumulation not only by electromigration, but also by corrosion and creep. Failure mechanisms that dominate under usual operating conditions may lose their dominance as the stress is elevated. Conversely, failure mechanisms that are dormant under normal-use conditions may contribute to device failure under accelerated conditions. Thus, accelerated tests require careful planning if they are to represent the actual usage environments and operating conditions without introducing extraneous failure mechanisms or nonrepresentative physical or material behavior. The degree of stress acceleration is usually controlled by an acceleration factor, defined as the ratio of the life of the product under normal-use conditions to that under the accelerated condition. The acceleration factor should be tailored to the hardware in question, and can be estimated from an acceleration transform (that is, a functional relationship between the accelerated stress and the life-cycle stress), in terms of all the hardware parameters.

Once the failure mechanisms are identified, it is necessary to select the appropriate acceleration load; to determine the test procedures and the stress levels; to determine the test method, such as constant-stress acceleration or step-stress acceleration; to perform the tests; and to interpret the test data, which includes extrapolating the accelerated test results to normal

operating conditions. The test results provide failure information for improving the hardware through design and/or process changes.

Manufacture and Assembly

Manufacturing and assembly processes can significantly impact the quality and reliability of hardware. Improper assembly and manufacturing can introduce defects, flaws, and residual stresses that act as potential failure sites, or stress enhancers or raisers later in the life of the product. The effect of manufacturing variability on time to failure is depicted in Figure 6. A shift in the mean or increase in the standard deviation of key geometric parameters during manufacturing can result in early failure due to a decrease in strength of the product. If these defects and stresses can be identified, the design analyst can proactively account for them during the design and development phase. Generally, qualification procedures are required to ensure that manufacturing specifications do not compromise the long-term reliability of the hardware. In some cases, lot-to-lot screening is required to ensure that the variability of all manufacturing-related parameters is within specified tolerances [14]. Here, screening ensures the quality of the product by precipitating latent defects before they reach the field.

Manufacturability

The design team must understand material limits, and manufacturing process capabilities to select materials and construct architectures that promote producibility and reduce the occurrence of defects. The team must have clear definitions of the threshold for acceptable quality and of what constitutes nonconformance. Nonconformance that compromises hardware performance and reliability is considered a defect.

A defect is any outcome of a process (manufacturing or assembly) that impairs or has the potential to impair the functionality of the product at any time. The defect may arise during a single process or may be the result of a sequence of processes. The yield of a process is the fraction of products that are acceptable for use in a subsequent manufacturing sequence or product life cycle. The cumulative yield of the process is approximately determined by multiplying the individual yields of each of the individual process steps. The source of defects is not always apparent, because defects resulting from a process can go undetected until the product reaches some downstream point in the process sequence, especially if screening is not employed.

It is often possible to simplify the manufacturing and assembly processes to reduce the probability of workmanship defects. As processes become more sophisticated, however, process monitoring and control are necessary to ensure a defect-free product. The bounds that specify whether the process is within tolerance limits, often referred to as the *process window*, are defined in terms of the independent variables to be controlled within the process and the effects of the process on the product or the dependent product variables. The goal is to understand the effect of each process variable on each product parameter to formulate control limits for the process – that is, the points on the variable scale where the defect rate begins to have a potential for causing failure. In defining the process window, the upper and lower limits of each process variable beyond which it will produce defects must be determined. Manufacturing processes must be contained in the process window by defect testing, analysis of the causes of defects, and elimination of defects by process control, such as by closed-loop corrective action systems. The establishment of an effective feedback path to report process-related

Figure 6 Influence of quality on failure probability

defect data is critical. Once this is done and the process window is determined, the process window itself becomes a feedback system for the process operator.

Several process parameters may interact to produce a different defect than would have resulted from an individual parameter acting independently. This complex case may require that the interaction of various process parameters be evaluated in a matrix of experiments. In some cases, a defect cannot be detected until late in the process sequence. Thus, a defect can cause rejection, rework, or failure of the product after considerable value has been added to it. These cost items due to defects can reduce a return on investment by adding to hidden factory costs. All critical processes require special attention for defect elimination by process control.

Process Qualification

Similar to design qualification, process qualification should be conducted at the prototype development phase. The objective is to ensure that the nominal manufacturing specifications and tolerances produce acceptable reliability in the product. The process needs requalification when process parameters, materials, manufacturing specifications, or human factors change.

Process qualification tests can be the same set of accelerated wear-out tests used in design qualification. As in design qualification, overstress tests may be used to qualify a product for anticipated field overstress loads. Overstress tests may also be exploited to ensure that manufacturing processes do not degrade the intrinsic material strength of the hardware beyond a specified limit. However, such tests should supplement, not replace, the accelerated wear-out test program, unless explicit physics-based correlations are available between overstress test results and wear-out field-failure data.

Process Verification Testing

Process verification testing is often called *screening*. Screening involves 100% auditing of all manufactured products to detect or precipitate defects. The aim of this step is to preempt potential quality problems before they reach the field. Thus screening aids in reducing warranty returns and

increases customer goodwill. In principle, screening should not be required for a well-controlled process. However, screening is often used as a safety net.

Some products exhibit a multimodal **probability density function** for failures, with peaks during the early period of their service life due to the use of faulty materials, poorly controlled manufacturing and assembly technologies, or mishandling. This type of early-life failure is often called *infant mortality*. Properly applied screening techniques can successfully detect or precipitate these failures, eliminating or reducing their occurrence in field use. Screening should be considered for use during the early stages of production, if at all and only, when products are expected to exhibit infant mortality field failures. Screening will be ineffective and costly if there is only one main peak in the failure probability density function. Further, failures arising due to unanticipated events such as acts of God (lightning, earthquakes) may be impossible to screen cost effectively.

Since screening is done on a 100% basis, it is important to develop screens that do not harm good components. The best screens, therefore, are nondestructive evaluation techniques, such as microscopic visual exams, X rays, acoustic scans, nuclear magnetic resonance, electronic paramagnetic resonance, and so on. Stress screening involves the application of stresses, possibly above the rated operational limits. If stress screens are unavoidable, overstress tests are preferred over accelerated wear-out tests, since the latter are more likely to consume some useful life of good components. If damage to good components is unavoidable during stress screening, then quantitative estimates of the screening damage, based on failure mechanism models, must be developed to allow the design team to account for this loss of usable life. The appropriate stress levels for screening must be tailored to the specific hardware. As in qualification testing, quantitative models of failure mechanisms can aid in determining screen parameters.

A stress screen need not necessarily simulate the field environment, or even utilize the same failure mechanism as the one likely to be triggered by this defect in field conditions. Instead, a screen should exploit the most convenient and effective failure mechanism to stimulate the defects

that can show up in the field as infant mortality. Obviously, this requires an awareness of the possible defects that may occur in the hardware and extensive familiarity with the associated failure mechanisms.

Unlike qualification testing, the effectiveness of screens is maximized when screening is conducted immediately after the operation believed to be responsible for introducing the defect. Qualification testing is preferably conducted on the finished product or as close to the final operation as possible; on the other hand, screening only at the final stage, when all operations have been completed, is less effective, since failure analysis, defect diagnostics, and troubleshooting are difficult and impair corrective actions. Further, if a defect is introduced early in the manufacturing process, subsequent value added through new materials and processes is wasted, which additionally burdens operating costs and reduces productivity.

Admittedly, there are also several disadvantages to such an approach. The cost of screening at every manufacturing station may be prohibitive, especially for small batch jobs. Further, components will experience repeated screening loads as they pass through several manufacturing steps, which increases the risk of accumulating wear-out damage in good components due to screening stresses. To arrive at a screening matrix that addresses as many defects and failure mechanisms as feasible with each screen test, an optimum situation must be sought through analysis of the cost effectiveness, risk, and criticality of the defects. All defects must be traced back to the root cause of the variability.

Any commitment to stress screening must include the necessary funding and staff to determine the root cause and appropriate corrective actions for all failed units. The type of stress screening chosen should be derived from the design, manufacturing, and quality teams. Although a stress screen may be necessary during the early stages of production, stress screening carries substantial penalties in capital, operating expense, and cycle time, and its benefits diminish as a product approaches maturity. If almost all of the products fail in a properly designed screen test, the design is probably faulty. If many products fail, a revision of the manufacturing process is required. If the number of failures in a screen is small, the processes are likely to be within tolerances and the observed faults may be beyond the resources of the design and production process.

Closed-Loop Monitoring and Root-Cause Analysis

Product reliability needs to be ensured using a closed-loop process that provides feedback to design and manufacturing in each stage of the product life cycle, including after the product is shipped and used in its application environment. Data obtained from periodic maintenance, inspection/testing, or health (condition) and usage monitoring methods can be used to perform timely maintenance for sustaining the product and preventing catastrophic failures. Figure 7 depicts the closed-loop process for managing the reliability of a product over the complete life cycle.

The objective of closed-loop monitoring is to analyze the failures occurring in testing and field conditions to identify the root cause of failure. The root cause is the most basic casual factor or factors that, if corrected or removed, will prevent recurrence of the situation. The purpose of determining the root cause(s) is to fix the problem at its most basic source so it does not occur again, even in other products, as opposed to merely fixing a failure symptom.

Root-cause analysis is a methodology designed to help (a) describe *what* happened during a particular occurrence; (b) determine *how* it happened; and (c) understand *why* it happened. Only when we are able to determine why an event or failure occurred, will we be able to determine the corrective measures over time. Root-cause analysis differs from troubleshooting, which is generally employed to eliminate a symptom in a given product, as opposed to finding a solution to the root cause to prevent this and other products from failing.

Correctly identifying the root cause during design and manufacturing, followed by appropriate actions to fix the design and processes, results in fewer field returns, major cost savings, and customer goodwill. Root-cause analysis of field failures can be more challenging if the conditions during and prior to failure are unknown. The lessons learned from each failure analysis need to be documented and appropriate actions need to be taken to update the design, manufacturing process, and/or maintenance actions or schedules.

After a product is developed, resources must be applied to managing its life cycle, including supply chain management, obsolescence assessment, manufacturing and assembly feedback, manufacturer

Figure 7 Reliability management using a closed-loop process

warranties management, and field failure and root-cause analysis. The risks associated with the product fall into two categories:

- managed risks – risks that the product development team chooses to proactively manage by creating a management plan and performing a prescribed monitoring regime of the field performance, manufacturer, and manufacturability; and
- unmanaged risks – risks that the product development team chooses not to proactively manage.

If risk management is considered necessary, a plan should be prepared. The plan should contain details about how the product is monitored (**data collection**), and how the results of the monitoring feed back into various product development processes. The feasibility, effort, and cost involved in management processes must be considered.

Summary

The development of a reliable product is not a matter of chance or good fortune; rather, it is a rational consequence of conscious, systematic, and rigorous efforts conducted through the entire life cycle of the product. High-product reliability can only be assured through robust product designs, capable processes that are known to be within tolerances, and qualified components and materials from vendors whose processes are also capable and within tolerances.

Quantitative understanding and modeling of all relevant failure mechanisms can guide design, manufacturing, and the planning of test specifications and tolerances.

When utilized early in the concept stage of a product's development, reliability serves as an aid to determine feasibility and risk. In the design stage of product development, reliability analysis involves the selection of materials, design of structures, design tolerances, manufacturing processes and tolerances, assembly techniques, shipping and handling methods, and maintenance and maintainability guidelines. Engineering concepts such as strength, fatigue, fracture, creep, tolerances, corrosion, and aging play a role in these design analyses. The use of physics-of-failure concepts coupled with mechanistic and probabilistic techniques are often required to understand the potential problems and trade-offs, and to take corrective actions. The use of factors of safety and worst-case studies as part of the analysis is useful in determining stress screening and **burn-in** procedures, **reliability growth**, maintenance modifications, field testing procedures, and various logistics requirements.

End Notes

^aOperational conditions are sometimes referred to as the *life-cycle application conditions*.

^bFor example, IPC SM-785 specifies the use and extreme temperature conditions for electronic products categorized under different industry sectors, such as telecommunication, commercial, and military.

^cDerating is the practice of subjecting parts to lower electrical or mechanical stresses than they can withstand, to increase the life expectancy of the part.

Software Failure Data Analysis

Some Definitions

Software failures are reported as a result of testing or regular usage by customers. They are recorded as modification requests (MRs), trouble reports (TRs), authorized program analysis reports (APARs), or some similar designation. Such reports document a departure from user requirements and performance deficiencies.

Developers can track the defect in the program that caused the failure. We call these defects *faults*. Another common term used to describe faults is *bugs*.

An error is the root cause of software faults that can potentially lead to software failures. This potential is realized when a user or a user-simulation triggers, under given conditions, an input stimulus that reveals the software fault, thus creating a failure.

These definitions of failures, faults and errors are based on the official terminology set in the IEEE Standard Glossary of Software Engineering Terminology [1] which specifies the following:

Error *Human action that results in software containing a fault. Examples include omissions or misinterpretation of user requirements in a software specification, incorrect translation, or omission of a requirement in the design specification.*

Fault (1) *An accidental condition that causes a functional unit to fail to perform its required function* (2) *A manifestation of an error in software. A fault, if encountered, may cause a failure. Synonymous with a bug.*

Failure (1) *The termination of the ability of a functional unit to perform its required function* (2) *An event in which a system component does not perform a required function within specified limits. A failure may be produced when a fault is encountered.*

Customer satisfaction is determined by experience with actual usage of the software. It is sometimes measured as *failures per 1000 CPU hours* or *failures per 1000 transactions*.

Process quality is determined by errors introduced during the process. Development process quality is often measured by *faults per 1000 source lines* or *faults per function point*.

The terms *defect*, *problem*, or *anomaly* are typically used in a generic sense. The terms *error*, *fault*, and *failure* will be reserved to have the technical definitions presented above. We will review how to track and analyze software failure data. Some basic IEEE references include [2], [3], and [4].

Problem Report Tracking

Problem report tracking provides the capability to gain insight into both product quality and the ability of the organization to maintain the software.

Figure 1 plots, by week, the total number of problem reports, those still open, and those that have been closed. At the start of a new test phase, such as software integration testing, or acceptance testing, the number of problem reports opened usually increases fairly rapidly, opening a gap between the number of problems reported and closed. If the problems are straightforward, we expect the gap to quickly decrease. If not, that could be an indication of a possibly serious condition or, alternatively, that the problems reported are of little operational consequence so that their resolution could be deferred to a later date. This suggests that to make more effective use of this chart, it is advisable to define categories of problem severity, and to overlay the number of problems open by severity category. For more on problem tracking and process improvement in software development see Kenett and Koenig [5], Humphrey [6], Kenett [7, 8], Fenton and Pfleeger [9], Kenett and Baker [10], Onoma and Yamura [11], Kan [12], and Laird and Brennan [13].

Control Charts of Newly Opened Bugs, by Week

Measures collected in real life environments often exhibit statistical variation. Such variation poses significant challenges to decision makers who attempt to filter out “signal” from “noise”. By signal we mean events with significant effects on the data such as short or long term trends and patterns or one time, sporadic spikes. We do expect the number of newly reported bugs to fluctuate.

It is in the context of such fluctuation that we want to determine if the number of opened bugs, in a certain day, exceeds the “normal” range of fluctuation. Another phenomenon we are interested

Figure 1 Problem report tracking

Figure 2 Control chart for number of newly opened bugs, by week

in identifying is a significantly decreasing trend in the number of opened bugs. Such a trend might be a prerequisite for a version release decision.

A primary tool for tracking data overtime, in order to identify significant trends and sporadic spikes, is the **control chart**. Control charts can be applied to individual data points such as the number of bugs opened, per week or to percentages, such as percent of line with comments. Sometimes data are collected simultaneously in several dimensions such as response times to a routine transaction at several stations in a network. Such multivariate data can be analyzed with **multivariate control charts**. The interested reader can find more information on control

chart in **Control Charts, Overview, Control Charts for the Mean, Moving Range and *R* Charts, Control Charts for Attributes**, and Kenett and Zacks [14].

Figure 2 consists of an individual (I) and a moving range (MR) control chart for the number of new bugs, per week, reported in a beta test of a new software product from a company developing rapid application development tools.

Analyzing the lower **MR chart** shows no unusual, nonrandom, patterns. The I chart however indicates a significant increase in the number of reported bugs on week 6 and a short run of three weeks below average toward the end. If this pattern is sustained

Figure 3 Control chart for number of closed bugs, by week

for three more weeks management could declare that the number of reported new bugs has significantly dropped, thus allowing for version release. Overall the average number of new bugs has been 38.2 per week. The next example tracks the number of closed or fixed bugs over the same time period.

Control Charts of Closed Bugs, by Week

In this example the number of closed bugs per week is tracked on an I and MR control chart (Figure 3). Analyzing the lower MR chart shows a period where the number of closed bugs per week remained almost constant (week 8–14), thus producing very low MRs (successive differences being almost zero). The I chart indicates a significant increase in the number of closed bugs on week 6 indicating a quick response to the significant increase in number of reported bugs identified above. Overall, the average number of bugs closed per week has been 37.3, just a bit lower than the number of reported new bugs per week.

Software Reliability Models

We proceed with an introduction to **software reliability** models that are used in the analysis of

software failure data. Software reliability estimation is an engineering management activity designed to

- Determine the reliability of delivered software
- evaluate the product at each milestone in the software life cycle
- formalize **data collection** and maintenance of historical data.

The basic steps in software reliability estimation and tracking are

1. Identify the system to be studied, including associated systems and hardware configurations that will be involved in system testing.
2. Determine reliability goals and classify failures into severity classes.
3. Develop operational profiles such as workload characterization of peak, prime, and off hours.
4. Prepare tools and procedures for testing according to the test plan.
5. Execute system tests.
6. Interpret failure data using tools such as **Pareto charts**, M-tests, and software reliability models.

The standard definition of software reliability is *the probability of execution without failure for*

some specified interval, called the mission time. This definition is compatible with that used for hardware reliability, though the failure mechanisms may differ significantly.

Software reliability is applicable both as a tool complementing development testing, in which faults are found and removed, and for certification testing, when a software product is either accepted or rejected. The now obsolete MIL-STD-1679 [15] document specified that one error per 70 000 machine instruction words, which degrades performance with a reasonable alternative work-around solution, is allowed; and one error causing inconvenience and annoyance is allowed for every 35 000 machine instruction words. However, no errors which cause a program to stop or degrade performance without alternative work-around solutions are allowed. These reliability specifications should be verified with a specified level of confidence.

Interpreting failure data is also used to determine if a product can be moved from development to beta testing with selected customers, and then from beta testing to official shipping. Both applications to development testing and certification testing rely on mathematical models for tracking and predicting software reliability. Many software reliability models have been suggested in the literature. For a review, see Wood [16], for an approach to determine when the software is ready for release, see Kenett and Pollak [17]. In this section, we cover two basic software reliability models. For more on software reliability models see **Software Reliability Modeling and Analysis**, **Software Reliability: Bayesian Analysis**, and **Sampling in Software Development**.

The Jelinski and Moranda “De-Eutrophication” Model

Jelinski and Moranda, while working for the McDonnell Douglas Astronautics Company, published one of the first practical software reliability models [18]. They developed a model for use on a number of modules of the Apollo program. The model assumptions are

1. The rate of error detection is proportional to the current error content of a program.
2. All errors are equally likely to occur and are independent of each other.

3. Each error is of the same order of severity as any other error.
4. The error rate remains constant over the interval between error occurrences.
5. The software is operated in a manner similar to the anticipated operational usage.
6. The errors are corrected instantaneously without introduction of new errors into the program.

Clearly, it is difficult to envision a situation in which a perfect error correction process is achieved. However assumption 6 can be avoided by not counting errors which were previously detected, but were not corrected. Assumption 2 can be avoided by dividing the errors into classes based upon severity. For instance, one might have a category for critical errors, a category for less serious errors, and one for minor errors. Separate software reliability models are then developed for each category. Using assumptions 1, 2, 5, and 6, the failure rate is defined as

$Z(t) = \phi[N - (i - 1)]$, where t is any time point between the discovery of the $(i - 1)$ th error and the i th error. The quantity ϕ is the proportionality constant given in assumption 1. N is the unknown total number of errors initially in the system. Hence, if $i - 1$ errors have been discovered by time t , there are $N - (i - 1)$ remaining errors so the hazard rate is proportional to this remaining number. Figure 4 is a plot of the hazard rate versus time. As can be seen, the rate is reduced by the same amount ϕ at the time of each error detection.

Let $X_i = t_i - t_{i-1}$, i.e., the time between the discovery of the i th and the $(i - 1)$ st error for $i = 1, \dots, n$ where $t_0 = 0$, using assumption 4, the X_i 's are assumed to have an exponential distribution with rate $Z(t_i)$. That is: $f(X_i) = \phi[N - (i - 1)] \exp\{-\phi[N - (i - 1)]X_i\}$.

The joint density of all the X_i , using assumption 2 is

$$\begin{aligned} L(X_1, \dots, X_n) &= \prod_{i=1}^n f(X_i) \\ &= \prod_{i=1}^n \phi[N - (i - 1)] \\ &\quad \times \exp\{-\phi[N - (i - 1)]X_i\} \quad (1) \end{aligned}$$

Taking the partial derivatives of $L(X)$ with respect to N and ϕ and setting the resulting equations equal to zero, the maximum likelihood estimators, $\hat{N}$ and

Figure 4 The De-Eutrophication process

$\hat{\phi}$, for N and ϕ are satisfy

$$\hat{\phi} = \frac{n}{\hat{N} \left(\sum_{i=1}^n X_i \right) - \sum_{i=1}^n (i-1)X_i} \quad (2)$$

and

$$\sum_{i=1}^n \frac{1}{\hat{N} - (i-1)} = \frac{n}{\hat{N} - \frac{1}{\sum_{i=1}^n X_i} \left(\sum_{i=1}^n (i-1)X_i \right)} \quad (3)$$

These equations can be solved using numerical techniques such as Newton–Raphson iterations.

The estimate of the mean time to failure (MTTF) is derived, after the j th occurrence, is

$$\begin{aligned} \text{Estimated MTTF after } j\text{th error} &= \frac{1}{\hat{Z}(t_j)} \\ &= \frac{1}{\hat{\phi}(\hat{N} - j)} \end{aligned} \quad (4)$$

The estimated time to remove the next m errors, after observing n failures, can be easily derived as:

$$\begin{aligned} \text{Estimated time to remove the next } m \text{ errors} \\ = \sum_{j=n+1}^{n+m} \frac{1}{\hat{\phi}(\hat{N} - j + 1)} \end{aligned} \quad (5)$$

The data required for the calculations of these estimates is either the time between error occurrences, X_i , or the time of error occurrences, t_i , $i = 1, \dots, n$.

The biggest problem in seeking these estimates is the difficulty in convergence of the numerical techniques employed to find the maximum likelihood

estimators. Difficulties include lack of convergence, sensitivity of the iteration scheme to the starting value, convergence to a saddle point or invalid estimate, and nonuniqueness of the estimates. Littlewood and Verall [19] show that a unique maximum at finite $\hat{N}$ and nonzero $\hat{N}$ is attained if, and only if,

$$\frac{\sum_{i=1}^n (i-1)X_i}{\sum_{i=1}^n (i-1)} > \frac{\sum_{i=1}^n X_i}{n} \quad (6)$$

If this condition is not satisfied, there is no convergence and $\hat{N}$ is infinity. Essentially this means that the model can only be applied to software that exhibits software growth, i.e. $X_i > X_{i-1}$. In any computer implementation of this model, the condition should first be verified to ensure a unique finite maximum exists.

The Jelinski–Moranda model cannot be applied to software programs which are not mature and are still under development. The program under test has to be relatively stable with a fixed but unknown total number of N errors present in the code. Various extensions of this basic model have been proposed including an adaptation to evolving a program which accounts for (i) the completion percentage, (ii) to error rates proportional to program size, (iii) to nonhomogeneous distributions of errors, (iv) to error rates proportional both to the number of errors remaining and to the time spent testing, and (v) of models accounting for varying testing efforts and programmers ability (see Kenett and Baker [10], Nelson [20], Musa *et al.* [21] and Neufelder [22]).

We present next an extension of the Jelinski–Moranda model proposed by Lipow [23]. The extension allows for more than one error occurrence during a testing interval. This is well suited to situations where data is aggregated overtime. Since failure data is usually reported on a weekly or monthly basis this extension proved very useful.

The Lipow Extension Model

The Lipow model assumes that

1. The rate of error detection is proportional to the current error content of a program.
2. All errors are equally likely to occur and are independent of each other.

3. Each error is of the same order of severity as any other error.
4. The error rate remains constant over the testing interval.
5. The software is operated in a manner similar to the anticipated operational usage.
6. During a testing interval i , f_i errors are discovered, but only n_i errors are corrected in the time frame.

Assumptions 1 to 5 are identical to the assumptions of the Jelinski–Moranda model. Assumption 6 is different. Suppose there are M periods of testing in which testing interval i is of length x_i . During this time frame, f_i errors are discovered, of which n_i are corrected. Assuming the error rate remains constant during each of the M testing periods (assumption 4), the failure rate during the i th testing period is

$$Z(t) = \phi[N - F_i], t_{i-1} \leq t \leq t_i \quad (7)$$

where ϕ is the proportionality constant, N is again the total number of errors initially present in the program, $F_{i-1} = \sum_{j=1}^{i-1} n_j$ is the total number of errors corrected up through the $(i-1)$ st testing intervals, and t_i is the time measured in either CPU or wall clock time at the end of the i th testing interval, $x_i = t_i - t_{i-1}$. The t_i 's are fixed and thus, are not fixed as in the Jelinski–Moranda model. Taking the number of failures, f_i , in the i th interval to be a Poisson random variable with mean $Z(t_i)x_i$, the likelihood is:

$$L(f_1, \dots, f_M) = \prod_{i=1}^M \frac{[\phi[N - F_{i-1}]x_i]^{f_i}}{f_i!} \times \exp\{-\phi[N - F_{i-1}]x_i\} \quad (8)$$

Taking the partial derivatives of $L(f)$ with respect to ϕ and N and setting the resulting equations to zero, we derive the following equations satisfied by the maximum-likelihood estimators $\hat{\phi}$ and $\hat{N}$ of ϕ and N :

$$\hat{\phi} = \frac{F_M/A}{\hat{N} + 1 - B/A} \quad (9)$$

and

$$\frac{F_M}{\hat{N} + 1 - B/A} = \sum_{i=1}^M \frac{f_i}{\hat{N} - F_{i-1}} \quad (10)$$

where

$F_M = \sum_{i=1}^M f_i$, the total number of errors found in the M periods of testing,

$B = \sum_{i=1}^M (F_{i-1} + 1)x_i$, and

$A = \sum_{i=1}^M x_i$, the total length of the testing period.

From these estimates, the maximum likelihood estimate of the mean time until the next failure (MTTF), given the information accumulated in the M testing periods $= 1/(\hat{\phi}(\hat{N} - F_M))$.

A Case Study of the Lipow Model

In order to demonstrate the application of Lipow's extension to the Jelinski and Moranda De-Eutrophication model, we use the data collected at Bell Laboratories during the development of the No. 5 electronic switching system, in Table 1.

The data consists of failures observed during four consecutive testing periods of equal length and intensity.

The Lipow model produces the following estimates: $\hat{N} = 762$ and $\hat{\phi} = 0.097$, i.e. an estimate of 762 for the initial number of failures and 0.097 for the proportionality constant representing the reduction in failure rate due to removing one fault from the system.

The column of predicted failures in test periods 5, 6, and 7 is computed from the Lipow model with the above estimates for ϕ and N . Comparing observed and predicted values over the first four test periods can help us evaluate how well the Lipow model fits the data. The χ^2 goodness of fit test statistics is 0.63, indicating extremely good fit (at a **significance level** better than 0.001). We can therefore provide reliable predictions for the number of failures expected at test periods 5–7, provided the test effort continues at the same intensity and that test periods are of the same length as before.

The Jelinski–Moranda model and the various extensions to this model are classified as time domain models. They rely on a physical modeling of the appearance and fixing of software failures. The different sets of assumptions are translated into differences in mathematical formulations (see Musa *et al.* [21], Neufelder [22] and Brown and Lipow [24]). A model free approach to tracking software **reliability growth**, that exploits optimality properties of Bayesian procedures known as *Shiryayev–Roberts procedures*, has been proposed by Kenett and Pollak [17, 25].

When software is in operation, failure rates can be computed by computing number of failures, say,

Table 1 Predicted failures using Lipow model

Test Period	Observed Failures	Predicted Failures
1	72	74
2	70	67
3	57	60
4	50	54
5		49
6		44
7		40

per hour of operation. The predicted failure rate, corresponding to the steady state behavior of the software, is usually a key indicator of great interest. The predicted failure rate may be regarded as high when compared to other systems. Kanoun *et al.* [26] analyze four systems (telephony, defense, interface, and management) and derive average failure rates over 10 testing periods and predicted failure rates. Their results are presented in Table 2.

As expected in any reliability growth process, the average failure rate over 10 test periods is higher than the predicted failure rates. However, the differences in the defense and management systems are smaller indicating that these systems have almost reached steady state, and no significant reliability improvements should be expected. The telephony and interface systems, however, are still evolving. A decision to promote the defense and interface systems to acceptance test status could be made, based on the data.

Pragmatic Software Reliability Estimation

A simple model for estimating software reliability has been proposed by Wall and Ferguson [27]. The model relies on the basic premise that the

failure rate of software decreases as more software is used and tested. The relationship proposed for this phenomenon is

$$C1 = C0 \left(\frac{M1}{M0} \right)^a \quad (11)$$

where,

$C1$ = future period cumulative number of errors

$C0$ = previous period cumulative number of errors – a constant determined empirically

$M1$ = units of test effort in future period (e.g. number of tests, testing weeks, CPU time)

$M0$ = test units in previous period – a scaleable constant

a = growth index – a constant determined, empirically, by plotting the cumulative number of errors on a logarithmic scale or by using the following formula:

$$a = \frac{\log \left(\frac{C1}{C0} \right)}{\log \left(\frac{M1}{M0} \right)} \quad (12)$$

The failure rate, $Z(t)$, is derived from the following formula:

$$Z(t) = \frac{dC1}{dt} = aC0 \frac{d \left(\frac{M1}{M0} \right)}{dt} \left(\frac{M1}{M0} \right)^{a-1} \quad (13)$$

This model is based on several assumptions:

1. software test domain is stable i.e. no new features are introduced.
2. software errors are independent.
3. errors detected are corrected within the same test period.

Table 2 Predicted software failure rates, by system type

System	Predicted failure rate	Average failure rate over 10 test periods
Telephony	$1.2 \times 10^{-6} \text{ h}^{-1}$	$1.0 \times 10^{-5} \text{ h}^{-1}$
Defense	$1.4 \times 10^{-5} \text{ h}^{-1}$	$1.6 \times 10^{-5} \text{ h}^{-1}$
Interface	$2.9 \times 10^{-5} \text{ h}^{-1}$	$3.7 \times 10^{-5} \text{ h}^{-1}$
Management	$8.5 \times 10^{-6} \text{ h}^{-1}$	$2.0 \times 10^{-5} \text{ h}^{-1}$

4. testing is incremental so that new tests are introduced in subsequent testing periods.

Revisiting the data used in the previous section, with an empirically derived estimate of 0.8 for a , we get the estimated number of failures for test period 5 to be 47.17 failures (see Table 3). The Lipow model predicted 49 failures.

Pareto Chart Analysis of Software Failures

When observing events, it is a universal phenomenon that approximately 80% of events are due to 20% of the possible causes. A classical application to software is the general fact that 80% of software failures can be attributed to 20% of the code. This universal observation was first made by Joseph M. Juran who, in the early 1950s, coined the term “Pareto principle” which leads to the distinction between the “vital few” and the “useful many” (see **Pareto Chart**). The Pareto chart is a graphical display of the Pareto principle. It consists of bar graphs sorted, by category, in descending order of the relative frequency of errors. Pareto charts are used to choose the starting point for problem solving, monitor changes, or identify the basic cause of a problem. An interesting example of a Pareto chart analysis of software failures is provided by data from Knuth [28] on changes made during a period of 10 years, in the development of TEX, a software system for typesetting. Knuth’s logbook contains 516 items for

the 1978 version, which is labeled TEX78, and 346 items for the 1982 version, labeled TEX82. These entries are classified into 15 categories ($K = 15$). The 15 categories are

- A – Algorithm: a wrong procedure being implemented
- B – Blunder: a mistaken but syntactically correct instruction
- C – Cleanup: an improvement in consistency or clarity
- D – Data: a data structure debacle
- E – Efficiency: a change for improved code performance
- F – Forgotten: a forgotten or incomplete function
- G – Generalization: a change to permit future growth and extensions
- I – Interaction: a change in user interface to better respond to user needs
- L – Language: a misunderstanding of the programming language
- M – Mismatch: a module’s interface error.
- P – Portability: a change to promote portability and maintenance
- Q – Quality: an improvement to better meet user requirements
- R – Robustness: a change to include sanity checks of inputs
- S – Surprise: a change resulting from an unforeseen interaction
- T – Typo: change to correct differences between pseudocode and code.

Table 3 Predicted failures using the pragmatic model

Test period	Observed failures	Cumulative failures	a	Predicted failures
1	72	72		
2	70	142	0.8	125.36
3	57	199	0.8	196.41
4	50	249	0.8	250.50
5	47.17		0.8	297.66

The A, B, D, F, L, M, R, S, T classifications represent development errors. The C, E, G, I, P, Q classifications represent “enhancements”, consisting of unanticipated features that had to be added in late development phases. These enhancements indicate a lack of understanding of customer requirements, and, as such, can be considered failures of the requirements analysis process. Figure 5 presents a Pareto chart of the TEX78 data. The chart does not show any dominant error category so that, apparently, the Pareto principle does not apply to this data. Figure 6 is the Pareto chart of the TEX82 data. Here we notice that categories C, R, G, I, and E contribute 71% of the errors. Categories C, G, I, and E being classified as “enhancements” which are therefore the main cause behind the logbook entries.

TEX82 contains significantly *more* errors in the Cleanup (C), Efficiency (E), and Robustness (R) categories than TEX78. Significantly *less* errors are found in Blunder (B), Forgotten (F), Language (L), Mismatch (M), and Quality (Q). Knuth gives us only clues as to the possible reasons for these differences. For more on statistical comparisons of Pareto charts see Kenett and Zacks [14] and Kenett and Baker [10]. We conclude by discussing the analysis of software failures uncovered in inspection and design reviews.

Software Trouble Assessment

The IEEE 730.1 standard on Software Quality Planning [29] stipulates that, as a minimum, eight types of reviews are to be conducted:

1. Software requirements review (SRR)
2. Preliminary design review (PDR)
3. Critical design review (CDR)
4. Software verification review
5. Functional audit
6. Physical audit
7. In-process audit
8. Managerial reviews.

These reviews generate data that can be further analyzed through root cause analysis.

The Software Trouble Assessment Matrix (STAM) is a tool that software developers can use to evaluate the design and effectiveness of software inspection and testing processes so that they can be improved [10, 30]. STAM is used to organize relationships between three dimensions:

- Where were failures detected in the software life cycle?
- Where were those failures actually created?
- Where could the failures have been detected?

Three measures are computed from a STAM analysis:

- **Negligence ratio:** this ratio indicates the amount of failures that escaped through the inspection process filters. In other words, it measures inspection efficiency.
- **Evaluation ratio:** this ratio measures the delay of the inspection process in identifying failures relative to the phase in which they occurred. In other words, it measures inspection effectiveness.
- **Prevention ratio:** this ratio is an index of how early failures are detected in the development life cycle relative to the total number of reported errors. This is a combined measure of the development and inspection processes. It assesses the software developer’s ability to generate and identify failures as early as possible in the development life cycle.

Process improvements are the result of attempts to learn from current and past failures. Prerequisites to such improvement efforts are that the processes have been identified and that process ownership has been established. Typical development processes consist of requirements analysis, top-level design, detailed design, coding, and testing. A causal analysis of software faults classifies faults as being attributable to errors in any one of these activities. For such an analysis to be successful, it is essential that there be agreement on the boundaries of the processes represented by these activities. In particular, the entry and exit criteria for each process have to be clarified and documented. Such definitions permit effective data collection.

As an example, consider a certain software version with a total of 110 reported failures at the completion of acceptance testing (see Table 4). The failures were reported throughout the software life cycle, with the following distribution:

Of the seven failures detected during top-level design, it was determined that two failures could have been detected in the review session that occurred after requirements analysis. These failures were missed by the reviewers. Of the 13 failures detected during acceptance testing, it was determined that one failure

could have been detected at the requirements analysis review session, one could have been detected after detailed design, six could have been detected during system testing, and five could have been detected only during acceptance testing. The implication is that eight failures escaped the inspection process filters. A similar analysis indicated that, of the five failures that could only have been detected during acceptance testing, one failure was due to a

requirement error, three were the result of errors in preliminary design, and one was due to a detailed design error.

A typical failure analysis begins with assessing where failures could have been detected and concludes with classifying failures into the life-cycle phases in which they were created. This procedure requires a root cause analysis of each recorded failure. As previously mentioned, the success of a failure

Figure 5 Pareto chart of TEX78 logbook data

Figure 6 Pareto chart of TEX82 logbook data

Table 4 Software failures by detection phase

Life-cycle phase	Number of failures
Requirements analysis	3
Top-level design	7
Detailed design	2
Programming	25
Unit tests	31
System tests	29
Acceptance test	13

causal analysis is highly dependent on clear entry and exit criteria for the various development phases.

Once the STAM analysis is completed, cumulative failure profiles are drawn depicting where errors were detected, where they could have been detected, and where they were created. The areas under these three cumulative frequency curves are defined as $S1$, $S2$, and $S3$, respectively (see Figure 7). These areas are determined by computing the cumulative totals over the seven software development phases.

A curve is drawn by connecting the results of these additions along the seven development phases. The area under the curve, labeled $S1$, is approximated by adding these numbers: $S1 = 3 + 10 + 12 + 37 + 68 + 97 + 110 = 337$. By referring to Figure 7, we see that the same procedure is followed to get the $S2$ and $S3$ computations ($S2 = 427$ and $S3 = 588$). The negligence ratio is computed using the formula: $100 \times (S2 - S1)/S1$. As previously mentioned, it measures the amount of errors that escaped through the inspection process filters, indicating inspection

efficiency. High inspection efficiency corresponds to low negligence ratios. For the data in Figure 7, the negligence ratio is $100 \times (427 - 337)/337 = 26.7\%$, which indicates an average gap of 26.7% of a life-cycle phase between actual error detection time and perfect detection under the current inspection process.

The evaluation ratio is derived using the formula: $100 \times (S3 - S2)/S2$. As previously mentioned, it measures the delay of the inspection process in identifying errors from the phase where they were created, indicating inspection effectiveness. High evaluation ratios correspond to low inspection effectiveness. For the data in Figure 7, the evaluation ratio is $100 \times (588 - 427)/427 = 37.7\%$, which signals the need to redesign the inspection process so that it can detect errors closer to their creation. The current inspection filters, under perfect conditions, detect errors with a delay of 37.7% of a life-cycle phase. The prevention ratio is computed using the formula: $100 \times S1/(7 \times total)$. As previously mentioned, it indicates how early errors were detected relative to the total number of reported errors (*total*) in the seven development phases. If all errors were created and detected during requirements analysis, the prevention ratio would be 100%. Since early errors are less costly to correct, a high prevention ratio implies a less costly development process. Conversely, a low prevention ratio indicates that errors were detected late in the process and therefore might negatively affect delivery schedules and customer satisfaction. In Figure 7,

**Figure 7** Graph of the curves determining the $S1$, $S2$, and $S3$ areas

the prevention ratio is 43.7%, which indicates that errors were detected late in the life cycle. Using the negligence, evaluation, and prevention ratios, software developers can better understand and improve their inspection and development processes. They also can use STAM to benchmark different projects within their companies and against those of different companies.

Life Testing from a Bayesian Perspective

The Role of Life Testing

Life testing is the name given to a variety of testing methods carried out to obtain failure data (*see Reliability Sampling*). Roughly speaking, life testing consists in putting on test a random sample of n units drawn from a (hypothesized) population of identical units under specified operating and environmental conditions. Clearly, the testing method changes according to a large variety of factors, among them the fact that the unit can be repaired or is discarded at failure.

In the case of unrepairable units, the life testing can be stopped when the failure of some or all the n units put on test occurs. If the failure time of each unit is observed, then the test is said to be a complete life test. When it is not practical, or economically convenient, to test all the units, for example due to a very high reliability level of the unit, an incomplete life testing is performed. Clearly, a large variety of incomplete tests can be performed. For example, the test can be stopped after a fixed period has elapsed, so that a random number m ($m < n$) of units is observed to fail. In this case, the test is said to be a time-truncated test. Again, if the test is terminated when a prefixed number of units failed, the test is said to be a failure-truncated test. In both the cases, some units may also have been withdrawn from the life test before they fail, so only their survival times are observed.

In case of repairable units, which are repaired at failure, the test is always truncated because the unit can achieve a theoretically infinite life, and more that one failure of each unit is generally observed.

When testing time is limited, the units are often subjected to accelerated life tests (*see Accelerated Life Tests: Classical Methods for Design and Analysis; Accelerated Life Tests: Bayesian Design*). Accelerated life testing is the process by which the units are forced to fail more quickly than they would under normal use conditions, so test time can be greatly reduced.

Irrespective of the testing method, the number of observed failures determines the accuracy of the resulting reliability estimates.

In classical estimation procedures, such as maximum-likelihood and least-squares methods, life tests constitute the exclusive source of information, whereas in a Bayesian perspective the purpose of life testing is to “confirm or deny expected performance as predicted from past experience” [1, p. 169]. In other words, life testing provides the Bayesian analyst new information (the so-called sampling information), which allows the current belief held prior to observing the new data to be revised (*learning from experience*). The revised belief, expressed in terms of subjective probability, constitutes the inferential result. Clearly, in a decision-making approach, revising belief leads the expert to confirm or change the choice he would have made among alternative courses of action on the basis of prior belief only.

The way in which the observed data modify the current belief is formalized by Bayes’ theorem [2] (*see Bayesian Reliability Analysis*). Bayes’ theorem for parameters and observations states that the posterior knowledge of Φ , formalized by the posterior distribution $\pi(\Phi|\mathbf{x})$, is obtained from the observed data $\mathbf{x}$ and the prior information of Φ , formalized by the prior distribution $g(\Phi)$, according to

$$\pi(\Phi|\mathbf{x}) = \frac{f(\mathbf{x}|\Phi)g(\Phi)}{f(\mathbf{x})} \quad (1)$$

where Φ is the vector of parameters which index the failure time model, $f(\mathbf{x}|\Phi)$ is the joint conditional distribution of $\mathbf{x}$ given Φ , and $f(\mathbf{x})$ is the marginal distribution of the data given by

$$f(\mathbf{x}) = \begin{cases} \int f(\mathbf{x}|\Phi) g(\Phi) d\Phi, & \Phi \text{ continuous} \\ \sum f(\mathbf{x}|\Phi) g(\Phi), & \Phi \text{ discrete} \end{cases} \quad (2)$$

If no prior information is available and hence the noninformative prior distribution (*see Prior Distribution Elicitation*) is used [3, pp. 25–59], life testing becomes the only source of information in a Bayesian framework also.

The main difficulties in performing a Bayesian analysis regard just the identification, selection, and justification of the prior distribution (*see Prior Distribution Elicitation*). The problem of prior identification concerns whether to use a continuous or discrete distribution, a noninformative or informative prior, or a mathematically convenient prior

distribution, such as a conjugate prior. Once the prior has been identified, the problem of prior selection concerns the fitting of the identified prior distribution on the basis of the available subjective data. This problem mainly concerns the choice of the procedure to be used in estimating the parameters of the prior distribution (often called the *hyperparameters*) and the way the subjective data have to be solicited and elicited. Finally, adequate justification for the prior selection should be given by the Bayesian analyst, by including a clear description of the data sources used to fit the prior distribution, the method used to fit the prior to the data, and a preposterior analysis of the fitted prior. Otherwise, the prior distribution can be suspected to have been chosen with bias to provide self-serving results and hence the resulting inferential results can be criticized [1, p. 186]. Wide overviews on the identification, selection, and justification of the prior distribution can be found, for example, in [1, Chapter 6] and [4, Chapter 3].

In calculating the posterior distribution, the concept of sufficiency can be helpful. Intuitively, a sufficient statistic is a function of the data $\mathbf{x}$ that summarizes all the available sampling information regarding Φ . Then, if $T = T(\mathbf{x})$ is a sufficient statistic for Φ with probability distribution $f(T|\Phi)$, Bayes theorem can be rewritten as

$$\pi(\Phi|\mathbf{x}) = \pi(\Phi|T) = \frac{f(T|\Phi)g(\Phi)}{f(T)} \quad (3)$$

The reason for deriving the posterior distribution $\pi(\Phi|\mathbf{x})$ from equation (3) is that both $f(T|\Phi)$ and the marginal distribution $f(T)$ are generally much easier to handle than $f(\mathbf{x}|\Phi)$ and $f(\mathbf{x})$ [4, p. 93].

Thus, the way the observed data modify the prior knowledge of Φ is through the joint conditional distribution $f(\mathbf{x}|\Phi)$ (or, equivalently, through the $f(T|\Phi)$). Bayes theorem works in a way that increases the belief in parameters values that are highly compatible with the observed data, whereas the belief in parameters values which are unlikely to have resulted in the data actually observed decreases. Then, if different experts possess different prior beliefs on Φ , the sampling information makes their posterior beliefs closer to each other than the prior beliefs are. Clearly, the more the sampling information dominates over the prior beliefs, the closer the posterior distributions are.

As newer data are observed, today's posterior information becomes tomorrow's prior information,

so that each time new data come in the current belief can be revised. In this context, the use of conjugate prior distributions (*see Prior Distribution Elicitation*) is very attractive since the posterior distributions are members of the same family of distributions but with parameters updated by the observed data. This updating of parameters provides an easy way of revising the current belief in the light of new observed data and of seeing the effect of prior and sample information on posterior distribution.

However, when the prior information dominates over the sampling information, slight changes in the prior can cause significant changes in the posterior results [1, p. 85]. Then, especially when the observed data are scarce, a sensitivity analysis should be performed to investigate how possible changes in the prior parameters (or, more generally, in the prior information) affect the posterior results. Such an analysis can identify the most important prior information and focus the effort of the analyst to better refine the form of the prior distribution or the values of the prior parameters. Again, in a decision-making context, the sensitivity analysis allows the analyst to assess whether reasonable changes in the prior distribution and/or in the loss function can lead to a different decision (see, for example, references [4, 5]). A comprehensive overview of the main topics in **Bayesian robustness** is provided by reference [6].

Simple illustrations of Bayesian learning process are given in the following examples.

Example 1

An upgraded type of reciprocating pump has been designed and the reliability team must verify, before starting mass production, whether the pumps satisfy a given reliability target at the lifetime $\tau = 0.7 \times 10^6$ cycles. The reliability target is assumed to be satisfied if the 90% lower probability limit on $R_\tau \equiv R(\tau)$, say $R_{0.10}$, is greater than 0.60. The failure times are assumed to be exponentially distributed

$$f(x|\theta) = \theta \exp(-\theta x), \quad x \geq 0 \quad (4)$$

where the parameter $\theta > 0$ is the (constant) failure rate. On the basis of previous experience, expert A possesses prior information on θ expressed in terms of a prior mean $E_A\{\theta\} = 0.58 \times 10^{-6}$ per cycle and a prior standard deviation $\sigma_A\{\theta\} = E_A\{\theta\}/2 = 0.29 \times$

10^{-6} per cycle. Expert A uses a gamma distribution to formalize the prior belief on θ :

$$g_A(\theta) = \frac{b^a \theta^{a-1}}{\Gamma(a)} \exp(-b\theta), \quad a, b > 0 \quad (5)$$

whose parameters a and b (often called *hyperparameters*) are $a = (E_A\{\theta\}/\sigma_A\{\theta\})^2 = 4.0$ and $b = E_A\{\theta\}/\sigma_A^2\{\theta\} = 6.9 \times 10^6$ cycles. By making the change of variables $R_\tau = \exp(-\theta\tau)$, the prior information on θ can be easily converted into prior information on the pump reliability at the time τ :

$$g_A(R_\tau) = \frac{(b/\tau)^a}{\Gamma(a)} [-\ln(R_\tau)]^{a-1} R_\tau^{b/\tau-1} \quad (6)$$

which is a log-gamma distribution with parameters a and b/τ [7]. The prior expectation and standard deviation are

$$E_A\{R_\tau\} = \left(\frac{b}{b+\tau}\right)^a = 0.679 \quad (7)$$

and

$$\sigma_A\{R_\tau\} = \sqrt{\left(\frac{b}{b+2\tau}\right)^a - \left(\frac{b}{b+\tau}\right)^{2a}} = 0.126 \quad (8)$$

respectively. From equation (5), the prior 90% upper credibility limit on θ is given by $\theta_{0.90,A} = \chi_{0.90}^2(2a)/(2b) = 0.969 \times 10^{-6}$ per cycle, where $\chi_{0.90}^2(2a)$ denotes the 90th percentile of the χ^2 distribution with $\nu = 2a$ **degrees of freedom**. The 90% lower credibility limit on R_τ results in $R_{0.10,A} = \exp(-\theta_{0.90,A} \tau) = 0.508$. Thus, on the basis of the prior information, the pumps do not satisfy the reliability requirements and its design should be improved.

However, before making a final decision regarding the reliability attainment, a life testing is performed. Fifteen pumps are then tested under use conditions (see Example 4.10 in reference [1, p. 125]). The test is initially stopped at the time of the fifth failure (failure-truncated sampling) and the observed cycles to failure are $x_1 = 237\,217$, $x_2 = 346\,704$, $x_3 = 430\,057$, $x_4 = 447\,737$, and $x_5 = 507\,746$. The joint conditional distribution of the observed data $\mathbf{x}_1$, given θ , is

$$f(\mathbf{x}_1|\theta) = \frac{n!}{(n-m_1)!} \prod_{i=1}^{m_1} f(x_i) \cdot [R(x_{m_1})]^{n-m_1} \\ \propto \theta^{m_1} \exp(-T_1 \theta) \quad (9)$$

where $m_1 = 5$ is the number of observed failures and $T_1 = \sum_{i=1}^5 x_i + (n - m_1)x_{m_1} = 7\,046\,921$ cycles is the **total time on test**.

Using Bayes theorem (equation 1), the prior information on θ is updated by the sampling information $\mathbf{x}_1$, and the posterior information on θ , given $\mathbf{x}_1$, results in

$$\pi_A(\theta|\mathbf{x}_1) = \frac{(b + T_1)^{a+m_1} \theta^{a+m_1-1}}{\Gamma(a + m_1)} \exp[-(b + T_1)\theta] \quad (10)$$

which is still a gamma distribution with parameters $a + m_1 = 9.0$ and $b + T_1 = 13.94 \times 10^6$ cycles. Then, the gamma density (equation 4) is the conjugate prior for the joint conditional distribution in equation (9), and the prior parameters a and b can be thought of as number of failures and time on test, respectively, in a pseudosample. Hence, the posterior parameters $a + m_1$ and $b + T_1$ can be thought of as the number of combined failures and the combined time on test, respectively. The posterior expectation of θ , i.e. the Bayesian estimator under the squared-error loss function, is

$$E_A\{\theta|\mathbf{x}_1\} = \frac{a + m_1}{b + T_1} = 0.645 \times 10^{-6} \text{ cycles}^{-1} \quad (11)$$

and the posterior 90% upper limit is $\theta_{0.90,A}|\mathbf{x}_1 = 0.932 \times 10^{-6}$ per cycle.

The posterior distribution of R_τ is still a log-gamma distribution:

$$\pi_A(R_\tau|\mathbf{x}_1) = \frac{[(b + T_1)/\tau]^{a+m_1}}{\Gamma(a + m_1)} [-\ln(R_\tau)]^{a+m_1-1} \\ \times R_\tau^{(b+T_1)/\tau-1} \quad (12)$$

with parameters $a + m_1 = 9.0$ and $(b + T_1)/\tau = 19.92$, so that the posterior expectation is $E_A\{R_\tau|\mathbf{x}_1\} = [(b + T_1)/(b + T_1 + \tau)]^{a+m_1} = 0.643$. The posterior 90% lower limit on R_τ results in $R_{0.10,A}|\mathbf{x}_1 = 0.521$.

The sampling information has slightly modified the prior belief on the pump reliability, with a slight improvement of the credibility limits, so that the reliability team decides to continue the life testing until three more pumps fail.

The observed cycles to failure during the second phase of life testing are $x_6 = 575\,877$, $x_7 = 1\,399\,019$, and $x_8 = 1\,502\,329$ [1, p. 125]. The resulting joint conditional distribution of the new data $\mathbf{x}_2$,

4 Life Testing from a Bayesian Perspective

given θ and data $\mathbf{x}_1$ observed during the first testing phase, is

$$f(\mathbf{x}_2|\theta, \mathbf{x}_1) \propto \frac{\prod_{i=m_1+1}^{m_1+m_2} f(x_i) \times [R(x_{m_1+m_2})]^{n-m_1-m_2}}{[R(x_{m_1})]^{n-m_1}} = \theta^{m_2} \exp(-T_2 \theta) \quad (13)$$

where $m_2 = 3$ is the number of failures observed during the second testing phase and $T_2 = \sum_{i=6}^8 (x_i - x_{m_1}) + (n - m_1 - m_2)(x_{m_1+m_2} - x_{m_1}) = 8916068$ cycles is the total time on test.

The posterior distribution $\pi_A(\theta|\mathbf{x}_1)$ of equation (10) becomes the prior distribution of θ for the new data $\mathbf{x}_2$. Then, combining equation (10) with the joint conditional distribution $f(\mathbf{x}_2|\theta, \mathbf{x}_1)$ in equation (13), the posterior distribution of θ , given the whole sampling information $\mathbf{x}_1$ and $\mathbf{x}_2$, say $\pi_A(\theta|\mathbf{x}_1, \mathbf{x}_2)$, is obtained, which is still a gamma distribution with parameters $a + m_1 + m_2 = 12.0$ and $b + T_1 + T_2 = 22.86 \times 10^6$ cycles. Likewise, the posterior distribution $\pi_A(R_\tau|\mathbf{x}_1, \mathbf{x}_2)$ is still a log-gamma distribution with parameters $a + m_1 + m_2 = 12.0$ and $(b + T_1 + T_2)/\tau = 32.66$. Note that the posterior distributions $\pi_A(\theta|\mathbf{x}_1, \mathbf{x}_2)$ and $\pi_A(R_\tau|\mathbf{x}_1, \mathbf{x}_2)$ depend on the sampling data $\mathbf{x}_1$ and $\mathbf{x}_2$ only through the whole number of observed failures, say $m_1 + m_2 = 8$, and the entire total time on test, say $T_1 + T_2 = 15.96 \times 10^6$ cycles.

The posterior expectations of θ and R_τ are $E_A\{\theta|\mathbf{x}_1, \mathbf{x}_2\} = 0.525 \times 10^{-6}$ per cycle and $E_A\{R_\tau|\mathbf{x}_1, \mathbf{x}_2\} = 0.696$, respectively, and the posterior credibility limits are $\theta_{0.90,A}|\mathbf{x}_1, \mathbf{x}_2 = 0.726 \times 10^{-6}$ per cycle and $R_{0.10,A}|\mathbf{x}_1, \mathbf{x}_2 = 0.602$.

Given the prior information on the failure rate and the observed data $\mathbf{x}_1$ and $\mathbf{x}_2$, the upgraded type of pumps satisfies the reliability requirements and mass production can start. Thus, the sampling information has led expert A to change the decision that would have been made before observing data.

Figures 1 and 2 show the updating effect of sampling information on expert belief as life testing goes on. In particular, the standard deviations of θ and R_τ decrease noticeably, changing from $\sigma_A\{\theta\} = 0.290 \times 10^{-6}$ per cycle and $\sigma_A\{R_\tau\} = 0.126$ to $\sigma_A(\theta|\mathbf{x}_1, \mathbf{x}_2) = 0.151 \times 10^{-6}$ per cycle and $\sigma_A(R_\tau|\mathbf{x}_1, \mathbf{x}_2) = 0.072$, respectively.

Now, suppose that another expert, say expert B, is more vague on the value of θ than expert A was.

Figure 1 Prior and posterior distributions of the failure rate θ in Example 1

Figure 2 Prior and posterior distributions of the reliability at $\tau = 0.7 \cdot 10^6$ cycles in Example 1

Before performing life testing, expert B elicits the prior belief on θ through a gamma density $g_B(\theta)$ having the same prior expectation elicited by expert A, say $E_B\{\theta\} = E_A\{\theta\} = 0.58 \times 10^{-6}$ per cycle, but larger standard deviation, say $\sigma_B\{\theta\} = 2 \cdot \sigma_A\{\theta\} = 0.58 \times 10^{-6}$ per cycle, so that the parameters of $g_B(\theta)$ are $a' = 1$ and $b' = 1.724 \times 10^6$ cycles. The prior distribution of R_τ , say $g_B(R_\tau)$, is still a log-gamma distribution with $E_B\{R_\tau\} = 0.711$ and $\sigma_B\{R_\tau\} = 0.214$. The sampling information $\mathbf{x}_1$ and $\mathbf{x}_2$ updates the belief on θ and, hence, on R_τ as shown in Figure 3, where the prior and posterior beliefs on R_τ of expert B are compared to the beliefs of expert A. It is evident that the sampling information made the posterior beliefs

Figure 3 Prior and posterior beliefs of experts A and B on the pump reliability R_t in Example 1

of experts A and B much closer to each other than the prior beliefs were.

Example 2

The reliability of the hydraulic system of a load–haul–dump (LHD) machine has to be estimated to verify if the probability that a new system, undergoing **minimal repair** at failure, experiences more than five failures within the first 1000 h is less than 0.40.

Owing to the minimal repair assumption, the failure process will be described through a **Poisson process** (see **Intensity Functions for Nonhomogeneous Poisson Processes**), so that the probability that a new system will experience k failures in the time interval $(0, T)$ is given by

$$\Pr\{N(T) = k | M_T\} = \frac{M_T^k}{k!} \exp(-M_T) \quad (14)$$

where $M_T \equiv M(T)$ denotes the expected number of failures in $(0, T)$. Hence, the reliability requirement

is met if

$$\Pr\{N(T) > 5 | M_T\} = 1 - \sum_{k=0}^5 \frac{M_T^k}{k!} \exp(-M_T) < 0.40 \quad (15)$$

for $T = 1000$ h.

Previous experience allows the expert to formulate a prior belief just on the value of M_T , in terms of a prior mean $E\{M_T\} = 6$ and a prior standard deviation $\sigma\{M_T\} = 3$. Again, he describes his prior belief on M_T through a gamma density

$$g(M_T) = \frac{b^a}{\Gamma(a)} M_T^{a-1} \exp(-bM_T), \quad a, b > 0 \quad (16)$$

whose parameters are given by $a = (E\{M_T\}/\sigma\{M_T\})^2 = 4$ and $b = E\{M_T\}/\sigma^2\{M_T\} = 2/3$. Then, on the basis of the prior belief, the prior probability $\Pr\{N(T) = k\}$ is

$$\begin{aligned} \Pr\{N(T) = k\} &= \int_0^\infty \Pr\{N(T) = k | M_T\} g(M_T) dM_T \\ &= \frac{\Gamma(a+k)}{\Gamma(a)k!} \frac{b^a}{(b+1)^{a+k}} \end{aligned} \quad (17)$$

which is a Pólya distribution (commonly known as *negative binomial distribution* [8, pp. 122–142]) with expectation $E\{k\} = a/b = 6$. The prior cumulative probability results is $\Pr\{N(T) > 5\} = 0.483$.

A copy of the hydraulic system is put on test, under use conditions, to verify the reliability attainment also on the basis of life testing information. The life testing is stopped when the 26th failure is observed. The times (in hours) to failure (drawn from [9]) are given in Table 1.

Because the truncation time $t_{26} = 3230$ h differs from $T = 1000$ h, the expert has to select the functional form for the **intensity function** $\lambda(t)$ of the Poisson process. On the basis of previous experiences, a nonhomogeneous Poisson process (NHPP), which has the power-law intensity function

$$\lambda(t) = \frac{\beta}{\alpha} \left(\frac{t}{\alpha}\right)^{\beta-1}, \quad \alpha, \beta > 0 \quad (18)$$

Table 1 Times to failures of the hydraulic system of an LHD machine (given in reference [10])

401	437	455	614	955	1126	1150	1500	1572

6 Life Testing from a Bayesian Perspective

is chosen, which is often referred to as *power-law process* (PLP) (see **Intensity Functions for Nonhomogeneous Poisson Processes**, [11]). The intensity function (equation 18) increases (decreases) with t when the power-law parameter $\beta > 1$ ($\beta < 1$), and hence the PLP can describe both deterioration and reliability improvement. The expected number of failures $M(t) = \int_0^t \lambda(x) dx = (t/\alpha)^\beta$ is linear with t in a log-log scale.

Then, the joint conditional distribution of $\mathbf{x} = (t_1, t_2, \dots, t_n)$, given the PLP parameters α and β , is

$$f(\mathbf{x}|\alpha, \beta) = \left(\frac{\beta^n}{\alpha^{n\beta}}\right) U^{\beta-1} \exp\left[-\left(\frac{t_n}{\alpha}\right)^\beta\right] \quad (19)$$

where $U = \prod_{i=1}^n t_i$. By changing variables $M_T = (T/\alpha)^\beta$, the joint distribution (19) can be easily reparameterized in terms of M_T and β :

$$f(\mathbf{x}|M_T, \beta) = \beta^n U^{-1} M_T^n \left(\frac{U}{T^n}\right)^\beta \times \exp\left[-\left(\frac{t_n}{T}\right)^\beta M_T\right] \quad (20)$$

and hence a prior distribution for the parameter β has to be elicited (see **Repairable Systems: Bayesian Analysis**). The only belief the expert possesses on β arises from the fact that the hydraulic system is subject to deterioration phenomena with operating time, and hence its failure intensity should increase with t . Thus, within the PLP assumption, β should be greater than 1 and, assuming M_T and β prior independent, the expert formalizes this belief by using a uniform distribution for β over the interval $(1, \beta_U)$ [12]: $g(\beta) = 1/(\beta_U - 1)$ (with $1 \leq \beta \leq \beta_U$). Then, the joint posterior distribution of M_T and β , given the life testing data $\mathbf{x}$, is

$$\pi(M_T, \beta|\mathbf{x}) = \frac{1}{f(\mathbf{x})} \beta^n \left(\frac{U}{T^n}\right)^\beta M_T^{a+n-1} \exp[-BM_T] \quad (21)$$

where $B = b + (t_n/T)^\beta$ and $f(\mathbf{x}) = \Gamma(a+n) \int_1^{\beta_U} \beta^n (U/T^n)^\beta B^{-(a+n)} d\beta$. The marginal posterior distribution of M_T results in

$$\pi(M_T|\mathbf{x}) = \frac{1}{f(\mathbf{x})} M_T^{a+n-1} \int_1^{\beta_U} \beta^n \left(\frac{U}{T^n}\right)^\beta \times \exp[-BM_T] d\beta \quad (22)$$

Figure 4 Prior and posterior distributions of the expected number of failures M_T up to $T = 1000$ h in Example 2

and represents the updated belief on M_T , as depicted in Figure 4 that compares the prior and posterior distribution of M_T .

Using equation (22), the posterior probability $\Pr\{N(T) > 5|\mathbf{x}\}$ follows:

$$\begin{aligned} \Pr\{N(T) > 5|\mathbf{x}\} &= \int_0^\infty \Pr\{N(T) > 5|M_T\} \\ &\quad \times \pi(M_T|\mathbf{x}) dM_T \\ &= 1 - \frac{1}{f(\mathbf{x})} \sum_{k=0}^5 \frac{\Gamma(a+n+k)}{k!} \\ &\quad \times \int_1^{\beta_U} \frac{\beta^n (U/T^n)^\beta}{(1+B)^{a+n+k}} d\beta = 0.347 \end{aligned} \quad (23)$$

The reliability requirement is then verified. Figure 5 gives the prior and posterior distribution of $N(T)$ and shows the updating effect of sampling information on prior belief.

To assess whether reasonable changes in the prior information can lead to a different result, a sensitivity analysis is performed with respect to the prior quantities $E\{M_T\}$, $\sigma\{M_T\}$, and β_U . As shown in Table 2, the posterior probability $\Pr\{N(T) > 5|\mathbf{x}\}$ remains less than 0.40 in all the cases but one, where the prior mean $E\{M_T\} = 7.0$. However, even in this worse case, the system reliability is very close to the reliability requirement, and then the reliability requirement is assumed to be met.

Figure 5 Prior and posterior probabilities of observing k failures until $T = 1000$ h in Example 2

Table 2 Sensitivity analysis *versus* the prior information in Example 2

$E\{M_T\}$	$\sigma\{M_T\}$	β_U	$\Pr\{N(T) > 5 \mathbf{x}\}$
6.0	3.0	5.0	0.347
5.0	3.0	5.0	0.300
7.0	3.0	5.0	0.405
6.0	2.0	5.0	0.399
6.0	4.0	5.0	0.321
6.0	3.0	3.0	0.347
6.0	3.0	7.0	0.347

It is interesting to note that simpler results could be obtained if the test were stopped just at $T = 1000$ h (time-truncated sampling). In this case the joint conditional distribution $f(\mathbf{x}|M_T, \beta)$ can be written as

$$f(\mathbf{x}|M_T, \beta) = \beta^n U^{-1} \left(\frac{U}{T^n} \right)^\beta \times M_T^n \exp[-M_T] \\ = f(\mathbf{x}|\beta) \times f(\mathbf{x}|M_T) \quad (24)$$

and, irrespective of the prior distribution chosen for β , provided β be prior independent of M_T , the posterior distribution of M_T is still a gamma density with parameters $a + n$ and $b + 1$. Thus, the marginal posterior probability $\Pr\{N(T) = k|\mathbf{x}\}$ becomes

$$\Pr\{N(T) = k|\mathbf{x}\} = \frac{\Gamma(a + n + k)}{\Gamma(a + n)k!} \frac{(b + 1)^{a+n}}{(b + 2)^{a+n+k}} \quad (25)$$

and belongs to the Pólya family as the prior $\Pr\{N(T) = k\}$ in equation (17), with expectation $E\{k|\mathbf{x}\} = (a + n)/(b + 1)$.

The Design of Life Testing

Previous examples illustrated the role and the effect of life testing in updating expert belief. Clearly, such an effect depended on the sample size and the manner in which the data have been collected, i.e. on the *design of life testing*. In Example 1, life testing design involved the number of units put on test (namely 15 units) and the truncation time. In general, the design of life testing is a very complex activity, which involves several quantities. For example, in accelerated life testing, given the total number of units to test, the experimenter has to choose the number of levels of the stresses, the values of the stresses, the number of units to test at each stress level, and the amount of censoring at each level before stopping the test (*see Accelerated Life Tests: Bayesian Design*). Because the design of life testing must be chosen before the data (and hence the posterior distribution) can be obtained, life testing design is frequently called *preposterior analysis* in Bayesian framework (*see Bayesian Design of Reliability Experiments*).

The choice of life testing design is commonly made by optimizing the design with respect to a given overall loss function, say $\Lambda(\Phi, \mathbf{d}, \mathbf{x}) = L(\Phi, \mathbf{d}) + C(\mathbf{x})$, which is the sum of a *decision loss* $L(\Phi, \mathbf{d})$, representing the loss associated with the decision $\mathbf{d}$ when Φ is the true state of nature, and a *cost of observation* (or *sampling cost*) $C(\mathbf{x})$, representing the cost of observing the data $\mathbf{x}$. Then, the Bayesian approach to life testing design optimization requires the specification of the decision loss function $L(\Phi, \mathbf{d})$ and the specification of the cost function $C(\mathbf{x})$, whereas the cost of conducting and analyzing the experiment is usually ignored. Note that decision loss and cost functions are in opposition to each other since “to lower the decision loss it will generally be necessary to run a larger experiment, whereby the experimental cost will be increased” [4, p. 281].

Hence, given the data $\mathbf{x}$ observed under a specified design D , the expected overall loss is

$$E_{\Phi|\mathbf{x}, D}\{\Lambda(\Phi, \mathbf{d}, \mathbf{x})\} = \int_{\Phi} \Lambda(\Phi, \mathbf{d}, \mathbf{x}) \pi(\Phi|\mathbf{x}, D) d\Phi \\ = \int_{\Phi} L(\Phi, \mathbf{d}) \pi(\Phi|\mathbf{x}, D) d\Phi \\ + C(\mathbf{x}) \quad (26)$$

where the expectation is made with respect to the posterior distribution $\pi(\Phi|\mathbf{x}, D) \propto f(\mathbf{x}|\Phi, D)g(\Phi)$. Thus, the optimal decision $\mathbf{d}_{\text{opt}}$, given the data $\mathbf{x}$, is the value of $\mathbf{d}$ that minimizes the expected decision loss $E_{\Phi|\mathbf{x}, D}\{L(\Phi, \mathbf{d})\} = \int_{\Phi} L(\Phi, \mathbf{d})\pi(\Phi|\mathbf{x}, D) d\Phi$ over the space of decisions. Then, the expected overall loss of acting optimally, given the data $\mathbf{x}$ under the design D , is $E_{\Phi|\mathbf{x}, D}\{\Lambda(\Phi, \mathbf{d}_{\text{opt}}, \mathbf{x})\} = E_{\Phi|\mathbf{x}, D}\{L(\Phi, \mathbf{d}_{\text{opt}})\} + C(\mathbf{x})$, often referred to as the *minimum posterior risk*. The preposterior expected overall loss, given the design D , also known as the *minimum Bayes risk*, is

$$\begin{aligned} E_{\mathbf{x}|D}\{E_{\Phi|\mathbf{x}, D}\{\Lambda(\Phi, \mathbf{d}_{\text{opt}}, \mathbf{x})\}\} \\ = \int_{\mathbf{x}} E_{\Phi|\mathbf{x}, D}\{\Lambda(\Phi, \mathbf{d}_{\text{opt}}, \mathbf{x})\} f(\mathbf{x}|D) d\mathbf{x} \end{aligned} \quad (27)$$

where $f(\mathbf{x}|D) = \int_{\Phi} f(\mathbf{x}|\Phi, D)g(\Phi) d\Phi$, and provides the overall loss of acting optimally averaged over all possible data $\mathbf{x}$ under the design D . From Bayes theorem (equation 1), the preposterior expected overall loss (equation 27) can also be rewritten as

$$\begin{aligned} E_{\mathbf{x}|D}\{E_{\Phi|\mathbf{x}, D}\{\Lambda(\Phi, \mathbf{d}_{\text{opt}}, \mathbf{x})\}\} \\ = \int_{\mathbf{x}} \int_{\Phi} \Lambda(\Phi, \mathbf{d}_{\text{opt}}, \mathbf{x}) f(\mathbf{x}|\Phi, D)g(\Phi) d\Phi d\mathbf{x} \end{aligned} \quad (28)$$

The **optimal design** is the one that provides the minimum preposterior expected overall loss [4].

Example 3

Again consider Example 1, where life testing design consists of choosing the number m of failures ($m \leq n = 15$) to observe before stopping life testing that minimizes the preposterior expected overall loss. The squared-error decision loss function $L(\theta, d) = c_1 \cdot (\theta - d)^2$ and the linear sampling cost $C(\mathbf{x}) = c_2 \cdot T$ are chosen, where the total time on test $T = \sum_{i=1}^m x_i + (n - m)x_m$ is a sufficient statistic for θ . Note that the (symmetric) squared-error loss is used here for its simplicity although an asymmetric loss function, such as the Linex loss [13], say $L(\theta, d, q) = c_1 \cdot [\exp[q(d - \theta)] - q(d - \theta) - 1]$, or the general entropy loss [14], say $L(\theta, d, p) = c_1 \cdot [(d/\theta)^p - p \ln(d/\theta) - 1]$, is usually more appropriate since an underestimation of the failure rate is

generally much more serious than an overestimation. The optimal decision d_{opt} under the squared-error loss, given the data $\mathbf{x}$ under the design $D = m$, is the posterior expectation $E\{\theta|\mathbf{x}, m\}$ of θ , and the expected decision loss $E_{\theta|\mathbf{x}, D}\{c_1 \cdot (\theta - d_{\text{opt}})^2\}$ of acting optimally is proportional to the posterior variance $V(\theta|\mathbf{x}, m)$. Then, under the gamma prior distribution of equation (5), the minimum expected overall loss $E_{\theta|\mathbf{x}, m}\{c_1 \cdot (\theta - d_{\text{opt}})^2 + c_2 \cdot T\}$ results in

$$E_{\theta|\mathbf{x}, m}\{c_1 \cdot (\theta - d_{\text{opt}})^2 + c_2 \cdot T\} = c_1 \cdot \frac{a + m}{(b + T)^2} + c_2 \cdot T \quad (29)$$

Under failure-censored sampling, the sampling distribution of T , given θ and m , is gamma [10, p. 103]:

$$f(T|\theta, m) = \frac{\theta^m}{\Gamma(m)} T^{m-1} \exp(-\theta T) \quad (30)$$

so

$$\begin{aligned} f(T|m) &= \int_{\theta} f(T|\theta, m)g(\theta) d\theta \\ &= \frac{\Gamma(a + m)}{\Gamma(a)\Gamma(m)} \frac{b^a T^{m-1}}{(b + T)^{a+m}} \end{aligned} \quad (31)$$

The preposterior expected overall loss, given the design m , is

$$\begin{aligned} E_{\mathbf{x}|m}\{E_{\theta|\mathbf{x}, m}\{c_1 \cdot (\theta - d_{\text{opt}})^2 + c_2 \cdot T\}\} \\ = c_1 \cdot \frac{\Gamma(a + m + 1)b^a}{\Gamma(a)\Gamma(m)} \int_0^{\infty} \frac{T^{m-1}}{(b + T)^{a+m+2}} dT \\ + c_2 \cdot \frac{\Gamma(a + m)b^a}{\Gamma(a)\Gamma(m)} \int_0^{\infty} \frac{T^m}{(b + T)^{a+m}} dT \end{aligned} \quad (32)$$

Table 3 gives the preposterior expected overall loss for $m = 2, \dots, n$, when the prior parameters are $a = 4.0$ and $b = 6.9 \times 10^6$ cycles, the loss factor is $c_1 = 10^6 \$ \cdot (10^6 \text{ cycles})^2$, and the cost factor is $c_2 = 1000 \$ / (10^6 \text{ cycles})$ or $c_2 = 2000 \$ / (10^6 \text{ cycles})$. The optimal life testing design is $m = 9$ when $c_2 = 1000 \$ / (10^6 \text{ cycles})$, and is $m = 5$ when $c_2 = 2000 \$ / (10^6 \text{ cycles})$, and the minimum preposterior expected overall loss is equal to \$50 700 and \$65 000, respectively. As could be anticipated, the optimal m value decreases when the sampling cost increases. When the sampling cost is null ($c_2 = 0$), the optimal choice is $m \equiv n = 15$ and the minimum preposterior expected overall loss is \$21 000.

Table 3 Preposterior expected overall loss (in $10^3\$$) for selected m values and cost factors c_2

c_2	Design m

Masked Failure Data

Introduction

In many life-testing situations one is only in a position to establish a subset of causes responsible for a given failure, but not the actual cause. This phenomenon is termed *masking*. For example, a typical failure of a personal computer results in error codes that enable one to identify the card (printed circuit board) responsible for the failure. However, in the vast majority of failures the actual offending component on the card remains unidentified. Situations of this type occur because of a number of reasons, the leading one being the cost of failure analysis (FA). Typically, the top priority in the wake of a failure is bringing the system back to operational state as quickly as possible. This is usually achieved through a modular system design and modular diagnostic tests. This approach to system design is the leading cause for the prevalence of masked in manufacturing, field, and warranty areas.

The key statistical problems related to masked data are those of modeling, **estimation**, and diagnostics. Most of the literature has been focused on **competing risk models**, which assume that there is only one cause of failure. However, models in which more than one component could be a culprit have also been considered [1]. As the concept of masked failure appears as a natural extension of the concept of completely identified failure, the whole spectrum of statistical models for lifetime data can be extended to accommodate these types of failures. The estimation and inference problems are typically handled *via* a conventional likelihood approach. One of the key estimation problems in this context relates to survival curves of the individual causes of failure. This problem is of special importance in the area of quality control associated with masked data. For example, one can find that there exists enough evidence to alert the manufacturer of a specific component that the reliability of that component is problematic, even though in most cases the component was not directly implicated in causing the system failure.

Another class of problems is related to estimation of parameters that govern the masking phenomenon itself. For example, in many cases one would want to estimate the probability that a failure of a particular component will lead to a given type of masking.

In situations where one is interested in setting up an efficient repair operation, the inverse problem is also of importance. For example, if we know that replacing a particular set of five components will take care of the failure, could we assert that replacing only components 1 and 3 will eliminate the failure with probability 0.99 or higher? Furthermore, what is the probability that each one of the components 1, 2, ..., 5 was the cause of the failure? The latter probabilities are not only important in the problem of diagnostics, but they also play a key role in quality reporting where it is frequently necessary to “assign the blame” or “allocate the failure” to several causes. Such reporting, in turn, enables one to use, in conjunction with masked data, a common set of reporting and monitoring tools, such as **Pareto** analysis and **control charts** for attribute data.

Model Specification and Parameters

Consider a system that contains k components in series. For simplicity, let us associate these components with causes of failure: we will say that a particular system failed because of component i (or because of cause i). Then one can typically prespecify the *masking groups*: for example, in the case $k = 5$ we could have just three masking groups, $g_1 = (1, 2)$, $g_2 = (1, 3)$ and $g_3 = (3, 4, 5)$. In other words, given that the masking group g_2 is feasible, we could have a situation where, in the wake of failure, we are definitely able to establish that the failure is due to either component 1 or 3, but we are not able to establish which of these components is culpable. In what follows, we will denote by G the set of the possible masking groups and use the symbol g to index these groups. If the cause i is part of the masking group g , we will express it as $i \in g$.

We must note that the problem of analysis of masked data has been studied extensively not only in the engineering and reliability literature, but also in literature related to biostatistics and medical research. Therefore, in what follows we will mention a number of publications from journals related to these areas.

A typical dataset associated with masked failures contains the following information [2]:

N is the number of systems tested.

n_0 is the number of systems that survived.

2 Masked Failure Data

$n_i, i = 1, \dots, k$ is the number of failed systems for which the failure is known to be caused by component i .

n_g is the number of failed systems for which it is known that the cause belongs to a masking group g (given for every $g \in G$).

$t_j^{(i)}, j = 1, \dots, n_i$ are the lifetimes of the n_i failures identified as caused by component i .

$t_j^{(g)}, j = 1, \dots, n_g$ are the lifetimes of the n_g failures identified as caused by one of the components in the masking group g .

$t_j^{(c)}, j = 1, \dots, n_0$ are the censored lifetimes.

The above data must satisfy the conditions $n_0 + \sum_{i=1}^k n_i + \sum_{g \in G} n_g = N$.

A typical model used in conjunction with the above data is defined in terms of the following functions:

$P_i(t), i = 1, \dots, k$, is called the i th *identification probability*. This is the probability that a system failure at time t that is due to cause i is identified as such (i.e., no masking occurs).

$P_{g|i}(t)$ is called the *masking probability*. This is the probability that a system failure at time t that is actually due to cause i will result in a masking group g .

Under the above setting, the above functions must satisfy the condition

$$P_i(t) + \sum_{g \supset i} P_{g|i}(t) = 1, \quad i = 1, \dots, k \quad (1)$$

The lifetime distributions of the individual components (causes of failure) are also of key importance. We will denote the density function and survival function corresponding to the i th component by $f_i(t)$ and $S_i(t)$, respectively ($i = 1, \dots, k$). A number of publications (for example, [3–5]) consider a *nonparametric* approach, in which no further assumptions are made about the nature of the distributions of individual causes of failure. However, in many problems originating in the area of engineering and reliability, there is a basis for assuming a more refined structure. In this case we could represent the density and survival functions in a parameterized form, $f_i(t; \beta_i)$ and $S_i(t; \beta_i)$, where β_i is the vector of parameters corresponding to cause i , and then use a *parametric* approach [6–12].

The primary quantities of interest are the survival curves corresponding to the individual causes, $S_i(t)$, the identification probabilities and the masking probabilities. Some derived parameters are also of interest in many applications. For example, one could be interested in estimating a survival curve of a system of different architecture constructed (wholly or partially) using the k components our system is based on. Problems of this type occur frequently in the process of designing subsequent versions of the system. Another derived quantity is the *diagnostic probability* $\pi_{i|g}(t)$ defined as a probability that a failure at time t that is associated with the masking group g is actually caused by the i th component:

$$\pi_{i|g}(t) = \frac{f_i(t)P_{g|i}(t)}{\sum_{j \subset g} f_j(t)P_{g|j}(t)} \quad (2)$$

Modeling and Analysis of Masked Data

The most popular and productive methods of analysis have been based on the likelihood. The complexity of the likelihood function depends greatly on further assumptions about the nature of failures, and we will only show the form that corresponds to *parametric analysis* under the assumptions that the competing risks are independent. Under this assumption the survival probability $S(t)$ of the system is given by

$$S(t; \beta_1, \dots, \beta_k) = \prod_{i=1}^k S_i(t; \beta_i) \quad (3)$$

and the likelihood function can be written in the form:

$$\begin{aligned} L = & \prod_{j=1}^{n_0} S(t_j^{(c)}; \beta_1, \dots, \beta_k) \\ & \times \prod_{i=1}^k \prod_{j=1}^{n_i} \left\{ f_i(t_j^{(i)}; \beta_i) P_i(t_j^{(i)}) \prod_{m \neq i} S_m(t_j^{(i)}; \beta_m) \right\} \\ & \times \prod_{g \in G} \prod_{j=1}^{n_g} \left[\sum_{r \subset g} f_r(t_j^{(g)}; \beta_r) P_{g|r}(t_j^{(g)}) \prod_{m \neq r} S_m(t_j^{(g)}; \beta_m) \right] \end{aligned} \quad (4)$$

In situations where the identification and masking probabilities are completely specified, the likelihood (equation 4) can be easily analyzed using

standard techniques. In other cases, however, one needs to deal with the parameters that determine these probabilities – and the likelihood analysis becomes rather difficult, because of both numeric issues and issues related to the identifiability and strength of the resulting inference. Therefore, a number of simplifying assumptions have been made in the literature. A number of papers discuss the situation where the identification and masking probabilities are not dependent on time, i.e.,

$$P_i(t) \equiv P_i; \quad P_{g|i}(t) \equiv P_{g|i} \quad (5)$$

(for example, see [12, 13]; however, some more general situations have also been discussed [5, 14]).

Estimability issues

Though the assumptions (equation 5) greatly simplify the likelihood analysis, it could still remain quite involved, even in the parametric case with relatively simple component distributions. One of the reasons for this is that in many applications one needs to take into account *covariates* corresponding to items on test that could reflect, for example, vintage characteristics or environmental conditions – and these usually inject additional parameters into the model [15, 16]. Furthermore, in the case of *proportional hazards*, i.e. when

$$S_i(t) = [S(t)]^{\phi_i}, \quad i = 1, \dots, k \quad (6)$$

with $\phi_i > 0$ and $\sum_{i=1}^k \phi_i = 1$, the problem is not estimable, even in the case where the survival function of the system $S(t)$ is completely identified (see Flehinger *et al.* [2]). For example, in the case $k = 2$ the likelihood function is proportional to $(\phi_1 P_1)^{n_1} \times (\phi_2 P_2)^{n_2} \times [1 - (\phi_1 P_1 + \phi_2 P_2)]^{n_{(1,2)}}$; therefore, only the products $\phi_1 P_1$ and $\phi_2 P_2 = (1 - \phi_1) P_2$ are estimable. Given that in most practical situations the assumption of proportional hazards (possibly involving only a subgroup of competing risks, which would be sufficient to undermine estimability) cannot be *a priori* excluded, the issue of estimability plays a prominent role in the analysis of masked data. In light of this issue, a number of further simplifications have been considered. One of the most popular ones is based on the *symmetry assumption* [17, 18]:

$$P_{g|i} = P_{g|j} \text{ for every } i, j \in g \quad (7)$$

Plausibility of the symmetry assumption typically depends on the reasons for masking. It can be justified, for example, in situations where any failed component in the group causes so much destruction that identification of the culprit is not possible without considerable expense (such situations sometimes occur in crashes of hard drives). This assumption could also be relevant in cases when masking occurs at random; in this case the masking phenomenon is quite similar to random censoring. However, in cases where masking patterns are determined by the FA strategy [19] one could find situations where the symmetry assumption could be *a priori* declared irrelevant. For example, when

1. the diagnostic procedure in the wake of a failure proceeds to examine all potential culprits in a given order (represented by a list),
2. the search for the cause of failure is time-censored, and
3. the inspection time of a given component is considerably shorter in the case when this component is faulty than in the case when it is healthy,

one could expect that for any given masking group (whose members are ordered in accordance with the list), the masking probability for the first component is smaller than that for the other components.

When the symmetry assumption is not justified, the estimability issues frequently necessitate use of more elaborate approaches to the problem of inference. In some cases, one could obtain fairly good estimates of the identification and masking probabilities based on external information. For example, in the situation described above where masking is determined by the postfailure diagnostics policy, one could sometimes obtain reasonable estimates based on the characteristics of this policy and information about the duration (or costs) of inspection under various scenarios. The evaluation can be typically carried out *via* a simulation study of various types of failure.

Two-Stage Models

In many cases one could take advantage of the fact that some of the masked cases can actually be resolved. This leads to *two-stage* analysis [2]. The data for the two-stage model is similar to one given in the section titled “Model Specification and Parameters”, with addition of the information on

how the selected cases were resolved. Use of two-stage models eliminates the estimability issue: one can carry out a likelihood analysis of the expanded dataset in a straightforward way, provided the policy that determines which masked cases are subject to resolution does not depend on the model parameters that we seek to estimate. Research results show that one can obtain a strong boost in statistical power by resolving only a small fraction of cases. Furthermore, one can control the strength of inference *via* a policy that determines which cases are to be resolved.

The two-stage data can be found in a large number of cases involving system manufacturing. The fact is that engineering departments normally do not allow situations generating exclusively masked data to persist for too long: inability to establish in a timely matter that a given component is causing reliability problems could mean exposure to significant financial losses related to warranty and maintenance costs, as large volumes of defective components continue to propagate through the supply chain and the field. However, the databases related to field failure/warranty records and to FA labs are frequently controlled by different organizations, which typically results in problems with compatibility of formats and policies. However, we found that in many cases creation of unified databases suitable for two-stage statistical analysis of masked data could lead to substantial reduction in quality and maintenance costs.

It is also important to note that in some cases, the data for two-stage analysis is potentially available at almost no additional investment and can be obtained *via* better defect documentation procedures. For example, some of the failures that are recorded as nonmasked in the data described in the section titled “Introduction” sometimes represent cases that were originally masked; however, the information about this masking was simply not recorded.

Dependent Causes of Failure

In some cases the basic assumption that the competing hazards are independent cannot be justified. In general, this assumption cannot be overturned on the basis of the observed failure data alone, since the marginal survival probabilities $S_i(t)$ are no longer identifiable when the causes of failure are dependent, even in the case where there is no masking. To see why this is the case, imagine that we have two types

of a two-component system, A and B. For a system of type A the components are independent, with survival curves $S_1(t) = S_2(t) = \sqrt{S(t)}$. For a system of type B the survival curves of both components are equal to $S(t)$, but the lifetimes are dependent in such a way that they are both almost identical, and the probability that component 1 has a shorter life (always by a minuscule amount) than component 2 is 0.5. Under such conditions, distribution of data from lifetime tests related to system A is basically indistinguishable from the similar data for system B.

The assumption of independence can, however, be overturned on the basis of the *a priori* engineering knowledge. For example, it may be known that the lifetime of a system is affected by a “frailty” parameter that affects several components, inducing dependence of the corresponding lifetimes. In the case of depending failures, analysis of masked data can be performed on the basis of *cause-specific hazards* defined by:

$$\lambda_i(t) = \lim_{\Delta t \rightarrow \infty} \left[\frac{\text{Prob}(t \leq T \leq t + \Delta t, C = i | T \geq t)}{\Delta t} \right] \quad i = 1, \dots, k \quad (8)$$

where (T, C) denotes the system lifetime and cause of failure. In this case, instead of representing $S(t)$ in the form of a product (equation 3), we represent $1 - S(t)$ as a sum of *cumulative incidence probabilities* $I_i(t)$ defined *via*

$$I_i(t) = \text{Prob}(T \leq t, C = i) = \int_0^t \lambda_i(u) S(u) du \quad i = 1, \dots, k \quad (9)$$

Now the likelihood function in the case of dependent causes of failure can be written in the form that is very similar to equation (4), but is based on the cause-specific density functions $g_i(t)$ defined by

$$g_i(t) = \frac{d}{dt} I_i(t) = \lambda_i(t) S(t) \quad (10)$$

see [2]. This approach enables one to estimate the parameters related to the cause-specific hazards, identification, masking probabilities, and other quantities of interest. Craiu and Reiser [20] developed an approach based on this technique for estimation related to a model with depending competing risks and piecewise-constant, cause-specific hazards.

Bayesian Approach and Computational Issues

Another method for incorporating external information about the model parameters (or even internal information, presented in the form of so-called non-informative priors) is to use Bayesian techniques. Literature on this approach to the problem of masking is quite extensive [11, 21–24]. In this context, the authors typically use the **Markov chain** (MCMC) techniques for estimation and inference.

In the frequentist setting, the inference can be carried out by maximizing the likelihood (for example, of type shown in equation (4), or its two-stage versions) *via* conventional nonlinear optimization techniques. Confidence statements and test statistics can then be obtained by using the *profile-likelihood* method. However, since the problem is naturally fitting the framework of estimation with missing data, the expectation-maximization (EM) algorithm is also most useful, e.g. see [5, 25, 26].

Cox Proportional Hazard Model

Introduction

D.R. Cox's article in the *Journal of the Royal Statistical Society* "Regression Models and Life-Tables" (Series B (Methodological), Vol. 34, No. 2 (1972), pp. 187–220) introducing the proportional hazard model is one of the most famous papers in statistics. According to Google Scholar, as of February 2007 it has received over 8500 citations. The volume of literature on the Cox proportional hazard model is wide and deep [1]. The theoretical foundations were secured years later with the development of the counting-process approach (see [2–4]).

What explains the unparalleled success of the Cox model? This contribution attempts to give insight into the reasons for its success and also its limitations. The presentation is quasiformal, ideas are introduced and motivated from sampling considerations rather than from theorems.

The guiding idea is model adequacy. Suppose you want to explain human life span in terms of "covariates" that influence the life span. The first idea might be to build a regression model; you obtain data on how long people live, how much they smoke, their body mass index, their income, years of schooling, sex, race, exposure to pollution, and whatever else you can think of and measure. You regress life span, or maybe log life span on these variables, to be able to argue "For someone in your situation, if you reduce smoking by A you can expect to live B years longer." But first the question of model adequacy must be addressed, how much variance in the life-span data do you explain with your model? If you are told someone's values on all these explanatory variables, how much better can you predict his/her life span than without this knowledge? If the answer is "not very much" then your predictions should not carry much persuasive force.

Or should they? Cox's key idea was to regress, not the life spans themselves, but the *failure* or *hazard rates* onto explanatory variables. However, we do not observe failure rates, just failures. How do we minimize mean square difference between observed and predicted failure rates? We do not; there is no residual in this sense. The beauty of Cox

regression is that it provides another way of finding optimal estimates of the covariates' coefficients. Very roughly, we find values of the **covariate** coefficients such that the people with shorter life spans tend to have larger failure rates. The method is called *maximization of partial likelihood*. It works when we can factorize the failure rate, or its time integral, the cumulative hazard function, into a time-independent part depending on covariates and a time-dependent part independent of covariates. That explains the cohabitation of the terms *proportional hazard model* and *partial likelihood*.

Is it all too good to be true? The goal of this contribution is to enable the reader to judge this for him/herself.^a

Proportional Hazard Model

To simplify the presentation, we consider the case of time-invariant covariates X, Y, Z without censoring and without ties. We consider data to be generated by the following hazard rate

$$h(X, Y, Z) = \Lambda_0(t)e^{XA+YB+ZC} \quad (1)$$

where the cumulative baseline hazard function $\Lambda_0(t) = \int_0^t \lambda_0(u) du$ is the time integral of the baseline hazard rate λ_0 . The covariates (X, Y, Z) are considered as random variables. The coefficients (A, B, C) and the baseline hazard Λ_0 will be estimated from life data. If this hazard function holds, then for an individual with covariate values (x, y, z) the survivor function is

$$e^{-h(x,y,z)} \quad (2)$$

Suppose we observe times of death $t_1, \dots, t_n$ such that $t_i < t_j$ for $i < j$. Let the covariates for the individual dying at time t_i be denoted (x_i, y_i, z_i) . The coefficients A, B, C are estimated by maximizing the *partial likelihood*

$$\prod_{i=1}^N \frac{e^{x_i A + y_i B + z_i C}}{\sum_{j \geq i} e^{x_j A + y_j B + z_j C}} \quad (3)$$

Note that the times of death t_i do not appear in equation (3). The intuitive explanation is as follows. *Given* that the first death in the population occurs at time t_1 , the probability that it happens

2 Cox Proportional Hazard Model

to individual 1 is $(e^{x_1 A + y_1 B + z_1 C} / \sum_{j \geq 1}^n e^{x_j A + y_j B + z_j C})$. After individual 1 is removed from the population, the same reasoning applies to the surviving population; *given* that the second time of death is t_2 , the probability that it happens to individual 2 is $(e^{x_2 A + y_2 B + z_2 C} / \sum_{j \geq 2}^n e^{x_j A + y_j B + z_j C})$, and so on. Kalbfleisch and Prentice [5] note that for constant covariates, equation (3) is the likelihood for the *ordering* of times of death. The baseline hazard can be estimated from the data as described in [5, p. 114].

Model Adequacy

With (x, y, z) fixed and T random, *and* with constant baseline hazard rate scaled to one, the survivor function (2), considered as a function of the random variable T is uniformly distributed on $[0, 1]$, that is

$$T \sim -\frac{\ln(U)}{h} \quad (4)$$

where U is uniform on $[0, 1]$. As this holds for each individual in the population $i = 1 \dots N$. If we order the values

$$e^{-t_i e^{x_i A + y_i B + z_i C}}; \quad i = 1 \dots N \quad (5)$$

and plot them against their number, the points should lie along the diagonal if the proportional hazard model is true with coefficients A, B, C and constant baseline hazard rate. The values in equation (5) are the exponentials of the Cox–Snell **residuals**; equal up to a constant to the martingale residual, used in the counting-process approach. The Cox–Snell residuals are exponentially distributed if the model is correct.

This would provide an easy heuristic check of model adequacy if the baseline hazard were indeed known to be constant and scaled to one. However, if the baseline hazard is also estimated from the data, then this simple test does not apply.

Testing model adequacy for the Cox model is not straightforward: This is a sampling of statements found in the literature regarding model evaluation: “... it is not apparent what kinds of departures one would expect to see in the residuals if the model is incorrect, or even to what extent agreement with the anticipated line should be expected” [5, p. 128]. “For most purposes, you can ignore the Cox–Snell and martingale residuals. While Cox–Snell residuals were useful for assessing the fit of the parametric

models in Chapter 4, they are not very informative for the Cox models estimated by partial likelihood” [6, p. 173]. “Unfortunately, this distribution theory [of the Cox–Snell residuals as exponentially distributed] has not proven to be as useful for model evaluation as the theory derived from the counting process approach”. [7 p. 202], “... there is not a single, simple, easy to calculate, useful, easy to interpret measure [of model performance] for a proportional hazards model” [7, p. 229]. “... the martingale residuals cannot play all the roles that linear model residuals do; in particular the overall distribution of the residuals does not aid in the global assessment of fit” [8, p. 81]. In many important studies, model adequacy is not examined, and only individual coefficients for the covariate of interest are reported, with Wald confidence bounds (e.g. [9, 10]). The coefficients are used to compute relative risk, and form the basis of (dis)utility calculations for different risk mitigation measures.

It may well arise that data generated with a constant baseline hazard appear to acquire a time-dependent baseline hazard as a result of missing covariates. Letting $\hat{\diamond}$ denote values estimated from the data, we may well find that the values

$$e^{-\hat{\Lambda}_0(t_i) e^{x_i \hat{A} + y_i \hat{B} + z_i \hat{C}}}; \quad i = 1 \dots N \quad (6)$$

plot as uniform, while the estimates do not resemble the values which generated the data. In particular, this may arise in the case of missing covariates. We identify some covariates but many others may not be represented in our model. For example, in considering the influence of airborne fine particulate matter on nonaccidental mortality [9, 10], covariates like smoking, sex, age, socioeconomic status, air quality, and weather are studied. However, time to death is obviously influenced by myriad other factors like occupation, genetic disposition, stress, disease prevalence, medical care, diet, alcohol consumption, home environment (e.g. radon), travel patterns, and so on.

The following type of simple numerical experiment, which the reader may verify for him/herself will illustrate the problems with model adequacy.^b

1. Choose coefficients (A, B, C) , choose a constant baseline hazard rate scaled to one, and choose a distribution for (X, Y, Z) .

2. Sample independently 100 values of (X, Y, Z) and 100 values from the uniform distribution on $[0, 1]$; compute failure times using equation (4).
3. Estimate the coefficients by maximizing equation (3), and estimate the baseline hazard.

This procedure does not require that the distributions of the covariates be centered at their means; indeed, centering is not a standard procedure in applications. However, the uniform distribution on $[-1, 1]$ used here is centered.

Let the model (1) be termed h_{XYZ} . To study the effects of model incompleteness estimate the coefficient A with a model h_{XY} using only covariates X and Y , and with a model h_X using only covariate X . For each of the models h_{XYZ} , h_{XY} and h_X , we repeat the above procedure 100 times with the same values for (A, B, C) , with (X, Y, Z) sampled independently from the (centered) uniform distribution on $[-1, 1]$; however, we change equation (3) so as to estimate A in the models h_{XY} and h_X . Figure 1 plots the ordered estimates of coefficient A .

Evidently, the models h_{XY} and h_X tend to underestimate the coefficient A . A theoretical explanation of this underestimation is given in [11, 12]. Hougaard [13] shows that missing covariates sometimes result in nonproportional hazard functions, which could be detected with sufficient replications. He concludes that “the regression coefficients cannot be evaluated without consideration of the variability of neglected covariates. This is a serious drawback of relative

risk models” [13, p. 92], leading him to promote accelerated failure or frailty models. The tendency to underestimate becomes more pronounced in Figure 2, where the missing covariate Z has coefficient $C = 5$. In spite of this, the ordered values of equation (6) plot along the diagonal, as shown in Figure 3. If we knew that the data was created with $\lambda_0(t) \equiv 1$, then we may impose this constraint on the survivor functions. From Figure 4 we see that uniformity is lost for the incomplete models h_{YXY} , h_X ; but not for the complete model h_{XYZ} . This would provide an excellent diagnostic for completeness if we had *a priori* knowledge of the baseline hazard rate; unfortunately in practice we do not have this knowledge. We can, however, find another diagnostic (see below).

Figure 5 shows the Wald 95% confidence bounds for A in model h_X , in each of the 100 repetitions of the experiment whose estimates are shown in Figure 2. These bounds are derived assuming asymptotic normality of the Wald statistic

$$\frac{\hat{A} - A}{\sigma_A} \quad (7)$$

where $\hat{A}$ is the estimate of A and σ_A is derived from the observed information matrix. If the likelihood function is correct, then the Wald statistic is asymptotically standard normal. In as much as these 95% confidence bands contain the true value $A = 1$ in only 7% of the cases, the wisdom of stating such

Figure 1 100 ordered estimates of A for h_{XYZ} , h_{XY} , h_X , $X, Y, Z \sim U[-1, 1]$, $(A, B, C) = (1, 1, 1)$; each estimate based on 100 samples

4 Cox Proportional Hazard Model

Figure 2 100 ordered estimates of A for h_{XYZ}, h_{XY}, h_X , $X, Y, Z \sim U[-1, 1]$, $(A, B, C) = (1, 1, 5)$ each estimate based on 100 samples

Figure 3 Ordered values of equation (6) for h_{XYZ}, h_{XY}, h_X , $X, Y, Z \sim U[-1, 1]$, $(A, B, C) = (1, 1, 5)$

confidence bounds when model adequacy cannot be demonstrated may be questioned.

The models h_{XY} and h_X are clearly incorrect and misestimate the covariate A . Relative risk coefficients based on these models would be biased. Without *a priori* knowledge of the baseline hazard function, their incorrectness cannot be diagnosed using Cox–Snell or martingale residuals, echoing the statements cited at the beginning of this section. The problem is that the **lack of fit** caused by missing covariates is compensated in the estimated baseline hazard function.

This observation suggests that we might detect

lack of fit in the covariates by comparing the estimated baseline hazard function with the population cumulative hazard function, that is, minus the natural logarithm of the population survivor function. From equation (6) it is evident that adding a constant to any covariate is equivalent to multiplying the baseline hazard by a constant. We therefore standardize the covariates by centering their distributions on the means (the distributions here already centered). This standardization can be motivated as follows. If the covariates X , Y , and Z have no effect, then their means in the set R_i of individuals at risk at the time t_i of death of the i th individual, are just their means

Figure 4 Ordered values of equation (6) for $h_{XYZ}, h_{XY}, h_X, X, Y, Z \sim U[-1, 1], (A, B, C) = (1, 1, 5)$ with $\hat{\Lambda}_0(t) \equiv t$

Figure 5 Wald 95% confidence bounds for A with model, h_X of Figure 2; each estimate based on 100 samples

$\bar{x}, \bar{y}, \bar{z}$. We write

$$\sum_{j \in R_i} e^{x_j A + y_j B + z_j C} \sim \sum_{j \in R_i} (1 + x_j A)(1 + y_j B)(1 + z_j C) \quad (8)$$

If X, Y , and Z are independent with mean zero then the mean of the right-hand side is just $\#R_i$. The

Breslow estimate [14] of the baseline hazard rate is

$$d\Lambda_0(t_i) = \left[\sum_{j \in R_i} e^{x_j A + y_j B + z_j C} \right]^{-1} \quad (9)$$

and the population cumulative hazard rate at t_i is $[\#R_i]^{-1}$. Hence, under these conditions, centering the covariates at their means, then replacing covariates with their mean value (zero), would equate the cumulative baseline hazard function and the population cumulative hazard function.

6 Cox Proportional Hazard Model

Figure 6 Cumulative population and baseline hazard functions for $h_{XYZ}, h_{XY}, h_X, X, Y, Z \sim U[-1, 1]$, $(A, B, C) = (1, 1, 1)$

Figures 6 and 7 show these comparisons for the two cases from Figures 1 and 2. Note the difference in survival times (horizontal axis); this is caused by the heavier loading of covariate Z in Figure 7. The Nelson–Aalen estimator is used for the population cumulative hazard function.

We see in Figure 7 that the cumulative baseline hazard functions for h_{XY} and h_X have moved closer to the population cumulative hazard, reflecting the heavier loading on the missing covariate Z .

If a Cox model had *none* of the actual covariates, this would be equivalent to having zero coefficients on all covariates; and in this case the baseline hazard would coincide with the population cumulative hazard. A simple heuristic test of model adequacy would test the null hypothesis that the cumulative baseline

Figure 7 Cumulative population and baseline hazard functions for $h_{XYZ}, h_{XY}, h_X, X, Y, Z \sim U[-1, 1]$, $(A, B, C) = (1, 1, 5)$

hazard function is equal to the population cumulative hazard function. If the null hypothesis cannot be rejected, then using the Cox model would not be indicated. In Figures 8 and 9 the asymptotic 2σ bands on the asymptotic variance of the Nelson–Aalen estimator of the population cumulative hazard function [5, p. 25] have been added to Figures 6 and 7. We see that with this simple test we would fail to reject the null hypothesis for model h_X after 100 observations in both cases. The greater loading of the missing covariate Z in Figure 9 causes the model h_{XY} to fail to reject the null hypothesis as well.

The more familiar partial-likelihood-ratio test calculates the test statistic G as twice the difference between the log partial likelihood of the model containing the covariates and the log partial likelihood for the model not containing the covariates. G is asymptotically χ^2 distributed under the null hypothesis. The above test may have some advantage in that it does not appeal to partial likelihood. However, it is unable to detect the lack of fit in the model h_{XY} when $C = 1$.

We note that for all the results mentioned above, the covariates are independent. In practice independence is not usually checked, and not always plausible. Figure 10 shows 100 estimates of the coefficient A for the models h_{XYZ}, h_{XY}, h_X where the covariates are uniformly distributed on $[0, 1]$ with correlations $\rho(X, Z) = 0.98, \rho(Y, Z) = 0.41$. Whereas missing covariates produce underestimation in the case of independence, we see that dependence in Figure 10 produces overestimation. Note also that the spread of estimates for the complete model h_{XYZ} is very wide.

Figure 8 Cumulative population and baseline hazard functions for $h_{XYZ}, h_{YXY}, h_X, X, Y, Z \sim U[-1, 1]$, $(A, B, C) = (1, 1, 5)$ with 2σ confidence bands (dashed lines)

Figure 9 Cumulative population and baseline hazard functions for $h_{XYZ}, h_{YXY}, h_X, X, Y, Z \sim U[-1, 1]$, $(A, B, C) = (1, 1, 1)$ with 2σ confidence bands (dashed lines)

Censoring and Competing Risk

The discussion of model adequacy with the proportional hazard model is sometimes clouded by the role of censoring. The following statement is representative: “A perfectly adequate model may have what, at face value, seems like a terribly low R^2 due to a high percent of censored data” [7, p. 229]. The reference to R^2 must be taken as metaphorical. The proportional hazard model proposes a linear regression of the log hazard function. The hazard function is not observed, and hence a measure of the difference between observed and predicted values, like R^2 is not meaningful. The point is that the ability of a proportional hazard model to “explain the data” might be obscured by censoring.

Right censoring of course is a form of **competing risk**. In this section we review some recent results from the theory of competing risk, and indicate how they may yield diagnostic tools in proportional hazard modeling. In the competing-risks approach we model the data as a sequence of independent and identically distributed (i.i.d.) pairs (T_i, δ_i) , $i = 1, 2, \dots$. Each T is the minimum of two or more variables, corresponding to the competing risks. We will assume that there are two competing risks, described by two random variables D and C such that $T = \min(D, C)$. D will be time of death, which is of primary interest, while C is a censoring time corresponding to termination of observation by other causes. In addition to the time T one observes the indicator variable $\delta = I(D < C)$,

Figure 10 Hundred ordered estimates of A for $h_{XYZ}, h_{XY}, h_X, X, Y, Z \sim U[0, 1]$, $(A, B, C) = (1, 1, 1)$ with dependent covariates

which describes the cause of the termination of observation. For simplicity we assume that $P(D = C) = 0$.

It is well known (Tsiatis [15]) that from observation of (T, δ) we can identify only the subsurvivor functions of D and C :

$$S_D^*(t) = P(D > t, D < C) = P(T > t, \delta = 1) \quad (10)$$

$$S_C^*(t) = P(C > t, C < D) = P(T > t, \delta = 0) \quad (11)$$

but not in general the true survivor functions of D and C , $S_D(t)$ and $S_C(t)$. Note that $S_D^*(t)$ depends on C , though this fact is suppressed in the notation. Note also that $S_D^*(0) = P(D < C) = P(\delta = 1)$ and $S_C^*(0) = P(C < D) = P(\delta = 0)$, so that $S_D^*(0) + S_C^*(0) = 1$.

The conditional subsurvivor functions are defined as the survivor functions conditioned on the occurrence of the corresponding type of event. Assuming continuity of $S_D^*(t)$ and $S_C^*(t)$ at zero, these functions are given by

$$\begin{aligned} CS_D^*(t) &= P(D > t | D < C) \\ &= P(T > t | \delta = 1) = S_D^*(t) / S_D^*(0) \end{aligned} \quad (12)$$

$$\begin{aligned} CS_C^*(t) &= P(C > t | C < D) \\ &= P(T > t | \delta = 0) = S_C^*(t) / S_C^*(0) \end{aligned} \quad (13)$$

Closely related to the notion of subsurvivor functions is the probability of censoring beyond time t ,

$$\begin{aligned} \Phi(t) &= P(C < D | T > t) \\ &= P(\delta = 0 | T > t) = \frac{S_C^*(t)}{S_D^*(t) + S_C^*(t)} \end{aligned} \quad (14)$$

This function has some diagnostic value, aiding us to choose among competing-risk models to fit the data. Note that $\Phi(0) = P(\delta = 0) = S_C^*(0)$.

As mentioned above, without any additional assumptions on the joint distribution of D and C , it is impossible to identify the marginal survivor functions $S_D(t)$ and $S_C(t)$. However, by making extra assumptions, one may restrict to a class of models in which the survivor functions are identifiable. A classical result on competing risks [15, 16] states that, assuming independence of D and C , we can determine uniquely the survivor functions of D and C from the joint distribution of (T, δ) , where at most one of the survivor functions has an atom at infinity. In this case the survivor functions of D and C are said to be identifiable from the censored data (T, δ) . Hence, an independent model is always consistent with data.

If the censoring is assumed to be independent then the survivor function for T , the minimum of D and C , can be written as

$$S_T(t) = S_D(t)S_C(t) \quad (15)$$

If we assume that D obeys a proportional hazard model, and that the censoring is independent, then we may estimate the coefficients by maximizing the partial-likelihood function adapted to account for censoring:

$$\prod_{i \in D_N} \frac{e^{x_i A + y_i B + z_i C}}{\sum_{j \geq i}^n e^{x_j A + y_j B + z_j C}} \quad (16)$$

where D_N is the subset of observed times $t_1, \dots, t_N$ at which death is observed to occur, and j runs over all times corresponding to death or censoring.

If we now substitute the survivor function with estimated coefficients in equation (15), and use the familiar Kaplan–Meier estimator for S_C , then we may apply the ideas of the previous section to assess model adequacy [17].

Conclusions

The user of the Cox proportional hazard model may be assured that *if* the model is correct, then the coefficient estimates will converge to the true values, and the confidence bands will accurately reflect sampling fluctuations around these true values. If the model is *not* correct, however, then the coefficients' estimates may not be correct, and the confidence bands may give a misleading picture. If the covariates are independent, and if one or more covariates is omitted, then the coefficients of the other covariates will be underestimated in absolute value. If there is dependence between missing and included covariates, then nothing can be said about the direction of the error.

How can we check whether the model is correct? This remains the difficult point. We can test whether covariates are significantly different from zero. However, when covariates pass this test, it does not mean that they will be estimated correctly.

ROGER M. COOKE

Process Reengineering

Background and Definition

Business process reengineering (BPR) is the *fundamental* rethinking and *radical* redesign of *business processes* [1, 2] – that is, the flow of work and information within and between organizations. Its purpose is to achieve *drastic* improvement over existing performance in quality, cost, service, and cycle time. It is also known as business process *redesign*, business process *transformation*, or business process *innovation*.

Rather than pursuing continuous, but incremental improvement like some of its predecessor methodologies such as **Kaizen**, and total quality management (TQM), BPR seeks radical improvement in a single effort.

BPR reached the peak of its popularity in the mid-to-late 1990s after Michael Hammer and James Champy published their best-selling book *Reengineering the Corporation* in 1993.

Use of the Methodology

BPR was initially intended to significantly improve, in current terms, the business performance and competitiveness of the enterprise. The extensive reengineering of administrative, information systems, procurement, and manufacturing processes in the early 1990s is the well-known result of this approach. More recently, management has discovered that business performance can further be improved by the systematic reengineering of its *core* processes: the aggregation of work that creates customer value.

Accordingly, the selection of business processes for reengineering predominantly targets those core processes that directly affect the customers of the firm: manufacturing, distribution, customer service, invoicing, and order entry.

Process reengineering is not intended to replace or substitute for *automation*, *software reengineering*, or traditional *reorganization*. Its original proponents (Hammer [2] and Davenport [3]) and other lead practitioners also emphasized that reengineering should not lead to *downsizing* – its basic concept is to “do more with the same”.

Although it is difficult to offer general guidelines on the use of BPR, certain conditions are conducive to its application:

- There are serious quality and customer satisfaction concerns.
- Continuous improvement methods are not producing satisfactory results.
- Competition is consistently outperforming the enterprise.
- The organization exhibits considerable internal organizational conflict.
- The company is experiencing excessive product and administrative cost overruns.

Most of the companies with one or more of these conditions have clearly differentiated functions: vertical organizational “silos” – structures built around the concept of the division of labor and hierarchical management. These functional silos comprise only narrow pieces of a multitude of processes that in total make up the workings of the enterprise. Managers and executives are in charge of increasingly large segments of the *function*, but no one is in charge of the *processes*. This is known as *process fragmentation*. Because of process fragmentation, handoff problems between functions proliferate throughout the organization.

As a result, processes become highly error prone as each handoff requires coordination and communication and entails wait times and mismatches in schedules. And while these processes have always existed – they are, in essence, the way work is done by the enterprise – only a few people are aware of them, and they are not managed in any consistent or rational way.

Traditional BPR is about the reintegration of work and the elimination of process fragmentation and the related handoff problem.

Basic Concepts and Methods

In many cases, radical redesigning and reorganization of an enterprise is necessary to lower costs and improve the quality of products and services. Information technology (IT) is the key enabler of such radical change. The nine principles of successful reengineering to achieve quantum performance improvement include:

2 Process Reengineering

1. Develop the business vision and process goals.
2. Identify all the processes in an organization and prioritize them in order of redesign need (based on the importance of the process, its level of dysfunctionality, and the likelihood of success).
3. Understand and measure the performance of existing processes.
4. Organize around results and customers, not tasks or departments.
5. Place decision points where the work is performed by building appropriate controls into the process.
6. Treat geographically dispersed resources as if they were concentrated.
7. Capture information only once and do this at its source.
8. Identify IT resources and capabilities; integrate IT into the material workflow for maximum leverage.
9. Design and build a prototype of the new process as the base for successive design iterations and tests.

IT plays a critical role in implementing the BPR concept. It is viewed as an important enabler of new ways of communicating and collaborating within an organization and across organizational boundaries.

Generally, the application of IT to process reengineering requires *inductive* thinking in that its power of disrupting existing rules and paradigms is first recognized, and then process situations are sought out where this provides a radically new solution. As part of the BPR approach, *workflow management* systems are considered as significant contributors to process improvement.

Where an enterprise resource planning (ERP) solution is an integral part of the BPR effort, the project planning and management function of the ERP system may be utilized. Major ERP systems offer these capabilities as part of their system packages.

BPR treats business processes as proceduralized workflows. It links functional expertise with process management teams to reintegrate the existing, fractionated workflow into contiguous, cross-functional work processes that are driven by *customer needs*.

Infrastructure

Reengineering is done by trained and qualified people. Selecting and organizing those who actually

implement reengineering is critical to success. Certain people have unique roles that focus either on the individual process, or on aligning multiple processes at the enterprise level; others play dual roles as they carry out the tasks of bridging and integration at both levels.

Although there is no one-size-fits-all list of roles, many years of reengineering experience have helped identify the following generic reengineering infrastructure:

- *Enterprise transformation executive*—the senior executive who has the authority and resources to decide and motivate the overall reengineering endeavor.
- *Enterprise transformation council*—a group of influential policy makers who develop and champion the overall process reengineering strategy of the enterprise, commit the necessary resources, and oversee its progress. They are responsible for achieving synergy across the separate, individual reengineering projects of the enterprise and for creating optimal leverage on overall business performance.
- *Process management executive* – a senior manager who is the owner of the enterprise methodology of business process management, and is responsible for developing and maintaining methods, tools, and techniques – including the latest IT and computer software – related to BPR.
- *Business process owner* – an executive or middle manager with the responsibility and accountability for a specific, single business process, its reengineering, and subsequent operational implementation. There are usually a number of business process owners within an enterprise.
- *Business process management team* – a group of selected individuals (usually managers or senior professionals) working with the process owner and committed to the reengineering and subsequent operation of a specific, single business process.
- *Business process management team leader* – a member of the business process management team selected by the process owner to lead and administer the day-to-day work of the process team.

These roles do not represent a hierarchical set. Rather, they are part of a two-level team structure where the transformation council is the strategic

entity, and the business process management teams represent the operational part.

Budget

The process implementation budget contains both expense and capital items. It is always preferable to establish a consolidated process reengineering budget, as opposed to distributing the cost implications among the affected functional operating budgets.

Costing methods used in establishing the implementation budget should be consistent with those employed to plan and measure the continuing process costs once the reengineered business process has become operational. Since most process costing methods are activity or task based, it is recommended that *activity-based costing* (ABC) be used in building the process implementation budget.

It is important to point out that all implementation activities in the project plan must contain, beyond people and technology, all the required resources: materials, energy, plant and facilities, intellectual capital, and other assets needed to ensure the successful plan implementation.

It may happen at times that the deployment of a newly reengineered business process may take more time and effort than its design. This will more likely be the case where a massive upgrading of IT, such as the implementation of an ERP system, is part of the reengineering effort.

Strengths

If implemented properly and with the committed and continuing support of senior management, BPR can yield very significant returns. It helped corporate giants like Procter & Gamble and General Motors recover after financial drawbacks due to competitive pressures; Southwest Airlines reengineered the company using IT; Michael Dell understood how and where to apply the concept of BPR to reengineer Dell Computers; Ford reengineered its manufacturing processes where *job #1* is product quality.

Through a smoothly functioning reengineering infrastructure, accountable process ownership, and effective teamwork, reengineering provides the solution to the two known dilemmas of process management:

- variation and dispersion and
- scale and complexity.

Variation and dispersion is the apparent conflict between the need for process consistency across the enterprise and the variation caused by geographic dispersion and differences in market requirements. Reengineering tries to solve this dilemma by creating different versions of the same basic process flow, each under the leadership of a working owner, and assigning an operations director to each instantiation of each version, to deal with variation in market (customer) requirements.

Scale and complexity are the combined effects of process size (amount of resources, number of operating locations) and structure (number of constituent subprocesses and activities, handoff points, multiple process versions). Scale and complexity can make a single process owner's job extremely challenging. Again, the suggested approach is subdivision of the process and the assignment of additional process management resources. Subprocess owners operate under the overall management umbrella provided by the executive process owner.

The idea of reengineering was rapidly adopted by a huge number of firms around the world, but most notably in North America. They were striving for renewed competitiveness, which they had lost due to:

- the market entrance of new foreign competitors (e.g., Japanese manufacturers in the United States);
- their inability to satisfy changing customer needs (e.g., IBM in the mid-1980s); or
- their flawed cost structure.

Reengineering was implemented at an accelerating pace and by the late 1990s more than half of the Fortune 500 companies claimed to either have actually initiated reengineering efforts, or to have firmly planned to do so.

Weaknesses

To this day, a number of critics claim that BPR dehumanizes the workplace. By the late 1990s, BPR gained the somewhat unfair reputation of being an outright excuse for "downsizing", e.g. major and irreversible reductions of the workforce.

A number of factors can cause BPR initiatives to fail to reach their initial objectives. The reasons for

4 Process Reengineering

such failure are many; however, most can be avoided or corrected:

- lack of sustained management commitment and leadership;
- unrealistic scope and expectations, or prior constraints on problem definition or project scope;
- underestimation of the cultural resistance to change;
- overconfidence in technological solutions;
- poor **project management**;
- concentration on redesign as the only alternative;
- neglecting people's values and beliefs;
- settling for partial or minor results, or quitting too early;
- making reengineering happen as a grassroots effort;
- dissipating energy and resources across an excessive number of reengineering projects; and
- failure to distinguish reengineering from other improvement programs.

The traditional process reengineering methodology evolved around the concept of physical and material workflow, its improvement and redesign. This is because the underlying methodologies have their roots in manufacturing and, in particular, in IT, whose purpose is to automate defined procedures.

This approach to BPR has led to the development of skillful ways of redesigning business processes to measurably improve performance, and to use IT for the streamlining and coordination of complex workflows. However, as companies embarked on using this approach to performance improvement, it eventually became clear that some important things were being overlooked.

The traditional process reengineering approach did not adequately address several fundamental areas [4]:

- the human dimension, including the flow of people-to-people communications in the process;
- the planned adaptability of redesigned processes to deal with further unpredictable change, and
- overall economic and business performance of the enterprise.

Overlooking the Human Dimension

Overlooking the human dimension – mobilizing and motivating people – has been viewed as a major

shortcoming of classic workflow-based process reengineering. The downsizing, done without concern for the people, has made the term *reengineering* imply that people do not matter because the approach taken is mechanical and impersonal.

Another limitation of traditional reengineering is its inherent difficulty in harnessing the great variety of intellectual, managerial, and professional communications where there are no easily definable physical work products – e.g., most work results are agreements, decisions, commitments, and the transfer of information and knowledge.

Problem with Unpredictable Change

One of the greatest challenges to BPR is that it must engender thinking that helps anticipate and deal with *unpredictable change* – the ability to quickly identify and abandon old paradigms that underlie current operations.

The Process Paradox

Success at the business process level, but no improvement or even negative overall impact at the enterprise level, is the essence of what has become known as the *process paradox*. After months or even years of careful process redesign, many companies have achieved impressive improvements in individual business processes – only to watch overall results still decline. By now, paradoxical outcomes of this kind have become almost proverbial.

- IBM's small business division won the Malcolm Baldrige Award in 1992 in recognition of the successful redesign of the development and production processes that produced one of IBM's all-time success products: the AS400. At the same time, the IBM Corporation was facing the worst crisis of its history including the downsizing of half of its workforce worldwide.
- In 1995, Corning's telecommunications products division earned the Malcolm Baldrige Award. Six years later the company was experiencing what many believed was its fight for corporate survival.

Summary

Today, defining business processes as the starting point for business analysis and redesign is a widely

accepted practice and standard part of the change management portfolio. Change, however, is sought and implemented in a less radical way than what was originally proposed by BPR.

The key task of twentieth century executives and managers was *performance improvement*. The solutions of TQM and BPR were *process solutions* – focusing primarily on key, individual business processes.

Now, management faces the compelling requirement of doing all this continuously, faster, and better than competition – and in the face of accelerating and unpredictable change. The double challenge of the twenty-first century is to be successful while continuously *adapting* and responding to a highly competitive, fast moving, information-driven, and near-turbulent environment. In fact, “continuous adaptation” is the motto for the new century.

Kaizen

Introduction

Process improvement involves the use of many tools and techniques. Always the aim is to improve some aspect of performance, quality, productivity, competitiveness, or profitability. One appealing technique is Kaizen. Kaizen is a Japanese word which may be translated as gradual change for the good or continuous improvement. Kaizen projects often feature as part of a lean **six sigma** initiative.

A characteristic of Kaizen projects is that they are typically targeted at “quick fix” improvements that can be achieved through a short and intense period of project work (generally no more than one week). Kaizen projects, therefore, differ from lean six sigma projects which are usually expected to take a period of months.

Kaizen projects are tackled during what is often termed a *Kaizen event* or *Kaizen blitz* [1]. For a project to be suitable for a Kaizen event it must be well defined and have clear boundaries. In addition, it must be possible unambiguously to measure the results, for example, the time taken to complete a task, the number of steps taken, or the number of defective units. A Kaizen event can be used to tackle one component of a larger project as long as the scope of the Kaizen subproject is well defined.

The most common objective of a Kaizen event is to improve process flow by attacking process waste. The solutions identified are generally low tech, for example, the rearrangement of process steps into a more efficient order. Kaizen is suitable for production and nonproduction areas of a business [2]. Examples of Kaizen projects include streamlining an invoicing process, or reducing waiting time in one section of a process.

Teams

Kaizen events are carried out by small teams of people. Kaizen is a powerful improvement tool because team members are taken out of their day-to-day responsibilities and allowed to have ring-fenced time to think about a problem and its solution. Price and Williams [3] state that “companies which use Kaizens have found they generate energy among those who

work in the area being improved, and produce immediate gains in productivity and quality”.

For Kaizen to be successful the team members have to be open-minded and treat everyone in the team as equal partners. The following are guidelines:

1. Encourage all team members to think.
2. Think positively and focus on “how” rather than reasons why not.
3. Think widely rather than being tied to fixed, conventional ideas.
4. Try to get to the root cause of a problem; the five why technique, for example, may be useful. Many Kaizen solutions seem obvious in hindsight.
5. Take action rather than holding out for perfection. Do what can be done now with the resources at hand.
6. Use the ideas and insights of everyone in the team. If someone suggests a solution that works well in another department, then consider it as a potential solution for the department currently in focus, even though the situations may be different.

As the implementation of new ideas is an integral part of a Kaizen event it is vital that the Kaizen team members have the authority to put process improvements in place. The team working on a Kaizen process improvement project should either include the process owner or have their authorization to implement the solution. Otherwise, there will be a delay before the results of the Kaizen event can be put into practice. “Quick wins” are often achieved at Kaizen events but it is important that whatever is changed as a result of the event, can be changed back, if necessary, to reduce the risk of unforeseen consequences. This is particularly important in highly interrelated specialties such as healthcare.

Not everyone who will be directly affected by changes will be in the Kaizen event. The concerns of other individuals should therefore be taken into account. Good communication is vital.

Types of Projects

Kaizen projects are typically aimed at reducing waste within a defined process. The following types of project can be well suited to Kaizen events:

2 Kaizen

- Projects which seek to increase throughput in a particular process.
- Projects which seek to decrease waiting times for internal customers.
- Projects that look to improve staff or resource utilization.
- Projects that aim to address processing time for tasks – or to introduce same day processing for tasks.
- Projects that aim to reduce the amount of physical space required for a process.

Each potential Kaizen project should be judged individually on its ease of implementation and potential benefit. This can be done using a payoff matrix. The matrix has two axes; the x-axis is the business impact of the subproject, the y-axis the ease of implementation of the subproject.

Each member of the Kaizen team rates each possible project for ease of implementation and potential improvement impact. Those projects falling into the upper right quadrant of the matrix should be tackled first.

Ease of implementation	Easy		
	Hard		
		Low	High
		Business impact	

Often the initial scope of a project may be too wide to make it suitable for a Kaizen event. The payoff matrix can be a simple and effective tool for sorting through possible subprojects within a larger project scope. Later on during the Kaizen event the payoff matrix can also be used to sort through and prioritize potential solutions.

Following Kaizen processes are generally considered to have improved if:

- Their duration time has decreased.
- The space required for the process has decreased.
- Fewer resources are used (e.g., people, machines, material, energy, and information).
- Outcomes improve (e.g., quality, customer satisfaction, and cash flow).

Kaizen projects are about identifying and trying possible solutions to a problem within a short space

of time. The project will run smoothly if necessary supporting evidence and data are available and accessible at the start.

Kaizen Project Worksheet

Once a Kaizen project has been selected it is a good idea to develop a Kaizen project worksheet. The worksheet should contain all the project details, including an outline of the problem to be addressed and the project objectives. The worksheet is useful for: clarifying the problem, ensuring the problem is understood by the whole team, and recording the current state of play. The worksheet is also useful for referring back during the course of the project to ensure that the original issue is still the one being addressed, in other words that the project scope has not inadvertently changed.

Kaizen Methodologies

Methods and tools used during a Kaizen event may include any of those encountered in the define, measure, analyse, improve and control (DMAIC) stages of a lean Six Sigma project. The event works best if data, such as demand, cycle time, voice of the customer information, waiting and process times are already available. Summary statistics, such as the mean cycle time are estimated. This makes sure that specific, measurable, achievable, realistic, and with a known time scale (SMART) objectives can be set. It may be possible to determine an optimal rhythm for the process in terms of available time per unit of demand (sometimes called the *takt time*). Particular emphasis is placed on understanding the process as it currently is. Often the process is walked through and the team make observations and talk to people involved in the process. The team members create a **process map** that shows the flow and any rework loops. They try to quantify the basic process steps in terms of activity times and waiting times. Value adding and nonvalue adding process stages are identified. The team then tries to come up with possible process changes and solutions; techniques such as brainstorming, theory of inventive problem solving (TRIZ), and six hats can be used to help. When solutions are identified, the results of implementing them can be investigated empirically or by simulation.

Outline of Kaizen Event

Clear examples of step-by-step procedures are given in [3] and [4]. In summary, the steps are:

- Select the project area and a small number of relevant team members.
- Develop a project worksheet.
- Assess the current situation in appropriate ways, such as looking at process data, stepping through the process, assessing the voice of the customer, identifying value adding and nonvalue adding process stages. Agree SMART objectives.
- Through brainstorming and other methods, identify factors that could be causing variation, inefficiencies, waste, or delay.
- Refine the factors to be investigated using the payoff matrix to find a subset to be addressed.
- Explore possible quick fix options to check their feasibility and check for any adverse effects. Refine the options using the payoff matrix to find a subset to be addressed.
- Trial implement of possible solutions by stepping through the alternative processes, maybe use simulation.
- Inform people affected by the changes and inform everyone involved about the changed work practice.
- Document, implement, evaluate change, celebrate, and agree follow-up procedures to ensure that the change is part of continuous improvement.

Example of a Kaizen Worksheet for a Health Care Kaizen Project [5]

Date: 27/02/06

Team: J. Richards, S. Smith, T. Jones, and D. Young

Project Location

Admission and testing facility.

Problem Statement

Patients presenting for admission are asked to wait before being called for admission. Once called, they are admitted and asked to wait in another waiting room.

Waiting time can be up to 2h resulting in poor patient satisfaction.

- Patients have no information on how long they will wait.
- Staff roles and responsibilities are not clearly defined resulting in poor patient case management.
- Patients and patient notes are moved around the facility from room to room.
- Reception and admission staff are frequently interrupted adding to wait times.

Current State Measurements and Demand Requirements

Average wait time in waiting room prior to first call = 52 min.

Average total lead time = 132 min.

Rough estimate of initial takt time for assessing process (one member of staff).

Takt time = Net available time to work/customer demand.

Shift length = 7.5 h; lunch break = 1 h; net avail time = $7.5 - 1 = 6.5$ h.

Current customer demand = 10 patients per day.

Takt time = $6.5/10 = 0.65$ h (39 min), one patient every 39 min.

Objectives

To reduce the average patient waiting time at first wait point to 20 min.

To reduce average lead time by 25%.

Process Owner

Strengths and Weaknesses of Kaizen

The strengths of the Kaizen method include:

- If quick wins exist they are likely to be achieved.
- Involves people, but only needs a small time commitment.

- Can be done with short notice.
- Relatively low cost.
- Flexible.
- Equally applicable in production and nonproduction.
- People oriented.
- Enjoyable and strengthens team.

The weaknesses of the method include:

- High expectations and potential for disappointment.
- If problem is not well chosen it fails.
- Limited time for training in methods.
- May not lead to workable solutions.

Summary

Kaizen is a positive way to address well-defined problems with clear boundaries. It increases the chances for a quick solution by bringing relevant people together with a mutual aim of spending ring-fenced time thinking about a problem. Practitioners find the method useful and interesting. It brings a team together and is good for addressing high priority issues especially those that lead to waste, delays, and inefficiency.

Work-Out

Introduction and Background

Jack Welch developed the GE Work-Out in the late 1980s as a unique approach to improvement in the workplace. He had recently developed the Crotonville leadership development center, and was delighted with the open atmosphere there, which allowed business leaders to share both their ideas and also their concerns about the issues facing GE. Although thrilled with the openness he saw in “the pit” – the main meeting auditorium at Crotonville – Welch remained frustrated that he did not sense a similar environment elsewhere in the business. In too many places he saw a bureaucracy filled with controlling leaders who pretended to have all the answers, and a stifled workforce afraid to open up and share their true feelings.

Realizing that he could not bring all GE employees to Crotonville, Welch decided to take Crotonville to all the employees. He created a process that mimicked what he experienced at Crotonville, and could be replicated in various locations around the world. Perhaps owing to his Massachusetts roots, Welch decided to model the process after a New England town meeting. There would typically be 40–60 people, facilitated by someone outside of GE (originally local college professors) to ensure that people felt free to speak openly. The fact that the managers of the participants were not invited to the Work-Out was critical! The facilitator would define the scope of the issue being addressed, and then get people to share their ideas and frustrations about it. Welch [1] notes that at some of these meetings people shared such passionate feelings that they began to swear at each other. However, they got past the bureaucracy to the core issues, which often involved unnecessary reports and meetings that got in the way of serving customers. Much of the focus was, and still is, on eliminating nonvalue-adding work.

The Work-Outs were a big success, and eventually involved hundreds of thousands of GE employees. Not only did they produce tangible results, but they also helped people feel empowered after some difficult years of downsizing in the company. They helped create an atmosphere where employees worked across global and organizational boundaries for the benefit of

GE as a whole, and where good ideas were respected regardless of the rank, gender, age, or ethnicity of the person submitting the idea. This atmosphere was later given a name by Welch – *boundarylessness*. Of course, GE Work-Out has morphed and evolved over the years. However, it has retained the key principles upon which it was founded, and is still used today at GE and many other companies.

The Essence of GE Work-Out

So, what are the essential elements of GE Work-Out that make it a unique approach to improvement? It was founded on the following core principles:

- an open environment where people are free to speak their mind, without fear of retribution by management;
- enlistment of the “frontline” workers – those most familiar with the issue at hand, rather than a “panel of experts”;
- use of impartial facilitators rather than management to conduct the meetings;
- short interactions (2–3 days) and immediate decisions by management for at least 75% of the team suggestions – no burying of the proposals by sending them to committees for “further study”;
- an emphasis on “busting bureaucracy”, that is, eliminating unnecessary meetings, reports, approvals, and so on.

One may immediately see some similarities between the principles of Work-Out and those of lean *kaizen* events (see **Lean Methods, Creating Flow with**), and perhaps also to those of quality circles. Through the years, GE Work-Out has evolved. Today, it may involve only a small team of 5–10 people, and may only last a day or even an afternoon, depending on the circumstances. As GE gained more experience with Work-Outs, it began using internal facilitators rather than relying on external resources. However, GE has maintained a focus on these original principles. For example, when an internal facilitator is used, this person will be impartial, and not have a clear stake in the solution selected.

The process for conducting a GE Work-Out is fairly simple, at least in principle. Typically a business leader initiates the Work-Out by stating the problem, defining the scope, and explaining any constraints on the solution (e.g., “we can’t spend

any more than \$20 000”). The business leader then departs, leaving a facilitator in charge of the process. The facilitator walks the group through a team problem solving process (see, for example, Hoerl and Snee [2]). This process provides plenty of time for the Work-Out team to discuss the problem in detail and brainstorm ideas for solutions, perhaps in subgroups. The facilitator collects the ideas and ensures that the entire team carefully considers and debates them. The best ideas may rise to the surface, or the facilitator may use some type of prioritization method to identify the most promising potential solutions.

Regardless of which method is used, the team needs to refine the ideas into a few specific suggestions for management. These cannot be vague concepts, such as “improve morale”, but must be tangible, specific suggestions, such as “reduce the approvals needed on this form to two: the shift supervisor and the plant manager”. Once the suggestions have been carefully defined, they are presented to management at the end of the Work-Out. Management reserves the right to decline suggestions. However, as noted previously, they are expected to give an immediate answer on at least 75% of the proposals. On those suggestions for which management needs more time, they must give a date by which they will make a final decision.

The Role of Work-Out within a Process Improvement System

Clearly, the Work-Out approach is not the best method to solve every problem that may occur within an organization. There will be complex technical problems that require more sophisticated, data-based approaches, such as Six Sigma (*see Six Sigma*). However, for certain types of problems Work-Out is an excellent approach, and will likely produce better results more quickly than other options. Based on experience, Work-Out is best suited to attack problems that have the following attributes:

- We believe that a relatively simple solution exists, one that will not require extensive **data collection** and analysis to find.
- We believe that knowledge of potential solutions already exists in the people working within the process.

- We believe that the wisdom of good solutions will be readily apparent to those working within the process, minimizing the need for a “test period” to evaluate the solution.

The rationale for the first two points should be clear, given the nature of a GE Work-Out. It is a process designed to get the best ideas and knowledge out of people, rather than to create new knowledge. The reason for the third point is that we want management to make immediate decisions about the proposals, rather than sending them off for further review or study. If a trial period is required to evaluate the proposal, this will slow down the implementation of ideas, defeating the purpose of Work-Out.

Some example problems for which Work-Out might be appropriate include the following:

- Why are seven levels of approval needed on some financial documents? Is there no way we could simplify the approval system, and still maintain good control?
- We seem to spend way too much time preparing reports, many of which are not used. How can we reduce the time spent on report preparation, and still provide people with the information that they need to do their jobs?
- There have been a number of defects related to human errors on one step of our assembly process. How can we revise the way we complete this assembly step to eliminate the errors?
- The metrics that we are using in our operation are driving the wrong behavior. How can we revise the metrics to be more aligned with the behavior we actually want to see?

An organization’s process improvement system should include informal, knowledge-based methods like Work-Out, as well as more sophisticated approaches involving the use of statistical methods to develop new understanding of processes, through such tools as designed experiments. No one improvement method will be best for every problem, so organizations need a diverse improvement “toolkit”. Once a problem has been identified, scoped, and critically evaluated, people can make the decision as to which improvement method is best suited to attack it.

Interestingly, GE has occasionally found that after the Define, Measure, and Analyze phases of Six

Sigma projects, solutions to the problem are readily obvious to the people who work in the process. Rather than a rigorous Improve phase of the project utilizing statistical techniques, some teams have found that they can hold a one-day Work-Out and implement an effective solution immediately. After putting controls in place to maintain the improvement (Control phase), the project becomes a DMAWC (define, measure, analyze, work-out, control) Six Sigma project, rather than the typical DMAIC (define, measure, analyze, improve, control), and is completed more quickly than anticipated. This is one example of integrating improvement methodologies to obtain synergistic benefits.

Summary

GE Work-Out is a proven improvement methodology that has produced significant results not only for GE, but also for many other companies. It is most

appropriate for problems having a solution that is already captured within the collective knowledge and experience of the people working in the process. As such, it is typically classified as a “knowledge-based” rather than a “data-based” improvement approach. In addition to tangible business benefits, GE Work-Out can also help create a “boundaryless” work environment where people feel free to express their ideas and opinions, and are anxious to work across organizational and hierarchical boundaries.

Statistical Quality Control

Introduction and History

Statistical quality control (SQC) may be broadly defined as “the use of statistical methods in the control and improvement of quality in industrial production” [1]. Historically, these methods have included **control charts**, tolerancing methods, sampling inspection, and a wide variety of other statistical methods, though those listed are most commonly regarded as being the core of SQC. Ishikawa [2] says that “Expressed simply, the relationship between statistical quality control, total quality control, and research and technology is as follows: Good quality control is impossible without proper technology. The motive power behind the search for causes is research, technology, and technical skill (i.e., experience and training). However, technology improves rapidly through the use of the S part of SQC (statistical methods), i.e., through carrying out the quality analysis and process analysis using the statistical tools of the QC approach. We must use proper technology, statistical techniques, and control techniques as tools to control quality and promote effective TQC.”

The work of Frederick W. Taylor in the early twentieth century in introducing the principles of what he termed *scientific management into mass production* may be properly regarded as a precursor to the field of SQC. Taylor pioneered the use of the scientific method in the study and improvement of manufacturing processes. Although his image has historically suffered due to the perception of his work as leading to division of work into small tasks and consequent suboptimization, he clearly pioneered the development of standardized production and assembly methods and the study of the quality of manufactured goods.

The field of SQC may be regarded as having been launched, however, on May 16, 1924, when Walter A. Shewhart of Bell Telephone Laboratories circulated a memorandum which included a modern control chart, the first one known to have existed. Shewhart continued to evolve the concept of control charts, developing new charts for a variety of applications, and in 1931 published his classic book *Economic Control of Quality of Manufactured Product* [3]. Other names involved in the early history of SQC at Bell

Telephone Laboratories include Harold F. Dodge, Harry G. Romig, Thornton C. Fry, E. C. Molina, and W. Edwards Deming.

By the end of the 1920s, Harold F. Dodge and Harry G. Romig of Bell Telephone Laboratories had developed a comprehensive system for statistically based **acceptance sampling**, which could serve as an economical alternative to 100% inspection, which was in common use at the time. By the end of the 1930s, the methods of SQC were being used broadly at Western Electric, though not in industry at large.

In 1938, W. Edwards Deming convinced Shewhart to give lectures at the graduate school of the US Department of Agriculture on the subject of SQC.

With the advent of World War II, the method of SQC found broad usage in assuring the quality of products. This usage was often demanded by the US Government as a condition of purchase. This was necessary as the quality of manufactured goods plummeted due to the unavailability of skilled personnel driven by the war effort. Training courses were established by many companies as well as the War Production Board and the armed services. These courses covered the use of SQC, with the topics of control charts and acceptance sampling being taught in depth. The result was that many companies were using the methods of SQC by 1945.

Sadly it appears that these methods fell into disuse shortly after the end of World War II. Companies were able to sell all they could produce, and volume production was the rule of the day. The use of statistical control charts and inspection (acceptance sampling) methods declined for a while in the United States, and this trend was not actually reversed until the 1980s when the competitive position of US manufacturers was clearly in decline as compared to Japanese manufacturers, particularly in the automotive and electronics industries.

In spite of the decline beginning in use of SQC methods in 1945 with the end of World War II, the American Society for Quality Control was founded to sustain the quality-improvement techniques that had been used during wartime. The organization continues to this day (with its name being changed to American Society for Quality) as an advocate of modern methods of SQC as well as a broader advocate for quality.

The Japanese experience with SQC in the 1950s provides an interesting and notable contrast. Ishikawa

[4, pp. 18–19] says that SQC was overemphasized in Japan in the 1950s, creating problems including (a) workers rebelling because they felt their experience and common sense were more important, (b) lack of standards to use, (c) lack of data, (d) sampling methods not followed, and (e) measurement devices destroyed by workers suspicious of the reason for installation of the devices. Ishikawa summarizes [4, pp. 18–19] “It is true that statistical methods are effective, but we overemphasized their importance. As a result, people either feared or disliked quality control as something very difficult. We overeducated people by giving them sophisticated methods where, at that stage, simple methods would have sufficed Top and middle-level managers did not show much interest Those who were members of the Quality Control Research Group tried to persuade top managers to join, but perhaps because of our relative youth our efforts were met with little visible success.”

In recent decades the set of methods falling under the category of SQC has expanded. Recent textbooks on the subject often include not only control charts, tolerancing methods, and acceptance sampling, but also designed experiments – full and fractional factorials as well as **response surface** methods.

Controversy in the Field of Statistical Process Control

There have often been disputes in the field about the appropriateness of the use of sampling inspection methods. Deming [5, 6] has cogently argued the viewpoint that sampling should be either 100 or 0% for an in-control process (other than for the purpose of verifying the ongoing state of control of the process).

By-products of Use of Methods of Statistical Process Control

Grant and Leavenworth [7] point out that practitioners have often noted that the use of the methods of statistical process control tends to result in a greater knowledge through engineering and other staff of the real problems of production. In addition, there is the greater reality in specified tolerances which can result from a true knowledge of actual process capabilities.

The use of statistical methods for process study has the additional benefit of taking arguments between production, engineering, and quality

departments and enabling these arguments to be transformed to discussions based on real facts provided by the use of SQC techniques. In fact, SQC can constitute a common language to be used in communication between the three groups as they work to arrive at a reasonable solution to their common difficulties.

Tools of Statistical Quality Control

No proposed list of the tools of SQC could be complete. However, the following list is a portion of those covered by Wadsworth *et al.* [8] and is suggestive of the most commonly used tools and the breadth of application of the methods.

Control Charts: *P* charts, *C* charts, *U* charts, individuals and moving range charts, *X*-bar and *R* charts, **exponentially weighted moving average** (EWMA) charts, cumulative sum (**CUSUM**) charts.

Graphical methods: checksheets, histograms, **Pareto** diagrams, Ishikawa (cause-and-effect or fish-bone) diagrams, scatterplots, flow charts, location plots.

Acceptance sampling: single and double **attribute sampling** methods, **sequential sampling** plans for attributes or variables.

Tolerancing methods. *Designed experiments:* **factorial** experiments, **fractional factorial** experiments, evolutionary operation, response surface methods, analysis of means.

Reliability: reliability modeling, accelerated life testing.

Broadening the Application of the Methods of Statistical Quality Control by W. Edwards Deming

W. Edwards Deming was responsible for a significant broadening in the scope of application of the methods of SQC. He examined the use and philosophy of the control chart as invented and advocated by Walter Shewhart, and commented [5] “Elimination or reduction of common causes can be effected **ONLY BY ACTION OF MANAGEMENT.**”

He expanded on this in [6, p. 310] to say

“Shewhart used the term **assignable cause** of variation where I use the term special cause. I prefer the adjective special for a cause that is specific to some group or workers, or to a particular production worker, or to a specific machine, or to a specific local condition.”

And in [6, p. 314]

“The term common causes for faults of the system, was used first, so far as I know, in a conversation held about 1947 with Dr. Harry Alpert (deceased) on the subject of riots in prisons.”

And Deming in [6, pp. 320–321]

“Removal of common causes of trouble and of variation, of errors, of mistakes, of low production, of low sales, of most accidents is the responsibility of management.”

This significant philosophical broadening of the applicability of the methods of SQC has led practitioners to use the control chart as an analytical tool for deciding whether the responsibility for improvement in a given context is local (workers) or global (managerial). This broadening was instrumental in forging a pathway for providing insights from statistical thinking in the practice of management, and particularly that of process management.

Critical-to-Quality Matrices

Introduction

In the 1970s a new technique to quantify customer needs began to be applied in the shipyards of Kobe, Japan. In the 1980s, this approach began to spread to other countries, finding a particularly strong reception among automobile manufacturers in the United States. This technique became known in English by its literal translation from Japanese, **quality function deployment**, or QFD. The cornerstone of this method was the use of a sequence of matrices to translate and prioritize attributes at finer and finer levels of detail. For example, companies typically began with vague, fuzzy needs that they heard from customers, such things as “I want my car to have that new car smell,” “A good writing pen shouldn’t feel flimsy,” or “I want clear reception on my cell phone.” Companies needed to translate these needs into tangible metrics, things that could be measured in design and manufacturing, so that they could be confident that they were actually providing the characteristics that customers desired. They would further need to translate these overall performance metrics into functional requirements – performance metrics on subassemblies, then to prioritization of process steps to identify the “make or break” steps in the process where the performance metrics would be determined, and possibly to translate these into further detail, identifying the specific process control measures that could be used at these critical steps. See Cohen [1] or Clausing [2] for further details on QFD.

As should be evident from the above discussion, completing a complete, rigorous QFD study typically takes weeks, if not months. If this information is needed, then the time and effort will be well worth it. However, in many applications, a full QFD study is not needed. Rather, only the translation from fuzzy customer needs to tangible metrics, with prioritization, is required. This is often the case with **Six Sigma** projects. Many organizations have utilized only the first matrix in such cases, which also goes by the name House of Quality. In Six Sigma, the key performance metrics that teams try to improve are called *critical to quality* or CTQ metrics. Therefore, in the late 1990s the term *CTQ matrix*

began to become more popular than the term *House of Quality*. Whether used as part of a QFD study, within a Six Sigma project, or simply to clarify how to satisfy customer needs, the fundamental purpose is the same – to translate fuzzy, intangible customer needs into a set of tangible metrics, and to prioritize these metrics so that teams know on what to focus to ensure they are satisfying the customer.

The Elements of a Critical-to-Quality Matrix

Figure 1 shows one example of a CTQ matrix. This matrix is translating the needs of small business loan customers for a local bank, L&M Savings and Loan. Figure 2 shows a generic house, with each “room” labeled for reference. Room 1 lists the needs of the customer. These come from marketing research, focus groups, customer interviews, and so on. Note in Figure 1 that these needs are intangible, and stated in words that customers would use, such as “easy access to capital”. Toward the right of the graph, there is a column with relative priority ratings of these needs on a 1–5 scale, with 5 being the most important. These priorities should come directly from customers, through surveys, for example, rather than from the subjective opinions of people within the company.

In Room 2, L&M is comparing itself against key competitors, in terms of how well the customers’ needs are being satisfied. The key competitors in this case are First Union and County Bank. Note that these data are customer perceptions, obtained through customer surveys, or a similar customer-oriented method. This room does not list actual performance data on tangible metrics, which will come later. As we can see, L&M’s current offerings (the basis of the comparison) are better than competition in some cases, and worse in others. This room helps planners determine where they most need to improve with new products or services.

In Room 3 at the top of the graph, L&M has listed potential tangible metrics, that is, things they could actually measure, that might relate closely to customers’ perceptions of the needs listed in Room 1. For example, the ratio of the actual amount of the loan approved (how much was granted by the bank) to the amount requested – listed in the first column, is certainly measurable, and might relate to a customer’s perception of easy access to capital.

Figure 2 The rooms of the critical-to-quality matrix

needs in Room 1. This work is done in Room 4. Teams do this using the knowledge and experience that they have, which is why CTQ matrices are considered a knowledge-based tool. Of course, external data will typically be needed to identify and prioritize customer needs. Clearly, teams need to have the most knowledgeable people about these needs and metrics in the room when these decisions are made. Traditionally, teams assign one of four possible relationships to each what/how pair: strong, moderate, weak, or none/negligible not differentiating between a positive or negative correlation. As shown in Figure 1, these are often represented with symbols, which make it easier to see patterns in the graph. Note that each symbol also represents a numerical value, 9, 3, 1, or 0. These are traditionally on a nonlinear scale, as they are here, in order to highlight strong relationships. Here, the team believes that the ratio of approved to requested loan amount has a strong relationship to a customer's perception of easy access to capital.

Once the team has developed tangible metrics in Room 3, they have the ability to obtain actual performance data on competition and their own company's service, as shown in Room 5. In the case of physical products, such as an automobile, teams

can obtain data by physical tests of key metrics, such as horse power. For services, they need to obtain industry data, or data from third-party providers. In contrast to Room 2, these data represents hard metrics, not customer perceptions. Using these data, plus the relationship map in Room 4, the team can see which metrics they need to work on in order to impact customer perceptions. In fact, they can make this more formal by multiplying the need priority rating with the numerical relationship value, in order to obtain a relative importance for each metric. These values are shown at the top of Room 6 in Figure 1, and labeled CTQ priority. For example, the 56 associated with requested loan amount applied is obtained by multiplying 4.8 by 9 (strong relationship with easy access to capital), which equals 43.2, and adding $3 \times 4.3 = 12.9$ (moderate relationship with variety of terms/conditions), and rounding off to the nearest integer.

Using the above information, teams will often design the targets and possibly the specifications that they think they would need for the CTQs in order to achieve the customer perceptions they desire – in terms of needs being met – according to their intended brand positioning. That is, designers often manipulate Room 6, which they

4 Critical-to-Quality Matrices

have some degree of control over, in order to impact Room 2, for which they have no direct control. Obviously, modifying these targets in Room 6 will have cost implications that will need to be addressed.

When the team considers modifying targets in Room 6, it is often helpful to consider the potential interrelationships between these metrics. For example, if the team decides to increase the ratio of approved to requested loan amounts, that is, to give people more money, they might need to charge a higher interest rate to cover this additional risk. This would negatively impact the interest rate metric. In order to keep track of these interrelationships between the metrics, teams may choose to define and document these in Room 7 at the top. There are many scales that can be used for documenting these relationships. In this case, a plus symbol represents a positive relationship (if one metric is increased, the other is likely to also increase), a minus sign indicates a negative relationship, and no symbol indicates negligible interrelationship between the metrics. Due to the nature of this example, there are minimal interrelationships among the metrics.

Potential Benefits, Pitfalls, and Keys to Success for Critical-to-Quality Matrices

As seen in Figure 1, there is a tremendous amount of information that can be captured and easily communicated in a CTQ matrix. It lists customer needs and their relative importance, including how well the business is doing versus competition in terms of meeting these needs. It lists tangible metrics (CTQs), how these relate to the needs, their relative importance, and how well the business is doing versus competition on them. It may also include a depiction of how these metrics relate to one another. All of this information allows development of targets and possibly specifications that would be required to achieve a brand strategy. This is quite a lot of information on one graph!

Potential benefits of utilizing CTQ matrices include:

- As noted, the matrices capture a tremendous amount of information in one relatively simple graph.
- Cross-functional teams develop the matrices, enhancing organizational cohesiveness.

- Internal decisions are directly based on customer needs, and this fact can be easily communicated to others in the organization.
- Assuming that the needed information is available, the matrices can be completed fairly quickly, with minimal training of the team.

While there are several unique benefits of CTQ matrices, as with all improvement methods there are also limitations, or potential pitfalls. It is particularly important to understand such pitfalls when using knowledge-based methods, since the team may not have objective data to verify the results. Potential pitfalls of CTQ matrices include:

- Without proper information available, the team may end up guessing as to the real needs of the customer. The results of the process will never be better than the collective knowledge on the team.
- It is possible to arrive at the most popular answers, rather than the most accurate answers. This is referred to as *breathing your own exhaust*.
- The focus can divert toward filling in matrices, rather than understanding customers' needs and making important business decisions.

Given these benefits and pitfalls, we can derive keys to success that will help ensure good results. Keys to success when developing CTQ matrices include:

- Make sure that the team's opinions are based on objective data, especially as it relates to documenting customer needs.
- Fulfill the spirit of this method by having cross-functional teams work together. Have the right people in the room when their expertise is needed – avoid guessing.
- Have a strong, impartial facilitator lead the team through this process, someone who will ensure open participation, and prevent anyone from “taking over” the process.
- Verify the results *via* a “reality check” with key stakeholders. Ask if the results make intuitive sense.
- Remember that the process should work for the team, rather than the team working for the process. The focus must stay on satisfying customer needs, not on filling in matrices.

Summary

CTQ matrices are a proven method of developing products and services that will satisfy and delight customers. They can help translate fuzzy, intangible needs into metrics that organizations can measure and track. These matrices can also be used to prioritize customer needs and tangible metrics, helping organizations focus on the critical few variables. The process of having cross-functional teams complete the matrices helps organizational teamwork and communication. Properly completed, the matrix provides a tremendous amount of information on customer needs and their priority, key metrics on which the organization must focus to satisfy these needs, benchmarking of how well they are doing versus competition on both intangible needs and hard metrics,

and the targets and specifications needed to achieve the brand strategy. As with any knowledge-based method, teams must ensure that they have the right information on which to base their decisions, and that they verify their results.

ROGER W. HOERL

Concept Selection Matrices

Introduction

Concept selection refers to a step in a project during which several alternative approaches, design alternatives, architectures, or solutions – referred to as *concepts* – are evaluated and one of the concepts is selected for the project. The inputs to concept selection are the set of alternatives and a set of selection criteria, and the output is the selected concept – which may be one of the alternatives considered, or might be a new alternative generated during the concept selection process.

If there is only a single criterion for evaluation, then the concept selection process may involve optimization to that criterion. For example, if the decision will be based totally on a financial metric such as projected cost or profit, then the concept selection process could be based on **Monte Carlo** simulations of the financial results that would be forecast to result from each decision.

If there are both multiple alternatives and multiple selection criteria for a decision, a concept selection matrix approach may be appropriate. The goals of the selection process involve both tangible and intangible benefits. Not only should the selection process provide a superior product that will facilitate the development of a superior product, but it should also lend itself to “buy-in” from the team to go forward with the selected concept with confidence that a reasonable decision was made.

“Experience gained over many projects has led to the conclusion that matrices, in general, are probably the best way of structuring or representing an evaluation procedure the type of matrix referred to here is not a mathematical matrix; it is simply a format for expressing ideas and the criteria for evaluation of these ideas in a visible, user-friendly fashion” [1]. Let us illustrate with a simple example.

Example

Suppose that a family wants to consider doing something special together as a family. They come up with a set of selection criteria:

- It should be cost effective.
- It should have minimal impact on the children’s schoolwork.
- It should have minimal impact on mom and dad’s careers.
- Every member of the family should be able to get involved.
- It should include having the family members communicating with each other.

Each family member contributes one concept for doing something special together:

- Dad suggests a special “golf weekend”.
- Mom suggests preparing a pancake breakfast together (“breakfast of champions”).
- Susan, the elder daughter, suggests a “vacation in Rio de Janeiro”.
- Billy, the son, suggests having a “movie weekend”.
- Lisa, the younger daughter, suggests eating dinner out at a nice restaurant.

The family then chooses their current “family time” approach – watching television in the evening – as the benchmark, which Stuart Pugh referred to as the *datum*. Each of the concepts is compared against the datum, watching television, for each of the criteria.

As shown in Figure 1, the family would evaluate whether “vacation in Rio” is more cost effective (+), the same as (S), or less cost effective (–) than the benchmark, TV time, and would likely give it a (–). For the last criteria, all of the concepts except “movie weekend” would involve more communication than TV time; since the family talks a little during a TV show but are “shushed” if they talk during a movie, they give it a (–).

After filling out the matrix with +, –, and S symbols, the number of instances of each symbol is summed for each concept to provide a summary of how well each concept meets the selection criteria. In Figure 1, the first three concepts each have two pluses, but only “breakfast of champions” has no minuses.

Pugh Concept Selection Approach

The Pugh concept selection approach generally is applied in more technical situations, such as considering alternative designs for a product, or subsystem,

2 Concept Selection Matrices

	Datum/ TV time	Vacation in Rio	Breakfast of champions	Eat dinner out	Golf weekend	Movie weekend
Criteria						
Cost-effective		+ S —	+ S —	+ S —	+ S —	+ S —
Minimal career impact		+ S —	+ S —	+ S —	+ S —	+ S —
Minimal school education impact		+ S —	+ S —	+ S —	+ S —	+ S —
Every member of family can get involved		+ S —	+ S —	+ S —	+ S —	+ S —
Family time includes communication		+ S —	+ S —	+ S —	+ S —	+ S —
Sum of pluses		2	2	2	1	0
Sum of minuses		3	0	2	2	2
Sum of sames		0	3	1	2	3

Figure 1 Pugh concept selection matrix for family time example

or component of a product. It uses the method of controlled convergence, which can involve several iterations of the matrix.

Before the first iteration of controlled convergence, each of the alternative concepts should be developed to the same level of detail: if one concept involves a detailed sketch and a financial forecast, then all of the concepts should be developed to have a similarly detailed sketch and financial forecast so that the level of detail does not bias the evaluation process.

After the first iteration, the team can review the negatives of the strong concepts and propose ways to improve these negatives, generating more concepts. The team can also consider hybrids, where the negatives of a stronger approach coincide with positives of other approaches, suggesting a way to improve the stronger approach. It can also review some of the more promising of the weak concepts and propose ways to improve their negatives, generating more concepts.

The weakest concepts are then eliminated, reducing the matrix size. The best concept can now be used as the datum or benchmark, and the matrix rerun to see if the best concept continues to excel, converging on a superior concept to pursue. A second, more technical example of a Pugh matrix is shown in Figure 2,

for selection of technology for security by verifying a person's identity.

A major intangible benefit of the Pugh concept selection approach is that it is perceived by the team to be unbiased, so that the team can achieve consensus with the feeling that the best concept won.

It is also simple enough that the team does not require extensive training to use the approach, although it would be helpful if the facilitator has some training in terms of skills and understanding of the process.

Weighted Matrices

A question that often comes up with respect to concept selection matrices is whether the selection criteria should be weighted, so that a favorable result for a very important criterion carries more weight than a favorable result for a less important criterion (Figure 3). Stuart Pugh stated that weightings "... imply an attempt to impart to the procedure too much precision, and thus inhibit qualitative judgments" [1]. Furthermore, the determination of the relative weightings can involve considerable time for debates among the team, and can involve attempts to bias the weightings to favor a concept.

Figure 2 Pugh concept selection matrix for selecting a technology for security, verification of a person's identity. The datum is the current approach of entering a password or pass code

Criteria	Weight	Datum	Alternative 1	Alternative 2	Alternative 3	Alternative 4	Alternative 5
	1 ▲		+ ▲	+ ▲	+ ▲	+ ▲	+ ▲
	2 ▲		s ▲	s ▲	s ▲	s ▲	s ▲
	3 ▲		– ▲	– ▲	– ▲	– ▲	– ▲
	4 ▼		– ▼	– ▼	– ▼	– ▼	– ▼
	1 ▲		+ ▲	+ ▲	+ ▲	+ ▲	+ ▲
	2 ▲		s ▲	s ▲	s ▲	s ▲	s ▲
	3 ▲		– ▲	– ▲	– ▲	– ▲	– ▲
	4 ▼		– ▼	– ▼	– ▼	– ▼	– ▼
	1 ▲		+ ▲	+ ▲	+ ▲	+ ▲	+ ▲
	2 ▲		s ▲	s ▲	s ▲	s ▲	s ▲
	3 ▲		– ▲	– ▲	– ▲	– ▲	– ▲
	4 ▼		– ▼	– ▼	– ▼	– ▼	– ▼
Weighted sum of pluses			0	0	0	0	0
Weighted sum of minuses			0	0	0	0	0
Weighted sum of sames			0	0	0	0	0

Figure 3 Weighted version of concept selection matrix, with weighting for relative importance of each criterion

4 Concept Selection Matrices

Rather than weighting, Stuart Pugh suggested that “what has been found useful is the grading of criteria into three categories – important, moderately important, and desirable, or (high, medium, low).”

ERIC CHARLES MAASS

Process Maps, Construction of

What is Process Mapping

A process is a series of steps that converts an input(s) to an output(s). This series of steps is usually done repeatedly. As the familiar proverb says “A picture is worth a thousand words”, so a good way to explain these steps is pictorially. Therefore, process mapping is a key component in any quality effort to control, improve, document, and streamline a process. Process mapping can take on many forms but the commonality is that the specific steps or events that are required to provide a service or product to a customer are listed. The customer could be an external paying customer or an internal customer.

Process mapping can be called by several names as well as have several appearances. A generic process map may be called a *process flowchart*, *flowchart diagram*, or a *business map*. Specific maps can take on special names like SIPOC (suppliers–inputs–process–outputs–customer), functional deployment map (FDM), or opportunity map.

Reasons for Creating a Process Map

There are many reasons to create a process map. Four major reasons are to document the current state, to find opportunities for improvement in the current process, to document a change in the process, or to create a new process.

Many quality systems, such as ISO 9000, require documentation of key processes in the organization. Many companies also have their own internal requirements for process documentation. This documentation can be helpful to training employees or to get a common understanding.

One of the most common uses for maps is to identify changes to the process that would increase efficiencies, reduce cycle times, reduce costs, or decrease defects. Improvement teams often find steps that are redundant, unnecessary, and do not add value to the product or service. In the **Six Sigma** methodology define–measure–analyze–improve–control (DMAIC), mapping is used in the define phase to look for quick wins. Quick wins are improvement

ideas that can be implemented easily and quickly. In the measure phase, maps are used to identify points in the process to collect data to look for more complicated or less obvious improvements. In the improve phase, they are used to demonstrate the proposed new, improved process.

Process mapping has also been used as part of the groundwork before beginning to develop software programs to support the process. Software developers have long used mapping as a tool to help define the requirements for code. In addition, mapping is a precursor to the use of process simulation. Process simulation is the technique of creating a computer model of the process.

Process Map Formats

Process maps may take on many different looks. Some of the common ones are SIPOC, detailed process map, an FDM, and an opportunity map. Each map has its own purpose and therefore an appropriate time to use it.

SIPOC Map

A process map that has gained popularity with the increase of Six Sigma training is the SIPOC map. SIPOC is an acronym for suppliers–inputs–process–outputs–customers. The SIPOC is a very high-level map that does not use traditional mapping symbols. The first column of the SIPOC lists the key suppliers to the process. These may be internal or external suppliers. The second column lists the key inputs to the process. The inputs are usually those components that are transformed during the process to create the output. The third column is the process column where the major process steps are cataloged. Since this is a top-level map, there usually are only a few major steps listed. The fourth column is where the outputs of the process are listed. The last column would list the main customers or customer types of the outputs. Again, the customer could be an external or an internal customer.

Although the SIPOC is listed and displayed in this order, this does not imply that the SIPOC would be created in this order. Since there has been an increase in the focus on the process from the customers and their requirements, it makes sense to start mapping the process from the customer’s perspective. So, the

2 Process Maps, Construction of

mapping may start with a focus on who the customers are and what are the outputs of interest. To place this emphasis on the customer, there is a similar process map called *COPIS*. This is the SIPOC listed in the opposite way.

The SIPOC is good as a starting point for the team before adding additional detail. It is also good as a display to upper management to get a general sense of the process. It can help define who should be on the team for the more detailed mapping to follow.

An example of a SIPOC of purchasing a plane ticket is shown in Table 1. In this example, the customer could be either the traveler or a travel agent. The traveler is also a supplier in that she/he must supply information about travel requirements. The airlines also are supplier since they provide schedule information. Usually, the outputs and inputs listed are the few key ones. In this case, the key output would be the purchased ticket. The major steps of the process, listed without worrying about decisions or feedback loops, are as follows: entering information in computer system, review of flight schedules, flight selection, entering credit information, and then purchasing the ticket.

Simple Detailed Process Map

A simple detailed process map is usually done to a deeper level than a SIPOC. The detailed process map utilizes symbols to explain what happens in the process. The detailed process map is usually displayed to show the easiest flow going right to left. Many different symbols are used but there are some basic symbols that are traditionally used. The first symbol is the rectangle. The rectangle is used to indicate an activity or operation. The diamond is used to illustrate a decision point. Arrows indicate the flow of process. Ovals indicate the start and stop of the process. Circles are connectors between pages. Table 2 shows these symbols, the use of the symbols, and a simple example of what the symbols might represent.

The detailed process map is useful for finding areas for improvement, understanding redundancies in the process, to find waste, and to identify areas for collecting data to monitor the process.

An example of a simple detailed map of a customer service representative answering a customer's question is illustrated in Figure 1.

Table 1 SIPOC of purchasing a plane ticket

Suppliers	Inputs	Process	Outputs	Customers
Traveler Airlines	Traveler requirements Flight schedules	Enter information Review flight schedules Select flight Take credit information Purchase ticket	Ticket issued	Traveler Travel agent

Table 2 Traditionally used symbols for detailed process mapping including usage and a simple example

Symbol	Usage	Example
	Activity or operation	Assemble parts
	Decision	Request fulfilled?
	Flow	Go to next step
	Start or stop of process to be mapped	Receive customer request
	Connector to another page	Go to page 2

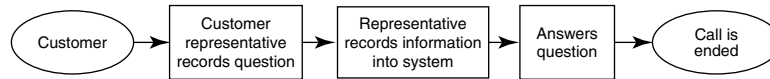

Figure 1 Detailed process map for the process of a customer service representative answering a customer's question

Besides indicating activities, decisions, and process flow, detailed process maps may include a myriad of other information. A partial list of this additional information is as follows:

- the number of people required for each step
- the machinery required at each step
- the tooling required at each step
- special inputs required
- information required
- the time to conduct the step
- the cost of performing the step
- the defects associated with specific points in the process
- delays
- queues
- setup times required at each step.

Beyond this list, there are two other types of information that can be added to a map that will make two specialized maps: a functional deployment map, also called a *swimming lanes map*, and an *opportunity map*.

Functional Deployment Map

An FDM takes a traditional detailed process map and adds an extra dimension by listing the functions that actually perform the process step. In an FDM, you would establish columns for each function, department, or person involved in the process. Then each activity or decision is placed in the associated column of the function that performs that step. The purpose of the map would be to identify the key communication or transfer points. These points are often where queues or defects occur. These maps are most useful in environments where the process involves many groups.

A very simple FDM for the process of a customer representative handling a customer call is shown in Figure 2. Three different groups are involved in this process: the customer, the customer service representative, and the engineer who handles the more difficult calls.

Opportunity Map

An opportunity map is a simple detailed process map with two additional columns. The two columns indicate whether a step in the process is either value added or non-value added. The purpose of the opportunity map is to identify opportunities to eliminate or reduce waste in the process. A value-added step is considered to be a step that is inherent to converting the inputs into the product or service. Non-value-added steps are associated with waste and can include, but are not limited to inspection, audits, queues, transportation of product, checking work, and so on. These activities just increase costs and should be primary targets of improvement.

An opportunity map for a very simple assembly process is shown in Figure 3. In this process, any assembly operation would be considered value added. These steps are turning the product into what the customer expects. The inspection and transportation steps are considered non-value added, or wasteful.

Creating the Process Map

Most process mapping sessions involve the participation of a team of people. Often, if the mapping session is designed to capture the current state of the process, the team finds differing views about what the real steps are. This is often a significant output from process mapping, getting the team to see the process from all points of view.

When doing mapping, there are some basic steps that the team should follow. These steps are as follows:

1. Establish the process to be mapped. Give the process a name.
2. Determine the objective of the mapping exercise – how will the map be used. This will influence your choice of the map that you create.
3. Invite the correct people to participate. Often it is helpful to include people who do not know

Figure 2 Functional deployment map for the process of a customer service representative handling a customer's call

- the process. These people may ask questions that people close to the process may not think to ask.
4. Define the boundaries to be mapped. These can change as the team finds that issues of concern may be influenced by upstream or downstream activities. The people involved in the mapping exercise may change as the boundaries are altered.
 5. Observe the process as it is operating. Make sure the team captures the information while observing.

6. Agree on the major steps and the order that they occur.
7. Add detail to the major steps as necessary.
8. Document in the appropriate format.
9. Validate the map with other people in the process.

If process mapping was part of a continuous improvement effort, after this “as-is” map is established, the team would start to question the status quo. Each step in the process should be reviewed to look for opportunities to eliminate unnecessary

Figure 3 Opportunity map for an assembly process

or redundant steps, combine steps to improve efficiencies, or rearrange steps to facilitate a cleaner, simpler flow. The team would then create the “to-be” process map based on the changes agreed upon.

Best Practices in Process Mapping

There are some key practices that will facilitate the mapping process: involving the right people, making the map understandable, and being clear in the purpose of the map.

If a map is created by one person, the perspective may not really reflect reality. Often, there is someone who originally defined the process. Their perspective may be the wished-for state. However, the people in the process may have intentionally or unintentionally changed the defined steps. One reason may be that the process users have a misunderstanding of what the process should look like. They might not have received proper training or the

steps were not properly communicated. Another reason might be that the process users discovered a better or easier way for the process to work. The original steps may not have covered all possible contingencies.

The process may also have been a change from previous steps and the process users did not see the benefit of the change, so they reverted back to the original steps.

For all these reasons, it is important to include the process users in the creation of the process map, to capture the true state of the process. Other people who might be included in the formation of the map are the suppliers, customers, and process owners.

Since there are many different kinds of process maps, and different levels of detail, it is imperative that the creator(s) specify up front what the purpose of the map is, so that the proper format is used. Often, it makes sense to start at a very top level and add complexity as required. Knowing the purpose will also help clarify the types of information to be added.

Difficulties in Process Mapping

One of the most difficult aspects of mapping is the level of detail required. Too much detail can waste time and will not be productive. Too little detail can prevent a deep enough understanding of the process to see how to improve or to provide complete training. It is important to move from less detail to more detail. If the team tries to jump into too much detail in the beginning, they can get very bogged down in things that may be of little consequence. More detail can be added as deemed necessary.

Another difficulty of process mapping can be that the team members are in different locations. Most mapping sessions are done on a wall with a group of people using sticky notes. However, in today’s global environment, it is becoming more frequent for the mapping session to take place in an electronic environment. Electronic conference tools can help facilitate the mapping session but it can still add a level of difficulty.

To capture all the information about a process on a document can create an overly complicated document. Since one of the primary functions of process maps is as a communication tool, too much text

6 Process Maps, Construction of

can be daunting. It is important that this additional information be displayed in as easy-to-read format as possible.

Summary

Process maps are a key part of any quality program for any kind of organization. People tend to

understand pictures better than words and understanding the process is the best way to maintain and improve it. Although a process map might take on several looks or formats, the primary goal should be to keep it simple enough to be appealing to read and understandable to all people involved in the process.

LORRAINE DANIELS

Project Management, Stage-Gate Approach to

Introduction

The project process is a predetermined set of repeatable steps, or stages, that are used in sequence to plan and implement a variety of project types. The term *stage-gate* has been around for quite sometime and is defined for this article on project process as the criterion or question which must be appropriately addressed prior to proceeding to the next stage in the project.^a

There is an old saying in the project management world – “Don’t work any harder than your project sponsor – or you and your team will surely be frustrated.” Keeping the project sponsor fully engaged and working on the right things at the right times before, during, and after completion of the project is one of the key elements necessary for a project’s success. As a project manager, you might think they should already know this and it is really not your job to manage the sponsor and the project too. However, many project sponsors are not fully aware of the scope and importance of their role supporting the projects they sponsor and may not even be aware of the appropriate sequence of events necessary to perform the project successfully. As the project manager you may need to become an educator and coach the sponsor on how to effectively perform this key role. After all, why risk your project’s success if you can influence the outcome by managing the project sponsor along with the rest of the project?

Every project an organization implements, must be evaluated as an investment of resources to produce a benefit or add value to the organization. Accordingly, a good project manager knows the value of killing a project early to ensure that not a moment of effort is wasted on a project that has no merit. Most organizations are faced with more work than they have the time and resources to complete, so with limited resources even a day spent on a project that will ultimately be canceled, is a day that could have been spent more productively on another project delivering value for the investment being made. As a project manager you also may be thinking, but I do not want to be known as the *project killer* in

my organization, what is in it for me? Would it not be better to be leading projects that are hugely successful and adding great value to the organization? This is not necessarily possible if you are working on projects that ultimately will not be implemented, and if they are, do not deliver value to the organization at least several times the investment made in the project.

This article provides an overview of the disciplined approach to project process that engages the right resources at the right time, only when predetermined criteria are met at planned points along the project’s timeline. It also ties in the role a project sponsor plays, at each phase in the project process, so the project can proceed in the most efficient and expeditious manner. The project process model applies to a wide variety of projects from Six Sigma and lean projects to laboratory, manufacturing, building construction, and IT projects. Asking the hard questions and responding with honest answers will set the project up for success – or, in some cases, take it off the project list as quickly as possible.

Project Process Model Summary

The project process model is an end-to-end process comprised of four main phases and nine stages within these phases. The key premise is that all projects will be appropriately vetted and prioritized against other opportunities the organization has to invest its resources, and realize the intended benefits. To do this requires that all those involved in the project prioritization and selection effort follow the same disciplined approach for all projects.

The use of a documented process signals to everyone involved, the importance of the process. Any deviation from the process can be flagged and its potential impact on the project’s success understood. Table 1 shows the stages in each phase of the project process.

Each project moves forward in a sequence and prior to proceeding to the next stage in the project, a stage-gate criterion or question must be appropriately addressed. Each phase is described further below with an outline of the roles of key players in the project process.

Roles and Responsibilities

Individuals have specific roles and responsibilities assigned during a project because of their position

2 Project Management, Stage-Gate Approach to

Table 1 Project process phases

Planning phase	Solution design phase	Implementation phase	Operational startup phase
<i>Stage 1</i> Inception <i>Stage 2</i> Feasibility	<i>Stage 3</i> Concept design <i>Stage 4</i> Scheme design <i>Stage 5</i> Detailed design	<i>Stage 6</i> Performance <i>Stage 7</i> Commissioning and Handover	<i>Stage 8</i> Process integration <i>Stage 9</i> Closeout and Benefits Realization

and level of influence within the organization or on a specific project. At a minimum, there are four key roles that need to be established for each project: project sponsor, project manager (or project director), project team, and stakeholders.

Project Sponsor

The project sponsor is accountable for the realization of the project's business benefits and has macrolevel scope control. The project sponsor also ensures the project is appropriately resourced to achieve the intended results and undertakes regular project reviews and makes necessary adjustments. The project sponsor may also hold the executive role as well. Staying connected to the executive or top governing level in the organization is necessary to ensure that the project has the appropriate level of visibility and support in the organization to be successful. If the project sponsor does not hold the executive role, he will need to periodically inform the executive of the progress the project is making against the intended objectives.

Project Manager (or Project Director)

The project manager (or project director) is responsible for leading the planning and execution of a project in a manner consistent with the needs of the organization and the directives of the project sponsor. He is also responsible for providing feedback on the project process in support of continuous quality improvement.

Project Team

The project team is responsible for planning and executing the project in a manner consistent with the needs of the organization, the directives of the project manager, and the approved project plan. They are also responsible for looking for ways of improving the

project process and providing feedback in support of continuous quality improvement.

Stakeholders

Stakeholders are individuals and groups who have a stake in the outcome of the project and whose interests must be recognized for the project to be successful. Customers are also considered stakeholders and are members of the project team.

Project Process Phases

Planning Phase

The time spent on planning a project returns many dividends over the life of the project. The planning phase has two stages, Stage 1 – Inception and Stage 2 – Feasibility.

Stage 1 – Inception. The inception stage initiates the project. The project sponsor, working with the senior leadership, determines what is needed by the organization to meet its strategic business objectives and assigns the appropriate resources to begin the inception stage. The project manager should be assigned to work directly with the project sponsor to gather data and begin the analysis to determine the nature of the project opportunity. The initial focus is on asking the right questions to understand why the project is needed and how the project fulfills these needs. At this stage, the unmet business needs will be identified by the customer and strategic alternatives that meet the business needs, generated. This will be summarized as business objectives.

Activities in this stage include determining the nature of the project or business opportunity; identifying strategic alternatives; evaluating potential risks and benefits; estimating costs to a Class I level $\pm 50\%$; and obtaining preliminary funding. The key

deliverable in this stage is a statement of business objectives, which answers the stage-gate question “Is the project needed?”

Stage 2 – Feasibility. In the feasibility stage, the anticipated business benefits gained by executing the project will be identified and quantified where possible. Further, the project description will be written to include how it directly supports the business strategy. The feasibility stage tests the fundamental economic soundness, and business and technical viability of the project. Based on the business needs and anticipated benefits of the project, detailed project objectives will be written.

At this point a clearly defined and agreed scope of work needs to be written, based on the project objectives approved by the project sponsor. Scope definition ensures there are clear boundaries and definitions of processes, facilities, and systems to be delivered. Scope definition is a key component for developing risk analysis, funding requests, and deciding on project controls strategy. Scope will define quality, quantity, and functionality of the end result of the project. Scope will also define work specifically excluded from the project where overlapping activities may occur.

The activities of this stage include defining the project’s objective and purpose; defining the general scope of work; addressing the project’s impact in relation to facilities, processes, software, and systems; and estimating capital and operational costs to a Class II level $\pm 20\text{--}25\%$. The conclusion of this stage answers the stage-gate question “Is there a business benefit?” prior to proceeding to the next stage.

Solution Design Phase

The solution design phase initiates project design activities based on the upfront planning efforts. In this phase the project team usually expands to include the designer and any subject matter experts necessary to complete the design in a manner consistent with the business and project objectives, and scope of work. Additional project team members may come from both internal and external sources.

During this phase the risk of the scope expanding beyond the original intent is the greatest, and the project sponsor’s role is to ensure the design work proceeds according to the agreed scope of work. Any changes to the scope of work places the project at risk. The project sponsor’s role during this phase

also includes reviewing the complement of project team members and making adjustments as needed, supporting the project in clearing funding hurdles, and keeping the executive leadership updated on the project’s progress and informed of any potential risks to the project success.

Stage 3 – Concept Design. The basis of design is written at the beginning of this stage. Sometimes called the *design program*, it is the detailed listing of specifications and design requirements written prior to beginning the solution design. Preliminary design options and the associated costs of each option are then generated and reviewed to determine which designs to pursue further. The project team will seek input from key stakeholders during the review and selection of design options. At the conclusion of this stage a single design option will be selected as the basis of the scheme design stage.

The activities of this stage include developing preferred designs with associated costs; selecting a single option as the basis of the scheme design stage; preparing the project execution plan; and estimating costs to the Class III level $\pm 15\text{--}20\%$. The conclusion of this stage answers the stage-gate question “Is this the right design option?” prior to proceeding to the next stage.

Stage 4 – Scheme Design. During the scheme design stage the designer continues design of the selected option and produces design documentation to 20–35% complete. The project team will involve and seek input from key stakeholders at key points as the scheme design efforts and costs progress. The designer provides other information needed to support a full funding request with cost estimates taken to a Class IV level $\pm 10\%$. The conclusion of this stage answers the stage-gate question “Should the organization commit full funding to the project?”

Stage 5 – Detailed Design. During the detailed design stage, design documents including flow diagrams, calculations, drawings, specifications, and other information are completed and bidding or pricing packages are produced for the procurement of equipment and services needed during the implementation phase. The project team will continue to involve stakeholders as the detailed design efforts are accomplished. Cost estimates are reviewed at the Class IV level $\pm 10\%$. The conclusion of this stage

4 Project Management, Stage-Gate Approach to

answers several stage-gate questions “Are these the right services providers, contractors and suppliers? Are these the right bidding or pricing packages?”

Implementation Phase

During this phase changes to processes, systems, software, and facilities are initiated and completed, and the resulting product is transferred to the operating group. In many cases, this is the most complex and time-consuming portion of the project, requiring constant communication among the project team members, the stakeholders directly affected by all the changes, and those performing the work activities.

Stage 6 – Performance. The performance stage is where changes to the processes, facilities, equipment, software, and systems are underway and completed. The progress and quality of the work during this stage will be tracked according to the design documents, time schedules, and approved costs. Any variances will be tracked and a strategy developed to return to the planned activities.

Activities concluding this stage are focused around review and acceptance of completed and substantially completed processes, facilities, software, equipment, and systems by the customer. The conclusion to this stage answers the stage-gate question: “Is the designed change complete?”

Stage 7 – Commissioning and Handover. Commissioning is the testing of the change (facilities, equipment, software, processes, and systems) to determine if they function as designed. It also includes the documenting of the test data supporting the findings. The commissioning effort begins with a commissioning plan which includes a schedule of activities and is integrated with the overall performance stage schedule.

Handover activities during this stage include training customer operations staff to use the new or changed systems, and then systematically transferring responsibility from the project team to the customer. The conclusion of this stage answers these stage-gate questions “Does the facility, process, software, or system function as designed? Does the business/customer accept operational responsibility?”

Operational Startup

This final phase of the project process has two stages which provide evidence that the designed

and implemented changes operate in a consistent manner and that the organization realizes the benefits promised at the beginning of the project, based on its investment in the project.

Stage 8 – Process Integration. The process integration stage, also called *validation in highly regulated environments*, is the implementation of rigorous activities which provide documented evidence that the specific process, facility, software, or system consistently produces results within the design specifications; and ensures product compliance with regulatory standards and full integration with other processes. The conclusion of this stage answers the stage-gate question “Does the facility, process, software, or system produce consistent results?”

Stage 9 – Closeout and Benefits Realization. Closeout and benefits realization stage concludes the project process with activities including final adjustments and repairs, record drawings, contract closeout obligations, financial accounting, customer satisfaction surveys, operation and maintenance lessons learned, and documented evidence that the intended business benefits were realized. This final stage concludes by answering the stage-gate question: “Are the anticipated benefits being realized?” prior to final project closeout.

Summary

Viewing each project as an investment made by your organization to achieve its strategic objectives, underscores the need to gain a significant return on that investment in the form of capability, flexibility, speed, cost, and competitive advantage in the industry. By applying the same disciplined approach to each project, your organization establishes ways of working that sets the organization up to reliably produce projects and have the greatest likelihood of gaining the return on investment promised at the outset.

Keeping the project sponsor connected to the process and aware of the role he plays during each phase, brings visibility of the importance of the project to all levels of the organization and contributes to the likelihood of having the necessary resources to ensure a successful outcome.

End Note

^a. The origin of the stage-gate methodology is based on the experiences, suggestions, and observations of a large number of managers and firms in over 60 cases as observed by Robert Cooper. The term *stage-gate* first appeared in an article by

Cooper in the *Journal of Marketing Management*, 3, 3, Spring 1988. An even earlier version can be found in Cooper's book: *Winning at New Products*, 1988 (http://www.12manage.com/methods_cooper-stage-gate.html).

THOMAS F. TRABERT

Team Building

Strategic Team Alignment

Team building is being used very successfully in different environments including technical Six Sigma project teams. Historically, teams have been used in every situation and program imaginable – process improvement teams, continuous improvement teams, total quality teams, continuous quality improvement teams, and many more. Some have been more successful than others. Today, teams and team building are working in companies and on very technically focused projects. Our work at North Carolina State University focuses on **Six Sigma** teams; we are seeing some amazing successes. Success may be linked to a slight variation in the team approach. The teams and team charters are intentionally linked to the strategic plan, to the vision and mission of the organization with meaningful metrics in place, have the buy-in of leadership, and can show financial gains or ROI within the first six months to one year. With these key factors in place, we are seeing a dramatic difference in how successful teams work. For possibly the first time at many companies, we are intentionally linking our team project charters to the organization's strategic plans. This can be attributed to the scientific or methodical approach of Six Sigma training and implementation. In order to ensure that our projects will have a measurable impact, and that they are important enough to the organization to dedicate critical resources, i.e. time and money on, we must ensure that our leadership can draw a line directly from the project to the strategic plan. While serving as a project champion early in the define phase for a service company, we were able to clearly link their black belt scheduling project to their strategic plan. This action enabled the team to focus on the bigger picture – the strategic objectives of the organizations – and verbalize how this team fit into the big picture. This created buy-in and focus for the team, as well as accountability. In terms of financial return on the projects, the best measurement we have so far is a form completed by each company on every project to report the financial gains; this is verified by their CFO. Completion of the data is required at the time of project certification. As one example, a service company reported over \$1 000 000 annual reduction in cost on a single black belt project. Most

savings range from \$25 K to \$50 K per project on average, and focus on reduction in cost or time, or increase in quality or capacity. The average size of a team varies from five to eight members; we have recorded teams as large as 12 members.

Team Outperform Individuals

According to Katzenbach and Smith [1] in *The Wisdom of Teams*, teams working together will outperform individuals acting alone. It is not a natural state to work in teams; we prefer to operate as individuals and do not readily take the responsibility for the dynamic work of others – even when part of an established, working group [1]. This is verified by a quick review of most reward systems; they are established to compensate us individually and not as teams. When working with others collaboratively on a project, we can frequently outperform individuals simply by assigning tasks and breaking down the project into workable pieces to get the work done. I conducted some informal research on this factor. During our Six Sigma green belt training classes, we conduct a hands-on team building training strategy. It is a group activity that compares individual behavior to group behavior. When analyzing results over a 5-year period in multiple industries, over 90% of the results validated that the team outperformed the individual acting alone during the staged team building activity. The fact that some individuals were reluctant to participate was also verified, indicating a nonnatural performance state, while some individuals scores did outperform the group results, although a very low percentage (<0.1) per team per training class.

Team Work in Industry

The success of teams and team projects in a technically focused environment is not tied to any specific industry. According to our records at the university collected over the last 5 years, 75% originates from manufacturing-based industries, while 25% comes from nonmanufacturing (service and health-care/bio/pharmaceutical based) industries. There is no clear distinction of particular team success tied to any particular industry. The team building component is more naturally formed in an industry that is accustomed to working in natural teams, such as manufacturing, and unlike healthcare. According to

2 Team Building

our records, healthcare is experiencing success with projects in Six Sigma; the cross-functional project teams may be more of a challenge in that industry owing to the individual nature of the work [2].

Project Team Roles

The teams on our technical projects have some similarities. The members are all viewed as problem solvers. Since we instruct our black belts at a more advanced technical level, they are relied upon for their statistical analysis and are frequently called upon to be team leaders. Green belts are extraordinary problem solvers and can lead tactical teams, or can be utilized to seek out solutions to a segmented project, or a smaller part of a very technical project. The necessary leadership depends upon the nature of the project and the available resources. While working with a service industry on a technical project, we observed that the black belt served as the leader and analyst, with green belts as members and **data collection** specialists. Master black belts are trained to “train the trainer”. The master candidates may be utilized as internal trainers, as a money saving tactic to continue training the organization’s internal resources. This adds to the return on investment for the overall strategy of the company’s Six Sigma implementation plan.

Optimizing Future Resources

The plan for the future of these teams looks very positive. We are seeing an increase in Six Sigma continuing education course enrollment at our university. Our percentage of completed projects for all industries is approximately 20% for both green and black belt projects, with enrollment in green belt classes nearly double the black belts. This may be indicative that training is more meaningful than project implementation, although the Return on Investment (ROI) is measured in projects completed, but there is no conclusive data. We are seeing very few companies with dedicated resources in green or black belts; they continue to incorporate their current positions into their project work. When current black belt team members in class are asked for impediments to their job, the frequent answer is too many assignments and not enough time to complete the project work. We are allowing our best resources to be trained

at a very high level, but we are not relieving them of their usual and customary duties, as reported in team building sessions in class. In reality, many of our attendees report they are a one-person team on many projects. This may impact future problem solving capabilities and impact turnover. In one major medical care facility, we know of dedicated resources that are operating at the highest level with optimized results. How resources are leveled and optimized should be a consideration in the future, as reward and recognition continue to be a factor for high-level project teams. According to Juran and Godfrey [3], high performing project teams are difficult to build, but when maintained, can help lead the company to a good competitive advantage [3].

Summary

While technical teams aligned to a systematic approach such as Six Sigma are not the only successful teams on record, there have been some very good results with our industry partners at our university. This is not to imply that teams are the only pathways to resounding success, as many of our companies are successful without the existence of ongoing teams. For more information on industry results, please visit our web site at <http://www.sixsigma.tx.ncsu.edu>. For additional information, please see other suggested resources.

Multi-Vari Charts

What are Multi-Vari Charts?

Multi-vari charts are a graphical form of analysis of variance. You can use them most effectively for problem solving. However, you can also use them to estimate variation in well-behaved processes.

Len Seder

Leonard Seder (1915–2004) invented multi-vari charts in the late 1940s. He published a two-part article “Diagnosis with Diagrams” in *Industrial Quality Control* in 1950 (January and March). Len gave credit to Dr Joseph M. Juran for the concept of graphing process variability in a manner similar to a stock report with daily high, low, and closing prices represented by a vertical line for the range and a point for the closing. Len described multi-vari charts as a diagnostic tool, and compared them to medical diagnostic tools like X-rays or electrocardiograms. He stressed the power of an effective graphical presentation. “The question is, then, how can these powerful techniques be made more available? One answer is to be found, in the author’s opinion, in the use of graphics in place of statistics. Much of the success of the simpler statistical quality control techniques is undeniably attributable to the forcefulness and conciseness of graphic presentation.”

Why do Multi-Vari Charts Work?

A well-planned and executed multi-vari chart will separate overall process variation into families. You will clearly see the family causing most of the change and patterns of variation within the largest family, which will provide further clues about the source of variation. The power of a multi-vari chart comes from the application of the **Pareto** principle to the sources of variation in a process.

Dorian Shainin

Dorian Shainin (1914–2000) attended MIT with Len Seder. The two men established a professional relationship with Dr Juran in the 1940s. At that time,

Dorian was in charge of quality and reliability at Hamilton Standard (a division of United Aircraft) and Len was with Gillette Safety Razor Company in Boston. Dorian was an early adopter of Len’s multi-vari charts. He was also an admirer of Dr Juran’s application of the Pareto principle to project selection.

In the 1950s, Dorian concluded that just as the Pareto principle applied to the effect individual problems were having on business performance, it must apply to the effect that individual variables had on changes in product or process performance. If a problem could be expressed in terms of variation, i.e., too much change in the values of product or process outputs, and then the Pareto principle requires that one cause must be responsible for most of the change. Dorian called this dominant cause the *big Red X*. The Red X paradigm does not suggest that the Red X is the only source of variation. In fact, it recognizes that there are thousands of potential causes. The Red X causes most of the variation. Find it and control it and you will make a significant improvement in performance.

Red X Paradigm

The Red X paradigm changes the way problems are attacked. If there is a dominant cause of variation, finding it and controlling it is the only path to improvement. The statistical law underlying analysis of variance states that independent sources of variation combine as the square root of the sum of the squares. If one source causes a range of 5 units and another independent source is causing 1 unit, the combined range will be 5.1 units (the square root of 26), not six (the sum of 5 + 1). The 5-unit cause is the Red X and it is 25 times stronger than the cause contributing 1 unit.

Once you focus on finding the Red X, the priority becomes finding it quickly, with minimal resources. The best approach is a progressive search, using a process of elimination. Eliminate everything that cannot be the Red X and whatever is left must be the Red X. This is a classic approach for solving criminal cases. Sherlock Holmes expressed it well in Sir Arthur Conan Doyle’s “*The Sign of the Four*”: “Watson, how often have I told you? When you eliminate the impossible, whatever remains, however improbable must be the truth.” Effective methods converge rapidly on the true root cause by eliminating the impossible.

2 Multi-Vari Charts

Dictionary Game Thinking

Dorian illustrated the concept with a parlor game called the *dictionary game*. A secret word is chosen. You may only ask questions that can be answered with a “yes” or “no”. And you are given a dictionary as a tool to help discover the word. Uninitiated contestants often use a 20-questions approach. The initial common questions are as follows:

- “Is it a person?”
- “Is it a place?”
- “Is it a thing?”

Since we are looking for a word, additional questions might be as follows:

- “Does it have more than five letters?”
- “Is it a noun?”
- “Does it have more than two syllables?”

The keys to the dictionary game are listed below:

1. Use a process of elimination.
2. Take advantage of the dictionary’s structure (it is alphabetical).
3. Start with broad questions (eliminate a lot).
4. Narrow the questions as the search progresses.
5. Ask questions that will narrow down the search no matter the answer.

Here is an example. Let us choose “desktop” as the secret word. Start the search by finding the center of the dictionary by page number. In my dictionary, the first “a” word is on page 43 and the last “z” word is on page 1373. The midpoint is page 708. The first word on page 709 is “lucky”. Asking, “does the word come before ‘lucky’ ”, will eliminate half the possible words. It does not matter if the answer is “yes” or “no”. In our example, the correct answer is “yes”. The word “lucky” and all words following it have been eliminated.

The next step is to divide the remaining section in half and repeat the process. The next midpoint is on page 375. The first word on page 375 is “domino”. The question is now: “Does your word come before ‘domino’?” Again the answer is yes and another quarter of the dictionary has been eliminated.

Within 10 questions, the search will be narrowed to a single page. In my dictionary, “desktop” is on page 344. The pages are divided into two columns. Applying the question to the word atop of column

two, “despair”, narrows the search to the first column. There are 26 words in the column. Word 13 is “desk”. The question is now: “Does your word come before ‘desk’?” The answer is no.

Within 17 questions, we would have eliminated all the words in the dictionary, except “desktop”. The first question eliminated half the words; the second a quarter; and the last question only eliminated one. Notice that even though the question form stays the same, the questions start broad and become narrower as the search progresses.

Dictionary Game Thinking with Multi-Vari Charts

A multi-vari chart is an important tool for finding a process Red X. By separating the overall process variation into families of variation, all but the largest family can be eliminated. The search for the Red X is quickly narrowed to a small part of the process.

The Case of the Incapable Lathe

In 1966, Dorian published an article in Industrial Quality Control. It was titled “The Case of the Incapable Lathe” and it illustrated the power of multi-vari charts in finding a Red X.

A manufacturer was making jet engine fuel pump controllers. A key component was a rotor shaft. Shaft diameter was an important dimension. The shafts were turned on a lathe. A capability study determined that the process was not capable. Management put pressure on manufacturing to fix the problem. After failing to get tolerance relief from engineering, manufacturing assigned a team of experts to examine the problem and recommend a solution. The team concluded that the lathe was old and worn out and simply not capable of maintaining the tolerance of ± 0.001 in (Figures 1 and 2). They believed the lathe had worn bushings and spindles and needed to be replaced. They recommended that management purchase a new lathe. Management was not convinced and asked Dorian to investigate.

The process produced shafts on the lathe. Finished shafts were deposited in a basket. After cleaning to remove oil and metal chips, the parts were inspected for size. By the time the parts were measured, part orientation on the lathe and order of production were lost.

Figure 1 Tolerances of incapable of lathe

Figure 2 Measuring the diameter of the rotor shaft

Planning the Multi-Vari

To start with, identify the families of variation present within the process. Three broad families combine to produce the overall observed variation: within piece, piece-to-piece and time-to-time.

- Within piece describes deviations from the intended shape of the parts.
- Piece-to-piece captures process changes from one machine cycle to the next.
- Time-to-time captures process trends, shifts, or cycles.

Within Piece. Study the physical process the machine uses to create shape. Then consider how the shape might deviate from the design. For example, the lathe will rotate the workpiece about its central axis as the cutting tool moves in from the outside. As the cutting tool meets the workpiece a circular

shape is produced. The cutting tool then moves down the workpiece creating a cylinder. A change in the relationship between the workpiece center and the cutting tool during a rotational cycle will create an oval shape (out of round), instead of a circle. A change in the relationship between the workpiece center and the cutting tool as the tool travels down the length of the workpiece will produce a tapered shape.

To capture these potential changes, Dorian had the setup man capture parts as they came off the lathe. The setup man marked the end of the part that was held by the lathe chuck for future reference. See Figures 3, 4, and 5. He then found and measured the maximum and minimum diameters at each end of the part (chuck and tail). Four readings represented the range of diameter values within each part.

Piece-to-Piece. Study the organization of the manufacturing process to find piece-to-piece families. If multiple lathes produced the rotor shafts, then

Figure 3 Components of variation for rotor shafts. C: chuck; T: tailstock

piece-to-piece would be consecutive parts from the same lathe, but a new family lathe-to-lathe would have to be captured. If the shafts had been produced on a six-spindle screw machine, then piece-to-piece would be consecutive pieces from the same spindle, not consecutive pieces from the machine. One machine cycle would produce six parts. These broader families come from parallel process paths. Create a detailed process flow diagram to find the parallel paths. Cavity-to-cavity, pallet-to-pallet and line-to-line are common examples.

Only one lathe produced rotor shafts, so there were no parallel paths. Piece-to-piece was captured by sampling consecutive parts from the lathe. Differences in size or shape from one part to the next would indicate instability in the equipment. A sample of three consecutive pieces will reveal trends, shifts, or cycles in the equipment.

Time-to-Time. Processes change over time. Operators make adjustments. They introduce new lots of material. Ambient conditions such as temperature and

humidity vary. These changes may cause changes in process outputs. Select sampling times that are likely to catch important changes. Machine start-up, tool changes, material changes, and operator changes are good candidates for sampling times.

Dorian decided to take samples each hour.

Completing the Plan

Once you identify the families of variation, develop a stratified sampling plan and lay out a graphical format to display the data. A stratified sample means the sample is in the order of production. Stratified samples are not random.

The graphical layout in Figure 3 will capture the data from three consecutive parts taken each hour from 8:00 a.m. to noon.

Executing the Multi-Vari Study

The number of samples required to find the largest family of variation cannot be predetermined.

Figure 4 Sources of variation for the rotor shafts. C: chuck; T: tailstock

Continue sampling until you capture variation of Red X magnitude (80% of the overall variation should be sufficient). During the sampling, do not try to control or vary specific process parameters. Let the process vary normally. Measure parts immediately and plot the data. Stop sampling when the Red X family is revealed. It is a bit like fishing. Cast your net in a small area. If you do not catch anything, progressively cast the net wider and wider until the catch is made.

Analyzing Multi-Vari Charts

Once the data are plotted, look for the largest family. Calculations are discouraged. The magnitude should be clear from the graph. Also look for patterns in the data. These provide important insights for those who understand the mechanics of the manufacturing process.

Figure 4 shows the multi-vari chart for the rotor shaft after the first three-piece sample at 8:00 a.m.

The vertical axis captures changes in part diameters. The distance from A to B represents out-of-roundness at the chuck end of the part. The distance from C to D is out-of-roundness at the tailstock end. Notice that the first three pieces have the same out-of-roundness at each end. The vertical distance from A to C represents part taper.

The multi-vari chart has revealed considerable diameter variation within each piece. The variation uses half the tolerance. However, we have not seen variation of Red X magnitude. The process capability study revealed variation exceeding the tolerance limits. More data are needed.

Figure 5 shows the multi-vari chart at noon.

Notice that the taper has increased and the out-of-roundness has stayed about the same. More importantly, changes in the position of the hourly subgroups exceed the tolerance and are the largest family. Whatever be the Red X, it is time based. Even though there is considerable within piece variation, that is not where the Red X resides and it must be eliminated for now.

Figure 5 Multi-vari chart for the rotor shafts illustrating that the biggest variation is hour-to-hour. C: chuck; T: tailstock

Multi-vari charts reveal the largest family and they also reveal patterns of change. The time-to-time family trends downward from 8:00 to 10:00 a.m.; it shifts between 10:00 and 11:00 a.m.; and it starts another downward trend from 11:00 a.m. to noon.

The statistical portion of the investigation is over. Now process knowledge and an understanding of the physical world take over. The manufacturing supervisor thought excessive tool wear caused the trend and a new tool explained the shift between 10:00 and 11:00 a.m. The tool comes from the outside. If the tool were wearing, the parts would get larger. Our parts are getting smaller. A material

lot change could explain a shift, but is not consistent with the trend.

A few questions revealed that the operator took a break at 10:30 a.m. During the break, the process shut down. Temperature is a time-to-time variable that fits the clues. Machining parts involves friction and raises temperature. Metal expands as it heats up. Expanding metal will cause the parts to be smaller after they have cooled. Shutting down the lathe during break provides time for cooling, allowing the process to go back to its eight o'clock state. The lathe has a coolant reservoir to control process temperature. An examination of the reservoir revealed that the coolant

was well below the prescribed levels. Adding coolant eliminated the time-to-time changes and made the process capable.

Multi-vari charts do not reveal the Red X. They reveal the Red X family. Further investigative steps are always required. Well-designed and well-executed multi-vari charts eliminate broad areas of the process. They allow the investigator to narrow down the search.

Kraft Paper Strength Case

Kraft paper is used for packaging. Paper strength is an important material property. A paper mill was losing market share because their paper strength was inconsistent. The paper process is more complicated than making rotor shafts on a lathe.

Trees are cut and the logs shipped to the mill. A chipper converts the logs to wood chips. A digester cooks the chips in a chemical soup that breaks down the glue that holds the fibers together. After rinsing, the wood fibers are suspended in water, creating a batch called a *furnish*. The furnish is fed into the paper machine where the fibers are distributed across a moving wire. The material dries as it moves down the machine and reels take up the finished paper at the end. The experts blamed the variation in paper strength on the trees. Some trees simply have stronger fiber than others and the paper mill cannot be held responsible.

A multi-vari chart was planned to reveal variation

- across the paper machine;
- in the machine direction; and
- from furnish-to-furnish.

The stratified sampling plan is illustrated in Figure 7. See Figures 6 and 7.

Figure 8 shows the resulting multi-vari chart:

There are several important observations and conclusions:

1. The largest family is furnish-to-furnish.
2. There is a nonrandom pattern in paper strength across the machine.
3. The furnish-to-furnish variation eliminates the paper machine and points to the digester.
4. The nonrandom pattern eliminates the trees. How would the weak fibers know to align on the right side of the paper machine?
5. There is more across machine variation with the weak furnish than with the strong furnish. This signals an interaction.

If every furnish could be made as strong as the best furnish, the across machine variation would not matter and the customers would be delighted. We do not know the name of the Red X, but we know where it resides. It is in the digester.

An investigation into the digesting process uncovered four variables that were supposed to be controlled:

Figure 6 Kraft paper process

8 Multi-Vari Charts

Figure 7 Stratified sampling plan for Kraft paper study

Figure 8 Multi-vari chart for the Kraft paper investigation showing that the biggest source of variation is furnish-to-furnish

1. Cooking temperature
2. Cooking pressure
3. Cooking time
4. Loading ratio (chips per gallon of water).

A full **factorial** designed experiment revealed an interaction between cooking pressure and loading ratio. See Figure 9. Once the interaction was understood and the levels controlled at their optimum, all paper reels were strong, exceeding customer

expectations. The lost market share was recovered and the share was raised to new heights.

A molder of plastic parts was having trouble maintaining the proper material packing. Packing is measured as part weight (grams). The families of variation were:

- Cavity-to-cavity
- Shot-to-shot
- Hour-to-hour

Figure 9 Kraft paper study: Using the interaction of two control variables to reduce variation

Figure 10 Kraft paper study: Multi-vari chart showing that the biggest source of variation is hour-to-hour. Also notice that cavity-to-cavity variation is the smallest at 9:00 a.m.

The multi-vari chart revealed an interesting pattern (See Figure 10). There is little variation in the shot-to-shot family. There is substantial variation in cavity-to-cavity at 8:00 a.m. and 10:00 a.m., but no cavity-to-cavity variation at nine o'clock. Another interaction has been uncovered.

There is an interaction between the cavity-to-cavity and hour-to-hour families. The investigative

team studied the cavities and could not find anything different about cavity C. When looking at the runners, they found C to be slightly smaller. The hour-to-hour variation was by the machine operator. When the operators saw a problem with the parts from cavity C being too small, they increased pack pressure. Notice that all the parts at nine o'clock are heavy. After a while, flash would increase, so they would decrease

pack pressure, thus turning on the Red X in cavity C. Increasing the runner size for cavity C solved the problem.

Using Multi-Vari Charts Effectively

The multi-vari chart is a powerful statistical tool without the statistical calculations. Properly planned and executed, the chart will reveal the largest family of variation and make a significant, early contribution to the search for the Red X.

Selecting the proper families requires an understanding of how the process creates the shape or

property desired. It also requires walking the process to see the parallel paths.

Be sure to take stratified samples and plot the data as soon as they become available. Stop sampling when variation of Red X magnitude is captured.

The chart will reveal the largest family of variation and patterns of change. The patterns will provide guidance on potential next steps.

Remember the multi-vari chart will not identify the Red X. However, as Sherlock Holmes might say, it will eliminate a great number of variables that cannot be the Red X.

RICHARD D. SHAININ

Total Productive Maintenance

TPM Definition

The total productive maintenance (TPM) definition was established by the Japan Institute of plant maintenance (JIPM) in 1971 as TPM was first introduced in industry. The initial emphasis of TPM was primarily on the production floor, but as the focus shifted to the company-wide implementation, a new TPM definition was introduced in 1989. While the new definition emphasizes “company-wide TPM”, the old definition focused on “TPM for the production sector”. The TPM definition, as it is used today, is as follows. TPM aims at:

- establishing a corporate culture that will maximize production system effectiveness;
- organizing practical shop-floor systems to prevent losses before they occur throughout the entire production system life cycle, with a view to achieving zero accidents, zero defects, and zero breakdowns;
- involving all the functions of an organization including production, development, sales, and management;
- involving every employee, from top management down to frontline operators, and;
- achieving zero losses through the activities of “overlapping small groups”.

Basic Concepts of TPM

The basic concepts of TPM are as shown in the following five items. Each is explained in relation to the above mentioned TPM definition, as follows:

1. Establish a corporate structure that will be profitable

TPM aims at establishing a corporate climate that will maximize production system effectiveness, as indicated in the first item of the TPM definition. To attain this, efforts should be made so that all possible losses may be prevented (the second item of the TPM definition) thus establishing a corporate structure, which will be profitable.

2. Prevention – to keep undesirable things from happening

A system should be built whereby all possible losses occurring in the entire production system life cycle will be prevented (the second item of the TPM definition). For this purpose, maintenance prevention (MP), preventive maintenance (PM), and corrective maintenance (CM) will be implemented. In common, among these, is the idea of prevention.

3. Total involvement – participative management and respect for humanity

As indicated in the third and fourth items of the TPM definition, every function and every member of an organization, from top management down to frontline operators, should participate, through overlapping small-groups’ activities, as indicated in the fifth item of the TPM definition. Thus, TPM is literally participative in nature, respecting humanity as advocated by Rickart.

4. “Genba” (work site) and “Genbutsu” (equipment itself) principles

In organizing a shop-floor system to prevent losses (the second item of the TPM definition), the focus should be on creating a loss-free system in equipment itself, that is, on “Genba” and “Genbutsu”, rather than on creating a system of control. In other words, efforts should be made to realize equipment “the way it should be”, to make “management by vision” possible and create a clean workshop to work at.

5. Zero-oriented approach

This approach inherently has no tolerance for loss, rather than allowing for a margin of loss in production systems. It requires a shift in attitude toward operations, away from “reducing” loss to “eradicating” loss. This is a breakthrough that causes a change in the way of thinking, from the notion that “some failures are unavoidable” to that “failures must be avoided”.

Visualization of Loss

In TPM loss needs to be expressed in numerical form. To this end, concepts like overall equipment efficiency (OEE) and overall plant efficiency (OPE) have been developed, as tools for identifying loss owing to equipment. (For more information on OEE and OPE, see Figures 1 and 2.)

2 Total Productive Maintenance

Figure 1 Overall equipment efficiency (OEE)

Figure 2 Overall plant efficiency (OPE)

Table 1 Case of results

	Target item	BM FY2004	Result as of September 2006
Cost	Total productivity improvement	100	112
	Processing cost loss amount	100	67
Delivery	Inventory asset turnover days	100	55
	Delivery punctuality rate	100	100
Quality	Number of installation defects	100	0
Productivity	Number of failures	100	7
	Equipment total efficiency	100	102
Safety	Number of accidents requiring absence * (Number of accidents not requiring absence)	0	0
Morale	Number of submitted proposals	100	119

Note: Mitsuba Corporation, Akagi Plant: "Let's make an evolving strong plant by TPM activities for making profits and winning", TPM awarded company presentation, 2006 *
Accidents accompanied by lost worktime

Result by TPM: from case show example of tangible effects of the company which presented TPM.

Table 1 shows indices before and 2 years after the actual implementation of TPM at a plant. Even a plant that has worked on various improvement activities before the TPM implementation proves that the TPM concept achieves sustainable operation with less loss.

TSUTOMU NAKAMURA

Lean Methods, Creating Flow with

Introduction

Lean is a management philosophy founded on the just-in-time (JIT) principles conceived by Japanese automobile manufacturers in the 1930s and perfected in the 1970s. In 1990, the book, *The Machine That Changed the World* [1] kindled interest in JIT and lean thinking in the United States. Subsequently, in 1996, Womack and Jones wrote the book, *Lean Thinking* [2]. In this book, they indicated that the goal of lean thinking is to eliminate *muda* (a Japanese word for wastefulness) and prescribed a specific course of action to implement lean concepts within an organization.

The Evolution of Lean Thinking

The principles in lean thinking were initially applied to the automobile industry in the United States. This was a natural consequence of the fact that JIT principles were specifically developed for the automobile industry in Japan. However, lean thinking is now being applied to a wide variety of industries. These concepts and principles have successfully been applied in industries as diverse as paints, furniture, electrical switchgears, aerospace, aircraft maintenance, electrical appliances, and office products.

As US organizations began to understand and embrace lean principles, the body of knowledge also started to grow and get disseminated. It was observed that lean principles, in particular, the concept of flow, could be extrapolated beyond internal operations to entire supply chains. Lean became a new model for making, distributing, and selling products that evolved from a marriage of new capabilities in manufacturing, information technology, and logistics.

Lean thinking focuses on eliminating wasteful activity at all levels in the organization (or the supply chain for that matter). Eliminating wasteful activity achieves two purposes. First, it reduces *lead times*^a and makes the organization more *flexible* and *responsive*. From the supply chain perspective, the

organization is more responsive to the downstream customers and provides smoother, more predictable demand for the upstream suppliers. For example, the Denso starter and alternator plant in Maryville, Tennessee, operates on a product cycle in which every product is made multiple times per shift. The short product cycles make it possible for both Denso and its upstream suppliers to produce virtually in lockstep with the automobile manufacturers that use these starters and alternators. Only a day or two elapses between the time a casting or a coil of wire is made at the Denso facility, and the time the casting or coil becomes part of a starter or an alternator on a completed car. The benefits of this short flow time – short quality feed back loop, responsiveness to the customer, elimination of supply chain costs related to inventory tracking – are primarily realized outside the four walls of Denso's operation. (In fact, if all elements of the supply chain in the automobile industry were as responsive as Denso, the automobile industry would be poised to adopt Dell Inc.'s direct sales model.)

Second, the elimination of wasteful activities frees up resources that could be deployed to grow its business. An organization that exemplifies such a growth model is Michigan-based Freudenberg NOK, the American partnership of German-based Freudenberg and Japan-based NOK, the world's largest producers of oil seals and custom molded rubber products. Created in 1989, this organization has relentlessly applied lean concepts to squeeze out the waste in its processes, freeing up capacity for further growth, while at the same time becoming more flexible and responsive. Freudenberg NOK had quadrupled its revenues by 2001 and its current revenues are more than \$1 billion.

Lean is More than Just Effective Operations Management

The preceding discussion should clearly convey to the reader that lean provides a set of concepts, tools, and management *prescriptions* aimed at strengthening the competitive advantages of the organization [3]. Lean is not just something within the domain of the operations function; rather, the business case for lean applies to the entire organization. To repeat a statement made earlier, lean allows organizations to pursue a *growth strategy*, a strategy aimed at uncovering additional capacity that could be deployed for

further growth. The greatest benefit of lean processes lies in the fact that organizations can grow their business *without having to spend money now* to build new plants, invest in a new warehouse, and so on. A lean implementation has the ultimate goal of delivering products that the customer values, as quickly as possible, further enhancing the organization's ability to grow its business.

Organizations that successfully implement lean concepts can, in fact, respond to customer demands faster and more reliably than their competition. In turn, that encourages the customer to place orders with the organization that are more reflective of the actual demand, rather than one that the customer has inflated in order to build a safety cushion, or deflated to reduce excess inventories. The organization is thus able to work with a smoother production schedule and consequently communicates a smoother material supply schedule to its suppliers. This facilitates strong relationships with suppliers, providing lean organizations with another competitive advantage. Lean organizations are thus able to build custom products for individual customers much more easily, without having to carry large amounts of inventory.

The Reasons for Working with Reduced Inventory Levels

Organizations often focus on reducing inventory levels to save on inventory carrying costs. However, there are arguably three other reasons that are more important – reasons that are more customer focused. First, reduction in inventory levels reduces lead times, enabling the organization to ship the product faster to the customer. For instance, if the organization has 2 weeks of work-in-process (WIP) inventory on the shop floor, then a new order that is processed using the First-Come-First-Served principle will take at least 2 weeks to complete processing. The organization is also more responsive to changing customer preferences. Second, the presence of large finished goods inventory of certain products is symptomatic of the organization having built the *wrong kind* of products, perhaps because it builds products in large batches to exploit scale economies. Finally, reducing inventory exposes problems such as poor quality, unreliable suppliers, scrap, large changeover times, and so on.

Tools for Creating Flow

To enable organizations to reduce inventory levels and create a smooth flow of products throughout the organization, or the supply chain for that matter, all the elements involved should work in concert. In the context of a supply chain, all the supply chain partners must work at the same pace. Similarly, within an organization, the most effective method of production is to have all processes work at the same rate. There is no point in having some of the resources work faster than the others, because that will invariably pile up inventory in front of the slower processes. Such a smooth flow of products is better facilitated if all resources respond to *pull* signals. The signal for a resource to produce could be generated simply when the downstream resource draws a unit of WIP from the buffer placed between the two resources.

Some of the important tools and techniques used by lean thinking to work with lower inventory levels and promote flow are: 5-S, total productive maintenance, *takt* time, standard work, mixed model scheduling, cellular layout and one-piece flow, point of use material storage, pull replenishment, and *kanbans*. Although these lean tools were originally developed for manufacturing organizations, many service organizations are finding them very useful as well. It is not possible to discuss these techniques within this short article. For more details, the reader can refer to *Streamlined* [4, Chapter 5], or numerous other books that treat this topic.

We note that before applying these tools, we must also address the scope of the lean implementation. Organizations often create lean cells to put out products at a rapid rate, only to find these products queuing up at a downstream work center. The questions that must first be addressed are as follows: should the organization implement lean on *all* its processes and activities or should it focus on a *subset* of its processes? Similarly, should it implement lean on all its products or on a subset of them? It is recommended that the organization choose one product family at a time and implement lean on *all* the processes and activities of this product family, before moving on to the next product family.

Continuous Improvement and the Pursuit of Perfection

Complacency can become the toughest challenge in any lean transformation process. Lean is not a

one-time implementation effort, nor is it a quality program of the month. It is an ongoing journey that requires a sustained effort at continuous improvement. The transformation to lean is not just an application of a few techniques; rather, it is a whole new way of looking at the operations of the organization. Because lean tools and techniques are often quite different from traditional tools, there must be a sustained effort to operate with these tools. Organizations that do not aim to continue an upward momentum will falter and fall behind their competitors. It is essential to continuously reexamine processes and look for ways to take out waste and nonvalue-added activities if organizations are to gain significant financial performance improvements.

To sustain lean implementations, it is therefore necessary for organizations to constantly initiate *kaizen* (continuous improvement) events that promote continuous improvements. At the same time, there is a need to promote *kaikaku*^b, the radical redesign of processes and methods geared for achieving breakthroughs in performance and growth. Once a *kaikaku* step is applied, *kaizen* becomes a powerful follow-up drive to perfect the processes and methods, and to continue to adapt and be relevant.

As Womack and Jones suggest, “dreaming about perfection is fun” [2, p. 26]. However, lean thinking provides ways to make these dreams a reality. Applying lean thinking and implementing the tools and techniques to create flow, result in a fundamental change in the way the organization thinks about its operations. The employees soon realize there is no end to the pursuit of perfection – efforts aimed at reducing effort, time, space, cost, and mistakes in the process of producing and delivering a product. When products flow faster through the organization, they expose hidden waste in the **value stream**. The harder you pull, the more the obstacles are revealed so they can be removed.

While lean implementations must have commitment and support from the top management, the shop floor personnel are also critical to the success of lean. Many organizations have initiated their lean efforts from the bottom up. Continuous improvement (*kaizen*) events play a vital role in getting them engaged in the lean journey, and that pays dividends. Managers at all levels became lean thinkers and change agents. A truly

lean organization makes it much easier for everyone, including shop floor employees, supervisors, lean champions, subcontractors, or first-tier suppliers, to discover better ways to create value. Because the feedback loops are significantly shortened, there is a faster feedback to employees, providing a more conducive environment for employees to pursue perfection.

Conclusion

Thomas J. Watson Jr. once said, “Whenever an individual or a business decides that success has been attained, progress stops.” Lean is a journey – an ongoing journey that requires a sustained effort to maintain the momentum. At the same time, once the initial resistance is overcome, it becomes much easier to maintain the tools and techniques of lean. Once there is a sharpened awareness among the employees, of the waste present in the system, there will be a concerted effort to maintain the momentum if the right incentives are provided. All types of organizations can benefit from lean thinking, regardless of whether they are involved in manufacturing, process, distribution, software development, or financial services. Some important points organizations should keep in mind when embarking on a lean journey are as follows:

1. While the goal of lean has often been identified as the removal of *muda* (waste), it is important to note that removing *muda* is just a means to an end. A major focus for lean is to reduce lead time. *Lean is all about lead-time reduction and creating flow.*
2. Some important steps organizations can take to create flow are, *takt* time, standard work, pull replenishment, and 5-S. Incidentally, all of these are steps that readily apply in a service setting as well.
3. Lean is a *journey* – one that really never ends.
4. Organizations that embark on the lean journey, typically should start by identifying a product family they can apply lean principles to. Lean thinking must be applied to all the processes in the organization that work on the selected product family(ies). The idea is *not* to simply lean out some of the process steps and create a few *islands of excellence*. While some waste may be removed in the process

of creating such islands, the products flowing out of these islands will end up waiting elsewhere in the organization. In particular, they will queue up in front of the constraint resources.

End Notes

- ^a. The lead time is defined as the elapsed time from the moment an order is received, until the time the order is executed and delivered correctly to the customer.
- ^b. This step is often referred to as a *kaizen blitz*.

MANDYAM M. SRINIVASAN

Error Proofing, Healthcare

Introduction

Human errors often have great effects on quality, safety, and efficiency in healthcare: e.g., giving a medication to the wrong patient, wrong-side surgery, overlooking patient's allergies, not connecting the monitoring system when the patient is moved, or filling prescriptions with the wrong drug [1]. To prevent these errors and their undesired effects, "error proofing" solutions are effective. Successful examples include distinguishing patients with a bar code, having the surgeon's initials placed on the surgery location, using color-coded wristbands on patients with known drug allergies, using a checklist in hand, and not using drugs having similar names/forms. The basic idea of error proofing is very simple. Although human beings are flexible and creative, they also often make errors. This characteristic cannot be changed. Therefore, improving the other element of the work system, i.e., "work operations" including medications, equipment, and documents is an effective way for tackling errors. Error proofing has many different names such as foolproofing, *poka-yoke*, mistake proofing, and so on. All can be explained by this simple concept, "changing work operations to fit human beings".

Although error proofing solutions are successfully applied in healthcare, most of them are generated individually as needed to suit each particular occasion without the benefit of the knowledge of the wider body of error proofing solutions. This paper extracts the error proofing principles and solution directions existing behind these proven solutions and provides a simple methodology for systematically generating workable solutions to reduce healthcare-related human errors. We build on a long-established practice of error proofing in manufacturing industries [2–6].

Error Proofing Principles for Healthcare

In spite of the simplicity of the basic idea of error proofing, there are various types of solutions. Error proofing is often taught by having people learn many examples. There, however, exist only a few basic principles to be known. Figure 1 illustrates the five principles of error proofing that have been extracted based on the investigation of more than 500 error proofing solutions implemented in healthcare and published in 30 articles and books [7–9]. The top part of this figure shows a process where human errors occur and cause incidents/accidents. Every operation has its own tasks and risks. Caregivers have to perform the required functions to accomplish these tasks, creating the potential for human error. These errors cause abnormalities, and if necessary actions are not taken, finally cause undesirable results such as

Figure 1 Principles of error proofing in healthcare

2 Error Proofing, Healthcare

human injury or death. The five principles correspond to the process.

The first three principles aim to prevent the occurrence of human errors. The most effective method of preventing errors is to eliminate operations susceptible to error from the process. The next most effective method, if the first cannot be applied, is to replace the human operations with more reliable machines/methods. The third most effective is to make the operations easier for caregivers to perform. These three principles belong to the first group: “prevention of occurrence”, and are called *elimination*, *replacement*, and *facilitation*, respectively.

On the other hand, the other two principles aim to suppress the development of errors into incidents/accidents. One method for attaining this is to detect abnormalities caused by human error and enable caregivers to take suitable corrective action. Another method is to mitigate the effects of human error. These two principles belong to the second group: “minimization of effects”, and are called *detection* and *mitigation*, respectively.

These principles have good consistency with those obtained in manufacturing [2]. However, the ratio of examples corresponding to each principle is different between healthcare and manufacturing as shown in Table 1. The application of “facilitation” in healthcare has a higher percentage of use than the application of “detection”.

Elimination

The principle “elimination” aims to change work object properties so as to remove operations susceptible to human error from the process. For example, an “elimination” solution against errors in the transfer of medication orders, charts, or specimens is to eliminate as many handoffs as possible.

The principle “elimination” can further be classified into two subprinciples:

1. **Task elimination** Eliminate error-prone tasks.
2. **Risk elimination** Eliminate risks inherent in objects or objects themselves.

The previous example corresponds to “task elimination”. On the other hand, removing concentrated potassium chloride solutions from the floor stocks in emergency rooms is an example of “risk elimination” to prevent misadministration of the medications.

The solutions based on the principle “elimination” can perfectly eliminate the possibility of human errors. In many cases, however, process/equipment design must be changed drastically, and it can have great side effects on cost, productivity, and performance.

Replacement

The principle “replacement” aims to replace the human operations with more reliable machines/methods. For example, a “replacement” solution against the error of forgetting to switch on a humidifier in a respirator is to link the switch of the respirator with the switch of the humidifier so that the humidifier is automatically switched on.

The principle “replacement” can further be classified into two subprinciples:

1. **Automation** Completely replace a particular human operation with machines.
2. **Support system** Give support tools such as checklists, reminders, guides, or samples to help caregivers to perform the operations more reliably.

The previous example corresponds to “automation”. On the other hand, using a partitioned cart that can contain only a certain number of medications is an example of “support system”. This makes counting by nurses unnecessary and prevents the error of counting medications incorrectly.

Various “replacement” solutions can be considered depending on how many functions are replaced. To replace all functions leads to large-scale and unrealistic solutions. Therefore, it is essential to focus on highly error-prone functions in the operations and replace them.

Table 1 Ratios of error proofing solutions

	Elimination	Replacement	Facilitation	Detection	Mitigation
Healthcare	7% (35)	26% (135)	48% (251)	14% (73)	5% (24)
Manufacturing	5% (56)	27% (276)	23% (234)	40% (402)	5% (46)

Facilitation

The principle “facilitation” aims to make the operations easier for caregivers to perform. For example, a “facilitation” solution against the error of mistaking the wrong concentration of morphine sulfate stocked in identical cartridges is to have the pharmacy label the high-concentration cartridge with bright orange tape.

The principle “facilitation” can further be classified into three subprinciples:

1. **Simplification** Decrease the number of changes or differences.
2. **Distinction** Distinguish changes or differences from each other.
3. **Adjustment** Adjust objects or operations to suit the individual’s capabilities.

The previous example corresponds to “distinction”. On the other hand, establishing standard drug administration times is an example of “simplification” to prevent forgetting to administer drugs at the ordered time. Making the size/form of the letters used in prescriptions easy to read also reduces the chance of misreading. This is an example of “adjustment”.

Individual “facilitation” solutions are not so effective, but their cost and side effects to operations are minimal. Therefore, it is possible and practical to use multiple solutions to increase overall effectiveness.

Detection

The principle “detection” aims to ensure that abnormalities caused by human error are detected and suitable corrective action is taken. For example, a “detection” solution against the errors in ordering medications is to use order entry systems that provide real-time alerts if a medication order is out of range for weight or age.

The principle “detection” can further be classified into three subprinciples:

1. **Recording and verification of motion** Record precedent motions and verify them at a subsequent point in time.
2. **Restriction of motion** Restrict motions to allow caregivers to notice abnormalities.
3. **Verification of result** Check the resultant medications/equipment/documents at a certain point in time.

The previous example corresponds to “verification of result”. On the other hand, using trays for surgical instruments having indications for each instrument, and nesting all of the instruments for a given operation in the tray so that it is clear if the surgeon has not removed all instruments from the patient before closing the incision is an example of “recording and verification of motion”. Redesigning anesthesia machines so that the connector for the oxygen tank cannot fit into the nitrous gas tank to prevent errors in setting the machines is an example of “restriction of motion”.

Because late detection leads to large correction costs, it is essential to develop techniques for detecting abnormal motions or their results as soon as possible. Another key success factor is to prevent hardware failures. Moreover, it is also essential to apply “facilitation” solutions at the same time because human beings sometimes ignore obvious abnormalities and continue procedures according to their understanding.

Mitigation

The principle “mitigation” aims to mitigate the effects of error by incorporating functional redundancies or using shock-absorbing materials/equipment. For example, a “mitigation” solution against errors in blood banks is to take two separate specimens from a patient and have two different technicians to test them independently. This solution introduces **redundancy** and ensures that the problem only occurs if both technicians make the same mistakes.

The principle of “mitigation” can further be classified into three subprinciples:

1. **Redundancy** Make same functions parallel.
2. **Fail-safe** Incorporate material/equipment to mitigate harmful conditions.
3. **Protector** Make harmful conditions not produce losses.

The previous example corresponds to “redundancy”. On the other hand, changing the design of the insufflators so that they are not capable of delivering pressure far exceeding any requirement for its intended use in surgery is an example of “fail-safe” to mitigate the effects caused by errors in operating gas insufflators. Requiring laboratory technicians to wear glasses and training them to immediately flush their eyes with water if they have been splashed with

4 Error Proofing, Healthcare

a toxic substance can mitigate the effects of being splashed with a toxic substance. This is an example of “protector”.

Systematic Generation of Error Proofing Solutions

Although the five error proofing principles described in the previous section are useful for understanding various error proofing solutions, we need some tools for systematically generating error proofing solutions that can attain the change required by each principle for the individual case.

Solution Directions for Error Proofing in Healthcare

When observing the process where each error proofing solution is generated, we find that there are some common directions of thinking to reach the solutions [10]. These directions were investigated and classified into the following 11 types:

1. *Trimming*: example, eliminate manual data entry.
2. *Self elimination*: examples, broken pills do not roll; pill trays.

3. *Standardization*: examples, make asymmetrical parts symmetrical; one size fits all; standard forms.
4. *Unique shapes/geometry*: examples, electrical outlets; pill shape; symbols.
5. *Copying*: examples, duplicate forms; blood ID barcodes; emergency power generator.
6. *Prior action*: examples, premeasured dose; supplier supplies 100% inspected parts.
7. *Flexible films or thin membranes*: examples, medicine bottle safety seal; prepackaged doses; coffee packs; rubber gloves.
8. *Color*: examples, color-coded charts; zones; medicines.
9. *Combining*: examples, patient records; medicine capsules with fast and slow release.
10. *Counting*: examples, tally sheets; count repetitive actions.
11. *Automatic inspection*: (presence/absence; property variation): examples, electronic verification (bar code; patient record validation; patient monitoring).

Relationships between the Principles and the Solution Directions

Table 2 shows the relationships between the error proofing principles and the solution directions. From

Table 2 Error proofing principles and solution directions for healthcare^(a)

Solution direction Principle		Trimming (7%)	Self elimination (7%)	Standardization (20%)	Unique shape/geometry (2%)	Copying (redundancy) (5%)	Prior action (23%)	Flexible films or thin membranes (2%)	Color (5%)	Combining (23%)	Counting (1%)	Automatic inspection (automation) (7%)	Total	Number of error proofing solutions

^(a)One error proofing solution may be reached using more than one solution direction

this table, we can see that there exist typical combinations of the principles and the solution directions, which are frequently used in many solutions: e.g., elimination by trimming, replacement by prior action, facilitation by standardization, detection by self elimination, and mitigation by copying.

Consulting Questions for Generating Error Proofing Solutions

Table 3 shows the consulting questions, which have been developed by focusing on the typical combinations between the principles and the solution directions. By answering each of the listed questions, we can generate error proofing solutions systematically for the individual case.

Let us consider the following assumed accident in a hospital: there are two patients per room; the medical charts are hung on the end of the patient's bed; the cafeteria worker unintentionally knocks both charts on the floor while removing the dinner trays and quickly replaces the charts, but on the wrong

beds; the nurse on the new shift gives the prescribed medicine to the wrong patient. This accident was caused by the combination of three human errors:

1. The cafeteria worker knocks both charts on the floor.
2. The cafeteria worker replaces the charts on the wrong beds.
3. The nurse did not notice the mismatch between charts and patients.

Therefore, the questions in Table 3 are applied to each of the above errors for generating error proofing solutions. Table 4 shows a portion of the generated solutions.

Conclusions

In our research, more than 500 error proofing solutions successfully implemented in healthcare were investigated and the principles of error proofing and the solution directions existing behind them

Table 3 Consulting questions for generating error proofing solutions

1. Eliminate tasks/risks
• Trimming – Can we eliminate the error-prone process or harmful objects? • Self elimination – Can harmful action or object eliminate itself?
2. Replace human operations
• Automation (Automatic inspection) – Can we automate the process to solve our problem? • Prior action – Can we do something beforehand to support human operations? • Combining – Can we combine (bring together/closer) two or more things to automate or support human operations?
3. Facilitate human operations
• Trimming – Can we trim similar or confusing things to facilitate human operations? • Standardization – Can we standardize the process to facilitate human operations? • Copying – Can we use redundancy to facilitate human operations? • Prior action – Can we do something beforehand to facilitate human operations? • Flexible films or thin membranes – Can we use flexible films or thin membranes to facilitate human operations? • Color – Can we use color to facilitate human operations? • Combining – Can we combine (bring together/closer) two or more things to facilitate human operations?
4. Detect abnormalities
• Counting – Can we count something to detect abnormalities in the human operations or their results? • Self elimination – Can we let people notice abnormalities by themselves? • Unique shape/geometry – Can we use shapes (1D, 2D, or 3D) to detect abnormalities in the human operations or their results? • Automatic inspection (automation) – Can we automatically inspect something to detect the abnormalities in the human operations or their results?
5. Mitigate effects
• Copying – Can we use redundancy to mitigate the effects? • Prior action – Can we do something beforehand to mitigate the effects? • Flexible films or thin membranes – Can we use flexible films or thin membranes to mitigate effects?

6 Error Proofing, Healthcare

Table 4 An example of generating error proofing solutions

Error	Principle	Consulting question	Generated solution
The cafeteria worker knocks both charts on the floor	Elimination	Trimming – Can we eliminate the error-prone process or harmful objects?	Ensure charts are not dropped by touching
		...	...
	Replacement	...	...
	Facilitation	...	...
		Prior action – Can we do something beforehand to facilitate human operations?	Move chart to new location.
The cafeteria worker replaces the charts on the wrong beds		...	...
	Elimination	...	...
		...	...
	Replacement	...	...
		Prior action – Can we do something beforehand to support human operations?	Paste a name tag at the end of the bed, on which the chart is hung
		Combining – Can we combine (bring together/closer) two or more things to automate or support human operations?	
	Facilitation	...	...
		Color – Can we use color to facilitate human operations?	Color ends of beds and charts to differentiate two patients
		...	...
	Detection	Self elimination – Can we let people notice abnormalities by themselves?	Change the shape of chart hanger so that the wrong patient chart cannot be hung.
...		Unique shape/geometry – Can we use shapes (1D, 2D, or 3D) to detect abnormalities in the human operations or their results?	
		...	...
	Mitigation	...	...
	...	...	...

were extracted. Using them enables us to systematically generate error proofing solutions to prevent healthcare-related errors and implement the activities for ensuring patient safety more effectively and efficiently.

Cost of Quality

Introduction

Cost of quality is a concept that has likely been around since the first caveman discovered his spear was broken just before the tiger pounced. Our understanding of these costs has evolved tremendously over the years driven by examples of costs eliminated and the stunning gains made through statistical **quality control**, continuous quality improvement, **reengineering**, or – more recently – **lean** and **Six Sigma** initiatives. The millions of cost reductions and substantial savings achieved by these activities have refined our thinking about the opportunities in managing the cost of quality. As examples of a \$4 million design change reducing \$20 million of warranty costs, of a \$1000-measurement system eliminating \$500 000 of waste, of a few million dollars in computer-assisted invoice checking saving tens of millions of dollars and many other examples were reported. Senior managers began to look for new ways to understand and find these costs.

For many years, people argued over whether we should discuss cost of quality or cost of poor quality. Most of these arguments were resolved by Joseph M. Juran many years ago with his clear explanation of the difference between features and failures. Adding features to a product or service almost always adds costs. In this definition of quality increased quality means higher costs. Failures almost always cost far more to the organization than they do to prevent, this poor quality is where many organizations found great opportunities for great returns on investment. Reducing failures almost always reduces costs.

But for a full understanding of the costs of our business we must consider both. Features are often a market decision. If the customer is willing to pay more for air conditioning and a superb sound system in an automobile than the cost to provide them, we have made a good decision in improving quality. If we offer features that add more costs than the customer sees as value, we have made a poor decision. If we are missing features that the customer finds absolutely necessary and refuses to purchase the product or service, we have made an even poorer decision and our organization has incurred an enormous cost due to our poor quality. It is hard to imagine a television being sold without

a remote control device. This points out one of the difficulties of feature quality. Many features that add value and increase market soon become necessary standard features. Noriki **Kano** has described this beautifully in his articles on attractive quality and necessary quality.

The Hidden Factory

Failure costs are where most organizations have focused their cost of quality efforts. These costs can be a substantial part of the organization's total operating costs. Both W. Edwards Deming and Joseph M. Juran estimated these failure costs to be as high as 30% of even well-managed companies. Juran's hidden factory example made this clear. He stated that every organization has two factories, one produces product that we sell, the other produces product that we throw away. If we could just find the hidden factory and close it down, we could save 20 or 30% of our costs.

These costs in a real factory are often quite visible: scrap, rework, machine downtime, recycled materials, and so on. The costs in white-collar work are harder to see, but usually far larger: reports that are not read, analyses never used, meetings with no value added, and so on. Even the basic traditional thinking of quality costs identified many of these costs and companies made substantial gains by reducing or eliminating these costs. Unfortunately, many of these quality costs were assumed to be part of the costs of doing business and unmeasured and hidden. Far too many companies only measured the "variance to standard costs" meaning that certain amounts of scrap, rework, machine downtime, work-in-process inventory, and other costs were necessary. Only the amount the standard costs were exceeded were considered a problem. Waste was built-in.

Traditional Quality Costs

For many years we had a limited view of the cost of quality. We defined it as four areas that were reasonably easy to measure: prevention costs, appraisal costs, internal failure costs, and external failure costs.

2 Cost of Quality

Prevention Costs

These costs are often the subject of much debate and confusion. Many people would include a number of design activities, reliability modeling, prototype testing, pilot runs, and other costs as prevention. Others call these standard design and development costs and only include the activities of the quality department in these costs. Some companies do not include these activities at all and just focus on the appraisal and failure costs.

Appraisal Costs

Appraisal costs are also measured differently in organizations. Some organizations include all checking, inspection, measurement, testing, field trials, auditing, and other appraisal costs no matter where they are done or who does them. Many of these costs are attributed to part of the time of assembly workers, supervisors, packagers, and even automated test equipment. Other companies just count the costs of people actually assigned to quality departments and their equipment, space, and other costs. There is also uncertainty about which costs should be included. If the tests are required by the customer, regulatory agencies, or others, are these really costs of quality or costs of selling the product. Most companies include all these costs in their definition of appraisal costs.

Internal Failure Costs

These costs include all costs incurred during the production of the product or service before delivery to

the customer. Thus all rework, machine downtime, delays, scrap, failure analysis, repair, retesting, bottlenecks, excessive work-in-process inventories, review meetings, and replacement parts are all counted.

External Failure Costs

These are the costs incurred after the product or service is delivered to the customer. Returned goods, warranty costs, repair costs, inventories of parts kept to make repairs, service staff, rebates, complaint handling, fines, penalties, lost revenue, and bad will are all counted in external failure costs.

Rethinking Optimum Quality

We also thought for many years that we could find the “optimum quality level”. This theoretical level would be exactly where the costs of preventing defects was equal to the cost of these defects. This is illustrated in Figure 1(a). This thinking led to concepts such as acceptable quality levels (AQLs) and other quality targets that have been discarded by most leading organizations in the past decades. There were many problems with the optimal quality level. The underlying assumption was flawed. We assumed that defects could only be eliminated by increasing costs – more appraisal or higher-quality parts or more careful assembly. Therefore, as quality levels were improved, costs necessarily went up. But there are many ways to improve quality. An automated test set may actually be cheaper and far more effective than inspection by operators thereby

Figure 1 (a) Old thinking of cost of quality and (b) New thinking of cost of quality

reducing inspection costs and improving quality. Statistical process control, error-proofing, and other methods may eliminate defects and reduce internal costs. Again quality is improved and costs are reduced. Better designs or parts from suppliers that are higher quality and lower cost may also change the curve.

There are many other problems with this model. Quality is dynamic. The costs of defects today may be far higher than a few years ago due to more complex systems, customer demands, or repair costs. Quality is relative. An optimum quality level calculated by the producing organization may be worse than what a competitor is offering at even a better price. We may lose market share or the entire market changing the cost calculations dramatically. New methods for checking and assuring quality are continually being developed changing the cost curves far faster than we change our model and calculations.

Today most organizations use a different model, Figure 1(b). The optimum quality level is thought to be zero failures or 100% conforming products. Pursuing perfection is a basic tenet of Six Sigma quality and other philosophies. Each reduction in defects is done on a return on investment basis. Improvements are implemented whenever the cost of the change is less than the savings. For some products or services, we may never actually achieve perfection, but each step toward perfection brings additional savings.

Quadratic Loss

A further understanding of optimum quality is often attributed to Genichi Taguchi although many others were also using this concept. This is the understanding that in many situations the terms defects, nonconformances, or defectives is inappropriate. For example, in producing copper wire for telecommunications or electric power grids, resistance is a key variable. Setting upper and lower limits and calling wires outside the limits defective and all wires inside the limits good misses the point. Any deviation from the target causes loss, the further away from the target the higher the loss. Machined parts, gears, bearings, electronic components, administration of medicines, and many other products and even services should be measured with respect to deviations from a target not in binary descriptions such as conforming and nonconforming.

Newer Thinking of Quality Costs

In doing the research for his Ph.D. thesis at Sweden's Royal Institute of Technology, Lars Sörqvist studied a number of companies' best practices in managing quality costs. Although none of the companies used all the methods, he found that all had expanded their quality cost management beyond the traditional understanding. He summarized quality costs in five categories.

Traditional Poor Quality Costs

These are the costs described above. These costs often just include the sporadic problems that disrupt operations or are measured by the company's traditional accounting system. Chronic problems – often thought to be the normal costs of doing business – are not measured and are not seen as opportunities for improvement.

Hidden Costs

These quality costs have been hidden in our usual accounting methods or have not been defined as quality costs by the organization. Failure costs in nonmanufacturing operations (service, white-collar work, sales, legal, marketing, and distribution) are often well hidden. Many companies use the iceberg analogy to show this, the traditional quality costs are measured and visible, but below the surface of the water are hidden numerous other quality costs (see Figure 2).

The largest hidden costs of quality are non-value-added work. These are work processes that are done without thinking, usually “because we have always done it this way”. Unnecessary forms, wasteful meetings, moving items from place to place, multiple approvals, unused databases, many surveys, and unread reports are all examples of non-value-added work. Reengineering activities were often quite successful by just eliminating or reducing these items. Other hidden costs include areas not usually thought of as quality costs such as employee turnover, expediting, and answering customer questions due to poor communications or instructions. Employee turnover can create huge costs. Recruiting, training, and lost productivity can result in some of the highest quality costs to organizations with positions where skilled workers are needed.

4 Cost of Quality

Figure 2 The hidden costs of quality

Lost Income

Another quality cost is income lost due to poor quality or the reputation for poor quality. Customers may perceive quality problems and not purchase, or purchase and return the product due to problems. Customers may demand their money back for services not at the quality level they expected. Companies may voluntarily rebate part or all of the purchase price due to product or service failures. Customers may change brand loyalties and switch to a competitor's product permanently creating long-term income losses. Customers may tell many others about their dissatisfaction leading to even greater lost income.

Customers' Costs

Leading companies are now beginning to understand that quality costs extend beyond their own costs to the costs the customers endure. The failure of a product may be totally covered by a warranty, but the customer has other costs due to time lost, the unavailability of the product, and other costs. Business customers may lose time, production, and even their customers due to failures of components, products, or services they have purchased. Sophisticated customers are now thinking in terms of total

life-cycle costs and product failures, lost time, extra inventories, delays, and other costs are considered in addition to initial price when making their purchase decisions. Customers who wait for hours in dentist's or doctor's offices or emergency rooms, or are put on hold on the telephone for many minutes, or wait for hours at home for deliveries are changing service providers.

Costs to Society

These are the costs to the community at large. Some of these are obvious: oil tanker spills in Alaska, disastrous side effects of drugs, nuclear power plant accidents. Other costs are harder to measure, but we are now beginning to be more sophisticated in estimating environmental costs, safety costs, time losses, security costs, and other costs incurred by various quality failures. Sometimes these costs are partially recovered through fines, lawsuits, and other means but usually they are borne by society as a whole or indirectly paid by higher taxes, regulatory fees, or other means. This new understanding of quality costs is including the producers' costs, the customers' costs, and the costs to society at large through the entire product life cycle.

Making a Cost of Quality Study

Frank Gryna in *Juran's Quality Handbook*, 5th Edition, gives a useful guide for studying quality costs and identifying opportunities for major savings. He suggests the following sequence:

1. Review the literature and consult others who have done similar studies.
2. Select part of the organization to serve as a pilot site.
3. Discuss the objectives of the study with key people in the organization.
4. Collect whatever cost data are conveniently available from the accounting system and use this information to convince senior management of the need for a complete study.
5. Make a proposal to senior management for the complete study.
6. Publish a draft of the categories defining the quality costs.
7. Finalize definitions and secure management approval.
8. Secure agreement on responsibilities for **data collection** and analyses.
9. Collect and summarize the data, involve the finance department as much as possible.
10. Present the costs to management along with specific recommendations and the results of an improvement project using the data.

Failure Modes and Effects Analysis

Introduction

Failure modes and effects analysis (FMEA) is a method of investigation for determining how a product, process, or system might fail and the likely effects of particular modes of failure. For example, a product, machine, or structure might fail physically as a result of a faulty part or user behavior. A manufacturing, business, or administrative process might fail operationally as a result of poor personnel training, faulty control, faulty design, or faulty equipment. In all of these cases and others, FMEA can be used to help assess the possible ways in which failures might occur, assess the magnitude of the effects of failure, uncover the possible cause or causes of failure, and understand what can be done to prevent such failures or mitigate the likelihood of their occurring.

Having originated in the U.S. military in the 1940s, FMEA today is an analytical tool widely employed in approaches to quality like ISO 9000, ISO/TS 16949, Six Sigma, and Design for Six Sigma (DFSS). FMEA is both a qualitative and quantitative technique. Ideally, a team undertaking an FMEA of an existing product or process would have historical data or data from monitoring systems that would indicate possible modes of failure and their most important causes. However, in many cases there may be no valid measurement system in place and, in the case of new products or processes, no historical data. In those cases, the team must determine subjectively, based on their knowledge and experience, the likely modes of failure, the practical consequences of failure, and potential causes of failure.

The team then evaluates the degree to which current control mechanisms or procedures are likely to detect the cause of failure before it occurs or before its effects occur, thus allowing time to take corrective action. For example, bald automobile tires indicate that the tires should be replaced, thus preventing a failure. But for other modes of failure, such as a blowout due to a sudden puncture, it is impossible to detect the causes prior to failure.

The team numerically rates each of those three elements: effects, causes, and detection. On a scale

of 1–10, an effect is rated for severity, where 10 is “catastrophic”. For causes of failure, the team rates likelihood of occurrence, with 10 being “highly likely”. For detection, the team rates the unlikelihood of detecting a cause or failure mode far enough in advance to prevent its effect, with 10 indicating that it is virtually impossible to detect before the effect occurs. The three numbers are then multiplied for each cause–effect–detection combination, of which there may be several for each failure mode, to arrive at a *risk priority number* (RPN):

$$\begin{aligned} &(\text{Severity of effect}) \times (\text{Likelihood of occurrence}) \\ &\times (\text{Unlikelihood of detection}) = \text{RPN} \end{aligned} \quad (1)$$

For example, an effect rated 10 for severity, 10 for likelihood of occurrence, and 10 for unlikelihood of detection (where 10 indicates *no* likelihood of detection) yields an RPN of 1000 – the worst possible case. Conversely, ratings of 1, 1, and 1, respectively, yield an RPN of 1, indicating a cause–effect–detection combination of no concern. RPNs can fall anywhere along this scale of 1–1000, and the higher the RPN, the greater is the cause for concern. Therefore, the FMEA team usually first addresses the potential failures of greatest concern. Corrective actions are identified and implemented. Subsequently, the FMEA ratings can be repeated to determine if the corrective actions have been effective, enabling the team to reduce levels of risk for the most critical factors over time.

Applications

Existing Products or Processes

The most common application of FMEA is in the improvement of existing products and processes. The analysis may be undertaken as part of a process improvement effort such as a Six Sigma program or as an *ad hoc* piece of work. For example, a team of investigators considering an existing product would typically begin with the question: *how could this product fail?* They might consider possible modes of failure both in the factory prior to release of the product as well as failure in the customer’s hands, and the effects of failure, known as *liability*. Here the RPN is helpful in attacking the areas of most likely failure and least available control or detection.

2 Failure Modes and Effects Analysis

Design of New Products or New Processes

FMEA can also be used during the design stage of a new product or process to determine the possible failure modes, their effects, and the most efficient approaches to reducing the risk of those failures. In this context, FMEA is often one of the analytical tools used in DFSS, a structured, risk-management approach to product and process development that aims to design-in a Six Sigma level of performance from the inception of a product or process.

To analyze the potential design of a new product, design engineers can use FMEA to determine the ways in which the product could fall out of specification and become unsuitable for release. They can also analyze the ways in which the product could fail in the hands of the customer. For example, possible failure modes, such as overheated material or improper production line speeds that could drive the product out of specification during production, are compiled and their causes are determined. Because the product is not in full-scale production, a relevant set of preventive controls and detection mechanisms can be audited or created. In many organizations, as there are only limited resources for these development efforts, RPNs can be used to determine which areas to attack and how much effort to invest in preventing each failure mode and the related out-of-specification condition.

Post-Failure Analysis

Following a failure, FMEA can be used to perform a “postmortem” of the event. In this case, FMEA provides a format for compiling the failure modes present, linking them to the known effects, and then auditing the effectiveness of controls. Because the effects are known and have already occurred, the RPN is not relevant in this instance.

FMEA as a Statistical Tool

Although FMEA is not a purely statistical tool, it is consistent with what may be more broadly characterized as statistical thinking, the three elements of which are process, variation, and data. Processes produce variation, and data are used to understand the sources of variation and eliminate it or keep it within acceptable limits. In 1996, the American Society for

Quality defined statistical thinking as a philosophy of learning and action based on the following fundamental principles:

- all work occurs in a system of interconnected processes
- variation exists in all processes
- understanding and reducing variation are keys to success.

It is those principles that underpin the FMEA approach to analyzing and improving processes. However, because FMEA depends on the FMEA team’s subjective knowledge of the process under investigation, the results of the analysis are only as good as that process knowledge.

The FMEA Session

Prior to undertaking FMEA, it is necessary to complete a process map of the process under study, which could include a specific product under investigation. A process map is a step-by-step pictorial sequence of a process, showing process inputs, process outputs, and processing steps. In addition, any specifications or fitness-for-use issues should be available for study. For example, for a product under study, it is helpful to understand the quantitative customer specifications and the more qualitative fitness-for-use criteria like reliability and durability. In assembling the team, it is advisable to include members representing all aspects of the process. For example, if a product is under investigation, the team should include members from product design through development and, finally, to operations.

For maximum efficiency, each session of an FMEA should be restricted to no more than a few hours. Typically, two to four sessions are required to complete an FMEA. At the beginning of a session, the team should develop scoring keys, including clear definitions of the numbers 1 through 10 for each of the factors of the RPN. These definitions should be reviewed each time the FMEA is restarted.

If there are numerous inputs for the process, the cause and effect (C&E), customer, or the super-focused approach, not the comprehensive approach, should be used. The C&E and the super-focused methods utilize a smaller number of inputs, which have been prioritized as to their relationship with various output measures. The customer method also

has a smaller number of inputs – those that have a direct relationship with very specific customer needs. The comprehensive approach analyzes each input with no prioritization, which increases the time devoted to the FMEA and leads to many inputs of lesser risk being studied.

When analyzing each individual failure mode, it should be remembered that a failure mode may have more than one effect and it may have more than one cause. Assuming a one-to-one relationship between failures and effects leads to missed causes of failure modes. (Because effects are generally easier to compile than causes, there is a far less chance of such assumptions leading to missed effects.) The failure to uncover causes can contribute to poor results, since, obviously, no action can be taken against them.

As controls or detection mechanisms are put in place, the RPN should be rescored. When the rescoring takes place, the RPN should be lower as a result of the controls, the lower RPN means that there is less risk to the process. Reduced process risk leads to more stable and improved performance, which is manifested in various output metrics. These output metrics can then be used as part of another process improvement initiative, and these metrics will be monitored within the project life and potentially, afterward as well. Improved metric performance can be measured more easily than iterative RPN rescoring over time, and they should be inversely related.

FMEA in Action: A Business Process Example

The mechanics of performing an FMEA for a business process can be illustrated by following its steps through a typical process improvement project, in this case, a faulty accounts payable process. In an accounts payable process, an invoice accompanies goods that are sent to the purchaser. The invoice is matched with the goods and a method of payment is set in motion to pay the invoice within the prescribed terms.

As with any transactional process, there are multiple possibilities for failure. Consider, for example, just one subprocess in the overall accounts payable process: invoice reconciliation. The goal of this subprocess is to reconcile invoices on a one-to-one basis with the goods received. As depicted in the typical FMEA table and rating chart in Figure 1, the FMEA

team begins by asking what can go wrong with the input for the process. In this case, one possibility is the arrival of an incomplete invoice. The team then asks what the effect might be of that particular mode of failure. One possible effect is the incurring of penalties for late payment.

Next, they ask what process variables could cause this failure mode – in this case, they believe that it is the incorrect placement of vendor information, such as shipping addresses, in the master vendor list. They then consider the current controls that are relevant to the prevention of this cause of failure and discover that although a process exists for signing up new vendors through a web-based tool, there is no comparable oversight for data on older vendors.

The team then scores on a scale of 1–10 the severity of the effect, the likelihood of its cause occurring, and the unlikelihood that current controls can detect the problem before its effects ensue. It should be noted that the rating of each of these three elements is performed at the end of the FMEA process, not at the time each element is first encountered in the investigation. Further, the highest effect of a failure mode drives the rating score or RPN. When there is more than one effect for the failure mode, the process of reducing causes of the failure mode will make all effects less frequent.

In this example, the team concludes that a late payment and the resulting penalties rate a 10 for severity. The team then rates the likelihood of an incomplete invoice occurring and assigns it a 6. They then calculate the unlikelihood of detection of the problem by current controls, with 10 indicating that there is no likelihood at all. Because there is virtually no real process in place to detect the problem, it is assigned an 8. The team then calculates the RPN:

$$\begin{aligned} (\text{Severity} = 10) \times (\text{Likelihood of occurrence} = 6) \\ \times (\text{Unlikelihood of detection} = 8) \\ = \text{RPN of 480} \end{aligned} \quad (2)$$

The team might then similarly investigate other possible combinations of effect–cause–detection, calculate the RPNs for each, and pursue corrective actions in the descending order of the RPNs.

4 Failure Modes and Effects Analysis

Figure 1 FMEA table and rating chart

FMEA in Action: A Manufacturing Example

The mechanics of performing an FMEA in manufacturing can be illustrated by following its steps through the solution to an equipment problem in a chemical manufacturing process.

A key production area is consistently hampered by a piece of equipment having pressure build-up issues as a result of severe fouling. The equipment stands at the end of a multi-step process where chemical solutions are made, then deposited on another material, and finally dried before final handling. The problem occurs at the drying stage. The team begins by conducting a Six Sigma investigation with many variables being studied in a hope that this equipment can be optimized to reduce the pressure build-up issues. After establishing a context with an overall process map and clarifying some of the output variable impact through cause-and-effect analysis, the team undertakes an FMEA.

In studying areas throughout the process during an FMEA session and feeling confident about the ability to detect and control problems in many of those areas, the team determines detection/control scores of 2 for them, leading to low overall RPNs. However, one major process area that has not been previously analyzed leads to highly technical discussions. The team realizes that it has little confidence that these issues can be detected and determines a score of 8

for unlikelihood of detection. Because the likelihood of occurrence of the problem at this level of analysis is unknown, the team, as a precautionary measure, scores this element as 10. The severity of the effect is determined to be 8, resulting in an RPN of 640, as depicted in Table 1.

As a result of this FMEA session, the team changes focus to an upstream technical problem versus a downstream optimization issue. After some study the phenomenon causing the pressure issues is located in a preparation process. Controls are put in place and the subsequent rise in the capacity of the process, system availability, and product quality confirms that the team has found the root cause of the pressure problems.

History

FMEA has its origins in the United States military, which first formalized it on November 9, 1949, in MIL-P-1629, "Procedures for Performing a Failure Mode, Effects and Criticality Analysis" (FMECA). Its stated purpose was to classify failures "according to their impact on mission success and personnel/equipment safety". FMECA provided the foundation for the military's subsequent refinements of the technique, embodied in MIL-STD-1629 (November 1, 1974), which encompassed FMECA, FMEA, and variants including damage

Table 1 Determining RPNs in a manufacturing process

Process step/input	Potential failure mode	Potential failure effects	SEV ^(a)	Potential causes	OCC ^(b)	Current controls	DET ^(c)	RPN
Raw material addition	Raw material (RM) flow rate is too high	Off-specification material	10	Weigh cell failure	1	Digital control system (DCS) program/lab verification	2	20
Raw material addition	RM flow rate is too high	Downstream equipment plugging	4	Weigh cell failure	1	DCS program/lab verification	2	8
Raw material addition	Moly flow rate is too low	Off-spec material	10	Weigh cell failure	1	DCS program/lab verification	2	20
Additive preparation	Concentration is too high	Precipitation leading to downstream equipment plugging	4	Weigh cell failure	1	Basic labs and appearance checks	2	8
Additive preparation	Concentration is too low	Off-spec product	10	Weigh cell issue	1	Basic labs and appearance checks	2	20
Additive preparation	Wrong or other concentration	RM does not dissolve	5	Operator loads wrong amount of additive bags	2	Basic labs and appearance checks and marked additive bags	2	20
Process setup (method A or method B)	Operational issues with method A	Downstream equipment plugging and product quality issues	8	RM physical property issues	10	Basic labs and appearance checks and equipment pressure	8	640
Process setup (method A or method B)	Method B operates as method A	Product quality	8	Incorrect time intervals	2	Sampling, operator checks on DCS, DCS alarms	2	32

^(a)Severity of Effect^(b)Likelihood of Occurrence^(c)Unlikelihood of Detection

modes and effects analysis (DMEA). MIL-STD-1629A was released on November 24, 1980, and was updated by MIL-STD-1629A change note 1 on June 7, 1983, and MIL-STD-1629A change note 2 on November 28, 1984. MIL-STD-1629 was canceled by MIL-STD-1629A change note 3 on August 4, 1998.

FMEA subsequently spread to other fields. In the 1960s, it was adopted by the aerospace industry and applied to the Apollo missions. In the 1970s, its utility was broadened to include the analysis of software-based systems. Also in the 1970s, Ford Motor Company used FMEA to troubleshoot potential design and safety failures following highly publicized lawsuits about the company's Pinto model. In the early 1980s, the automotive industry as a whole adopted FMEA when Ford, the Chrysler Corporation, and General Motors Corporation jointly developed the QS 9000 standard, known in other industries as ISO 9000, to standardize supplier quality systems. To comply with QS 9000, automotive suppliers were required to use FMEA. This initial effort culminated in SAE J-1739, an industry-wide FMEA standard adopted by the Society of Automotive Engineers in 1994.

Although FMEA is a relatively new tool in the field of process failure analysis, its use today includes manufacturing and transactional areas; process, product and software development; general process improvement and specific product failure work, and strategic planning review and capital project implementation.

Quality Function Deployment

Introduction

Quality function deployment (QFD) is a planning tool that allows the flow down of high-level customer needs and wants through to design parameters (DPs) and then to process variables (PVs) critical to fulfilling the high-level needs. By following the QFD methodology, relationships are explored between quality characteristics expressed by customers and substitute quality requirements expressed in engineering terms, also known as *critical-to-satisfaction (CTS) characteristics* within the terminology of Design for **Six Sigma**. In the QFD methodology, customers define their wants and needs using their own language, which rarely carries any actionable technical terminology. The voice of the customer (VOC) can be grouped (using affinity diagram) into a list of needs and wants, which can be used as input to a QFD's relationship matrix house of quality (HOQ).

Knowledge of customer's needs and wants is paramount in designing effective products and services with innovative and rapid means. Utilizing the QFD in the context of design for Six Sigma (DFSS) methodology allows the developer to attain the shortest development cycle while ensuring the fulfillment of customer needs and wants as depicted in Figure 1.

History of QFD

QFD was developed in Japan by Dr. Yoji Akao and Shigeru Mizuno in 1966 but was not westernized until the 1980s. Their purpose was to develop a quality assurance method that would design customer satisfaction into a product before it was manufactured. One of the first published applications of QFD happens to be in Bridgestone's Kurume factory by Kiyotaka Oshiumi who followed the steps of Dr Akao. For 6 years the methodology was enhanced from the initial crude usage of Kiyotaka Oshiumi of Bridgestone Tire Corporation. Following the first publication of *Hinshitsu Tenkai*, i.e. quality deployment in Japanese, by Dr. Yoji Akao [1] in 1972 the pivotal development work was conducted at Kobe Shipyards

for Mitsubishi Heavy Industry. Stringent government regulations for military vessels coupled with the large capital outlay per ship forced Kobe Shipyard's management to commit to upstream quality assurance. The Kobe engineers drafted the QFD matrix, which relates all the government regulations, critical design requirements, and customer requirements to company technical controlled characteristics of how the company would achieve them. In addition, the matrix also depicted the relative importance of each entry, making it possible for important items to be identified and prioritized to receive a greater share of the available company resources. The Kobe application resembles an application that is very similar to how QFD is defined today.

In 1978 the detailed methodology was published [2, 3] in Japanese and was translated to English in 1994.

QFD Methodology

QFD is accomplished by multidisciplinary teams using a series of matrices, or phases of the HOQs, to deploy critical customer needs throughout the phases of the design development. Figure 2 depicts the rooms and the generic HOQ. Going room by room, we see that the input is into Room 1 in which we answer the question "what". These "whats" are either the results of VOC synthesis for HOQ 1 or a rotation of the "hows" from Room 3 into the following HOQs. These "whats" are rated in terms of their overall importance and placed in the Importance column. This column contains the importance rating for each "what" or voice listed in Room 1 from the customer perspective.

Next we move to Room 2 and compare our performance and the competitors' performance against these "whats" in the eyes of the customer. This is usually a subjective measure and is generally scaled from 1 to 5. A different symbol is assigned to the different providers so that a graphical representation is depicted in Room 2. Next we must populate Room 3 with the "hows". For each "what" in Room 1 we ask "How can we fulfill this?" We also indicate which direction the improvement is required to satisfy the "what": maximize, minimize, or target. This classification is in alignment with the **robust design** methodology and indicates an optimization direction. In HOQ1, these become "How does the customer

2 Quality Function Deployment

Figure 1 The time-phased effort of QFD *versus* traditional design

Figure 2 QFD house of quality

measure the what?” In HOQ1, we call these *CTS measures*. In HOQ2, the “hows” are measurable and solution-free functions that are required to fulfill the “whats” of CTSs. In HOQ3 the “hows” become DPs and in HOQ4 the “hows” become PVs. A word of caution: teams involved in designing new services or processes often times jump right to specific solutions

in HOQ1. It is a challenge to stay solution free until HOQ3. There are some rare circumstances where the VOC is a specific function that flows straight through each house unchanged.

Within Room 4 we assign the weight of the relationship between each “what” and each “how” using 9 for Strong, 3 for Moderate, and 1 for Weak. In the actual HOQ these weightings will be depicted with graphical symbols, the most common being the solid circle for Strong, an open circle for Moderate and a triangle for Weak (Figure 3).

Once the relationship assignment is completed, by evaluating the relationship of every “what” to every “how”, the calculated importance can be derived by multiplying the weight of the relationship and the Importance of the “what” and summing for each “how” or CTS characteristic. This is the number in Room 5. For each of the “hows” we can also derive quantifiable **benchmark** measures of the competition and our company; in the eyes of industry experts; this is what goes in Room 6. In Room 7, we can state the targets and limits of each of the “hows”. Finally, in Room 8, often called the *roof*, we assess the

Strong	●	9
Moderate	○	3
Weak	▼	1

Figure 3 Rating values for the strength of a “what”–“how” relationship

interrelationship of the “hows” to each other. If we were to maximize one of the “hows”, what happens to the other “hows”? If both “hows” improve, then we classify their relationship as a synergy, i.e. improving one of the “hows” results in improvement of the other “how”, both in their respective direction of goodness, whereas if it were to move away from the direction of improvement, their relationship would be classified as a compromise. Wherever a relationship does not exist it is just left blank. For example, if we wanted to improve customer intimacy by reducing the number of call handlers then the wait time may degrade. This is clearly a compromise. Although it would be ideal to have **correlation** and regression values for these relationships, often they are just based on common sense or business laws. This completes each of the

eight rooms in the HOQ. The next step is to sort on the basis of the importance in Room 1 and Room 5 and then evaluate the HOQ for completeness and balance.

The QFD methodology is deployed through a four-phase sequence shown in Figure 4. Each phase is a replica of the QFD HOQ captured in Figure 2 with some incorporated changes due to a structured cascading process. The four phases are

- Phase 1 – critical-to-satisfaction planning – House 1
- Phase 2 – functional requirements planning – House 2
- Phase 3 – DP planning – House 3
- Phase 4 – PV planning – House 4

Figure 4 The four phases of QFD

4 Quality Function Deployment

Each of these four phases deploys the HOQ with the only content variation occurring in Room 1, the VOC room, also known as the “whats”, and Room 3, the design substitute quality characteristics that answer the “whats”, also known as the “hows”.

QFD Example

There was a business that purchased \$3 billion of direct materials (materials that are sold to customers) and \$113 million of indirect materials and services (materials and services that are consumed internally in order to support the customer facing processes) and yet the business had no formal supply chain organization [4]. The procurement function existed in each functional group so operations purchased what they needed as did human resources, legal, and information systems. This distributed function resulted in a lack of power in dealing with suppliers and mostly supplier favorable contracts and some incestuous relationships (lavish trips and gifts given to the decision makers).

The corporate parent required that all procurement be consolidated into a formal supply-chain organization with sound legal contracts, high integrity, and year-over-year deflation on the total expenses. The design team was a small set of certified Black Belts and a master Black Belt who were being repatriated into a clean-sheet supply-chain organization.

The design team tasked with the project identified the customers and established their wants, needs, delights, and usage profiles. In order to complete the HOQ, the team also needs to understand the competing performance and the environmental aspects that the design will operate within. The design team realized that the actual customer base would include the corporate parent looking for results, a local management team that wanted no increased organizational cost and the operational people who needed materials and services. Through interviews laced with a dose of common sense, the following customer wants and needs (the “whats”) were derived:

- Price deflation
- Conforming materials
- Fast process
- Affordable process
- Compliance
- Ease of use

The next step was to determine how these would be measured in the customer’s eye. The CTS measures (the “hows”) were determined to be

- Year-over-year price deflation (%)
- Defective deliveries (%)
- Late deliveries (%)
- Cost per transaction (\$)
- Cost to the organization per order (\$)
- Speed of order (hours)
- Number of compliance violations
- Number of process steps

Next the team used the QFD application, Decision Capture,^a to assign the direction of improvement and importance of the wants/needs, the “whats” or VOC, and the relationship between these and the “hows”, or CTS characteristics. Figure 5 shows the results. We can see that price deflation is moderately related to percentage of defective deliveries and number of compliance violations, it is weakly related to percentage of late deliveries and strongly related to year-over-year price deflation. We see that price deflation is extremely important and the direction of improvement is to maximize it.

In Figure 5, we can see that the importance of the CTSs has been calculated. The method of calculation is as follows for the top sorted CTS:

Year-over-year price deflation = 9 (strong) × 5 (extremely important) + 1 (weak) × 5 (extremely important) + 3 (moderate) × 4 (very important) + 1 (weak) × 3 (somewhat important) = 65. Thus, the CTS importance score is a product sum of the relationships in Room 4 (in the respective CTS column) by the corresponding “whats” importance rating listed in Room 1. In effect, it is a weighted sum by the importance to the customer. The other columns are similarly calculated.

The upper and lower halves of phase 1 HOQ are shown in Figures 6 and 7, respectively. Figure 6 shows the competitive ratings of the wants/needs (Room 2) and the technical ratings of the CTSs (Room 6). For this purpose the team used Competitor 1 as the incumbent process and used a sister business with a fully deployed supply-chain organization for Competitor 2. The synergies and compromises have also been determined.

The next step would be to assess the HOQ for any “whats” with only weak or no relationships. In this example no such case exists. Now we look for

Figure 5 Partially completed phase 1 QFD HOQ

“hows” that are blank or weak and also see there are none of these.

Summary

QFD is a planning tool used to translate customer needs and wants into focused design actions. This

tool is best accomplished with cross-functional teams and is key in preventing problems from occurring once the design is operationalized. The structured linkage allows for rapid design cycle and effective utilization of resources while achieving Six Sigma levels of performance.

To be successful with the QFD, the team needs to avoid “jumping” right to solutions and process

6 Quality Function Deployment

Figure 6 Upper half of phase 1 QFD HOQ

Figure 7 Lower half of phase 1 QFD HOQ

phase 1 QFD HOQ and other phases (Figure 4) thoroughly and properly before performing detailed design.

It is important to have the correct VOC and the appropriate benchmark information. Also a strong cross-functional team willing to think out of the box is required in order to truly obtain Six Sigma-capable products or processes. From this point the QFD is process driven, but it is not the charts that we are trying to complete; it is the total concept of linking the VOC throughout the design effort.

End Note

Cause-and-Effect Diagrams

Introduction

Statisticians have always been careful not to confuse **correlation** with causation (see e.g., Cox [1]). A famous example derived from statistics on the population of Oldenburg in Germany and the number of observed storks in the city in 1930–1936, demonstrates why correlation does not imply causation [2]. Figure 1 is a scatter plot of population size *versus* number of storks (see **Correlation**).

If we look at the data in Table 1, we quickly realize that time is a lurking variable and that both variables in the scatter plot grow with time, hence the correlation. Since storks need chimneys to make their nests, an increase in the number of buildings, due to an increase in population, explains why more storks are nesting in Oldenburg.

Correlation is therefore not causation, and scatter plots cannot be assumed to describe cause-and-effect

relationships. **Causality** is, however, a basic element of the scientific method and management skills. Establishment of causality relies on a combination of axiomatic thought and empirical evidence derived from **observational studies** or designed experiments (see **Assignable Cause**; **Measures of Association**; **Causality**). Cause-and-effect diagrams are used to present such relationships. We will present three such diagrams: Ishikawa diagrams, structural equation models, and **Bayesian networks**.

Ishikawa Diagrams

In the summer of 1943, at the University of Tokyo, Dr Kaoru Ishikawa was explaining to engineers from the Kawasaki steel works how various factors can be sorted out and related in specific ways. This was the origin of the cause-and-effect diagram later called the *Ishikawa diagram*. The Ishikawa diagram, also called a *fishbone diagram*, came into wide use in the Japanese industry and became a critical tool for **quality control** and quality improvement all over the world. It is one of the seven essential tools for quality

Figure 1 Scatter plot of number of storks *versus* population size

Table 1 Population and number of storks, by year

Year	1930	1931	1932	1933	1934	1935	1936
Population in thousands	50	52	64	67	69	73	76
Number of storks	130	150	175	190	240	245	250

2 Cause-and-Effect Diagrams

and process improvement also called the *magnificent seven* [3]. The Ishikawa diagram is used to identify, explore, and display possible causes of a problem or event. A typical diagram will have four to six main branches for causes affecting one type of event. Traditional classifications of these branches are five Ms: Manpower, Machines, Materials, Measurements, and Methods or, in administrative areas, the four Ps: Policies, Procedures, People, and Plant. A modern variation on the five Ms uses six categories: People, Machines, Materials, Measurements, Methods, and Environment. These are only suggestions typically used to jump-start the brainstorming session used to complete the diagram. Figure 2 is an example from an improvement project initiated by the dean of a school of management to improve the operation of his office, and, in particular, the scheduling of appointments [4]. The improvement team, consisting of the dean, two professors at the school and the two secretaries at

the dean's office, brainstormed to list causes for an unusually high number of "collisions" in the dean's schedule. Many meetings with the dean were delayed or even canceled at the last minute. This problem led to complaints by the faculty and staff about the poor service level of the dean's office. The possible causes that were listed included the open-door approach, lack of meeting agendas, interruptions of all sorts, and no scheduled end time to meetings. Following some more analysis, the dean's office instituted a procedure where all meetings were scheduled with an agenda and an end time. A confirmation note, with this information, was sent ahead of time to the meeting participants. "Collisions" dropped by 50% and the dean's office became a model of service quality on campus. The secretaries even started planning teleconference meetings for specific topics at everyone's satisfaction. For more on Ishikawa diagrams see Ishikawa [3], Brassard [5], and Kenett and Zacks [6].

Figure 2 Ishikawa diagram of causes for scheduling collisions at a dean's office

Structural Equation Models

The geneticist Sewall Wright developed a “method of path coefficients” which is partly graphical and partly algebraic to explain genetic phenomena. Path analysis allows researchers to compute the magnitude of cause-and-effect relationships from correlation measurements, provided the path diagram represents correctly the causal process underlying the data [7, 8]. Later, economists developed a similar approach labeled structural equation modeling. We use here both terms interchangeably.

Structural equation modeling involves the specification of an underpinning linear regression-model incorporating the structural relationships between unobserved or latent variables, together with a number of observed or measured indicator variables.

Structural equation models assume there is a causal structure among a set of latent variables, and that the observed variables are indicators of the latent variables. The latent variables may appear as linear combinations of observed variables, or they may be intervening variables in a causal chain.

As latent variables are, by definition, unobservable, their measurement must be obtained indirectly. This is done by linking one or more observed variables to each unobserved variable. A fully specified structural equation model is potentially a complex interplay between a large number of observed and unobserved variables, and residual and error terms. For more on structural equation models see Bollen [9], Hoyle [10], and Kline [11].

The American customer satisfaction index (ACSI) is a prime application example of a structural equation model. ACSI uses telephone customer interviews, based on a structured questionnaire, as inputs.

Figure 3 The American customer satisfaction survey index model

The latent variables in the ACSI model are presented in Figure 3 as a cause-and-effect model with indices for drivers of satisfaction on the left side (customer expectations, perceived quality, and perceived value), satisfaction (ACSI) in the center, and outcomes of satisfaction on the right side (customer complaints and customer loyalty, including customer retention and price tolerance). The indices are multivariable components measured by several questions that are weighted within the model. The questions assess customer evaluations of the determinants of each index. Indices are reported on a 0–100 scale. The survey and modeling methodology quantifies the strength of the effect of the index on the left to the one to which the arrow points on the right. These arrows represent “impacts”. The ACSI model is self-weighting, to maximize the explanation of customer satisfaction (ACSI) on customer loyalty. Looking at the indices and impacts, users can determine which drivers of satisfaction, if improved, would have the most effect on customer loyalty. For more on ACSI see Fornell *et al.* [12–15].

Structural equation models are also applied to integrated management models. An example of such an integrated model was implemented by Sears, Roebuck and Company into what they call the *employee-customer-profit model*. The cause-and-effect chain links three strategic initiatives of Sears: (a) a compelling place to work, (b) a compelling place to shop, and (c) a compelling place to invest. In order to push forward these initiatives Sears introduced an integrated structural equation model linking how employees felt about working at Sears, how employee behavior affected customers’ shopping experience and how customers’ shopping experience affected profits. The model identifies the drivers to employee retention, customer retention, customer recommendation, and profits. Specifically, the model predicts that five units increase in employee attitude drive a 1.3 unit increase in customer impression, which creates a 0.5% increase in revenue growth [16]. For more on integrated management models see Kenett [17] and Godfrey and Kenett [18].

Bayesian Networks

Bayesian networks combine Bayesian theory with graph theory for inferring probabilistic relationships among variables. They are used to handle complex

Figure 4 An example of causal network (adapted from Lauritzen and Spiegelhalter [19])

problems where variable interactions are too intricate for description by an analytic model. Bayesian networks represent current knowledge by graphically linking cause-and-effect variables. For example, consider a patient that visits a clinic with health related problems. The physician examining her wants to identify the disease and prescribe the correct therapy. Figure 4 is a graph representing cause-and-effect variables linked to tuberculosis and lung cancer. At the top are variables that describe the domain (“visit Africa”, “smoking”). The domain knowledge experts have linked variables describing an effect (i.e., “tuberculosis”) with possible causes (i.e., visiting Africa may cause tuberculosis).

Bayesian networks are directed acyclic graphs (DAGs) in which nodes represent random variables and arcs represent direct probabilistic dependencies among them. The structure of the directed graph provides insights into the interactions among the variables and allows for prediction of effects of external manipulation. Prediction consists of conditioning a causal variable to determine its effect on variables depending on it on the graph. Diagnosis is obtained by conditioning on an effect, in order to ascertain the profile of the causal variables linked to that effect. Conditional dependence probabilities, estimated from data, are used to generate a network representing learned causality. Bayesian networks represent the quantitative relationships among the modeled variables. Let $X_1, \dots, X_n$ be a set of variables and $P(X_1, \dots, X_n)$ be the joint probability defining the knowledge about the problem domain.

Numerically, a Bayesian network represents the joint probability distribution among the n variables. This distribution is described efficiently by

exploring the probabilistic dependencies among the modeled variables and the model size is reduced by conditional independence. Each node, X_i , is a random variable either with discrete or continuous states and is described by a probability distribution, $P(X_i | \text{parents}(X_i))$, conditional on its direct predecessors and quantifying parents’ effects on the node. Nodes with no predecessors are described by prior probability distributions. Then, by the Markov property and conditional independence, the joint distribution is simplified through conditional distributions to:

$$P(X_1, X_2, \dots, X_n) = \prod_{i=1}^n P(X_i | \text{parents}(X_i)) \quad (1)$$

A set of oriented arcs links a pair of nodes and identifies probabilistic dependencies. For more on Bayesian networks see Pearl [20–22], Cowell [23] and **Bayesian Networks**.

RON S. KENETT

Factor Relationship Diagrams

The Fundamental Elements of DOEs

Statistical design of experiments (DOEs) are commonly applied to supplement engineering and process knowledge regarding product compositions and manufacturing processes. The fundamental purpose of DOE techniques is to manipulate product or process factors (X 's) across certain levels to understand their impact on critical performance parameters (Y 's). However, DOEs are often inappropriately resourced, applied, and implemented owing to lack of consideration of key elements of DOE planning. Simultaneously, software models of DOE results are often naively accepted based on a technical consideration of statistical significance without understanding the risks of extrapolating the DOE results into future process, service, or product. Many of the issues with supporting, planning, and investigating DOE results are not technical or statistical in nature; they are based on the need to appropriately question DOE plans and subsequent results prior to making decisions based on a proposed DOE strategy. "Most mistakes in the use of DOE deal with investigating the same factors that are always investigated, rederiving basic first principles that should already be understood, underestimating the impact of noise, and focusing on the tool rather than the questions driving the need for the tool" [1].

A DOE consists of a set of process or product parameters, the *design factors*, deliberately manipulated as factors in the experiment. Additionally, the DOE is influenced by other sources of variation that are not deliberately manipulated but that can impact the experimental results. These nonmanipulated factors are often referred to as *noise*. How these noise factors are managed during the experiment provides insight into the *inference space* of the DOE. How the noise and nonmanipulated sources of variation are managed during an experiment is typically referred to as the *experimental unit structure*. The unit structure consists of the experimental units to which experimental treatments will be applied, uncontrollable factors that cannot be manipulated yet are believed to have an impact on the experimental response(s), as well as sources of variation that are deliberately held

constant during the DOE. Together, the design factors and the unit structure comprise the experimental design.

The Role of the Factor Relationship Diagram

Much of the planning and analysis of DOE focuses on the factor effects, the levels of the factors, and the interactions amongst the design factors, while work to understand the contributions to changes in Y due to the unit structure sources of variation is given much less consideration. However, both statistical and practical conclusions, such as a test for statistical significance, depend as much upon the management of the unit structure during an experiment as it depends on the manipulated factor effects. The factor relationship diagram (FRD) is a schematic tool used to visually display the relationships between the potential sources of variation in a DOE. The FRD shows the relationship between the design factors and the unit structure and provides insight into how this relationship influences the information obtained from the DOE. The FRD was introduced by Wendy Bergerud to assist the experimenter in clarification of the relationship of design factors to their appropriate experimental units in order to increase the likelihood of correct statistical tests [2]. Bergerud's tool was modified and expanded by Sanders and Coleman to provide a visual means for understanding the identification of the experimental inference space and the potential risk involved with restrictions on **randomization** [3]. Additionally, the FRD is coded by font or color to visually differentiate between the design factors, the unit structure, and any lines of restriction in the experimental design.

The basic elements of the FRD are illustrated in the oversimplified example of Figure 1. The example is based on a batch, mixing process without reaction. The three design factors, mix time, blade speed, and mix temperature, are each manipulated in the DOE at two distinct levels, denoted by $-$'s and $+$'s. These design factors are shown in boldface type. Additional sources that can change from one treatment combination to another, thereby influencing the value of the response Y , are shown in italics below the design factor combinations. These sources of variation changing between treatments, such as measurement error and within batch inconsistencies,

2 Factor Relationship Diagrams

Figure 1 Simple FRD for a DOE on a batch mixing process

which are not a part of the design structure of the DOE describe the experimental error for this experiment. Hence, if this experiment is analyzed under the assumption of scarcity using normal **probability plots**, the unit structure at the bottom of the FRD provides insight into sources of variation that can also be creating movement in the experimental response. Also, based on the FRD, one quickly interprets that each experimental treatment requires a batch of product; hence, for a full **factorial** DOE with eight runs, eight batches of product are required. These batches represent the *experimental units*, or the division of material such that any two experimental units receive different combinations of design factors.

Hence, in planning any experiment, it is important to understand the inference space within which the DOE is to be run. Since DOEs necessarily take into account only a small subset of all factors potentially impacting the response of interest, the experimenter must understand those unit structure factors that are

held constant and impact the ability to extrapolate experimental results and those which are changing from one treatment to another impacting the values of the experimental response variable.

The FRD and Restrictions on Randomization

As previously noted, the FRD contains information on the design factors, the unit structure, and any lines of restriction in the DOE. A line of restriction exists when material, personnel, or equipment is not randomly allocated across the treatments or when the treatment combinations are not run in random order. Figure 2 shows an alternative DOE strategy where only four batches are required to complete the DOE. However, the resulting DOE is a **split-plot** design, where mix temperature and blade speed are whole-plot factors and mix time is a split-plot factor. The

Figure 2 Alternative FRD showing a split-plot experiment

experimental units for the whole plot are the four batches, where the experimental unit for the split plot is within batch. The line of restriction (LOR) on the FRD indicates this partitioning of the unit structure in the experiment.

A common mistake is to ignore subsampling and the partitioned unit structure in the DOE of Figure 2 and, thus, to analyze the experimental results as if the DOE were completely randomized. When the restriction is not taken into account, the experimenter would assume seven **degrees of freedom** available for effect **estimation**. However, the FRD in Figure 2 quickly shows that there are only four whole-plot treatment combinations; hence, only three degrees of freedom are available for estimation of whole-plot effects. The remaining four degrees of freedom estimate the split-plot effects – mix time and its interactions with the whole-plot factors. Hence, the LOR provides a visual insight into the appropriate error structure of the experiment, assists in identifying the degrees of freedom available at each hierarchical level of the unit structure, and therefore encourages correct analysis and statistical testing.

Conclusions

The FRD provides a visual means for evaluating alternative DOE plans *a priori* to experimentation to compare potential cost of the proposed experiment with the information available from the experiment. The FRD also helps the experimenter to understand and communicate the inference space of the experiment. Since DOEs only take into account a subset of all of the factors potentially impacting the response of interest, the remainder of the factors are either intentionally neglected or not recognized as contributors to the experimental outcomes. These sources of variation in the unit structure are either held constant or they change across the experimental study, and their effects may be more important than those of the design factors being manipulated in the DOE [4].

Finally, the FRD is a powerful tool for helping the experimenter to understand the outcomes of a DOE. Possible outcomes of a DOE include, but are not limited to:

1. one or more factor effects are identified as statistically significant, or
2. no design factors or their interactions with other design factors are statistically important.

Any of these possible outcomes are not only impacted by the factor selection and the boldness of the levels at which the factors are set, but they are also determined by the management of other sources of variation during the DOE. For instance, if no factors are indicated to be statistically important, then there is evidence that the unit structure changing during the experiment created more variation than did the design factors. The FRD assists in understanding what sources did not vary and which sources of variation may potentially be more important to investigate in further studies.

In summary, the FRD is a visual tool for promoting the effective use of DOEs.

1. The FRD assists the experimenter in understanding the relationship between design factors and the unit structure. It therefore encourages correct statistical tests.
2. Multiple FRDs are useful for comparing multiple alternative DOE plans and communicating the resources required and the information available with each alternative plan.
3. The FRD helps to identify the inference space in which an experiment is run, and it helps to prevent the extrapolation of experimental results without appropriate validation.
4. The FRD visually illustrates the impact of restrictions of randomization in the experimental units, and it thereby encourages proper statistical analysis of DOE results.

Process Maps and Statistics

Introduction

A process map is an invaluable tool for directing the statistical study of a process. When we use statistical methods to gain knowledge of a process with the intention of improving that process, we are working with a process that is already in current operation. Consequently, the methods, materials, work practices, machine settings, and other operating conditions are already in place. At issue then is selecting what set of methods, practices, or parameters to change to improve operation. Our statistical study of the process can only be effective when it is coupled with knowledge of current process behavior. The process map is designed to capture, in the most effective manner, this kind of process knowledge.

In particular, the process map should include knowledge on the process that will guide process study and improvement. We should look to the process map to address the following required information:

1. What process output characteristics are critical for providing customer value?
2. What has been the past experience in maintaining appropriate variation and levels of critical characteristics?
3. What processing factors affect critical characteristics and are they or can they be managed?

The answer to the above questions will clearly require a mixture of organization, engineering, and statistical knowledge to answer. Organizing this information into a manner useful for process study is the aim of the process map.

How to Draw a Process Map

First, it is necessary to determine the scope of the process map. This will be a function of the traditional view of the process, the process owner's sphere of influence, and an expectation regarding the work necessary to improve the process. As a general comment, individuals constructing maps tend to make the scope

of the process too narrow [1]. Before finally deciding on the scope, we should consider those factors, which we are considering as initial inputs to the process. Are some of these inputs internal to the organization? If so, we should consider expanding the process map to include the activities that generated those inputs.

The second step in drawing a process map is to draw a flowchart or other graphical representation of the process. Instructions on flowcharting can be found in the literature [2]. Then, categorized inputs and outputs of the process are added. These inputs and outputs are similar to the kind of information shown on a **cause and effect** (C/E) diagram. The advantage of placing the inputs and outputs on a process map is that, where they effect the process is displayed. Consequently, the nature of how they impact the process can be better understood and **data collection** plans devised to evaluate their anticipated effects. Constructing the process map as described requires that the process be observed several times before the map can approach comprehensiveness and as work is done to improve and maintain the process, the process map will need to be revised to reflect these changes.

Further Characterizing the Inputs and Outputs

The critical outputs of a process (usually referred to as *the big Y's* in **Six Sigma** terminology) can be used to determine how the process is performing. Big *Y's* relate to the overall process and are typically those characteristics of prime importance to the customer. "Little *y's*", again in the parlance of Six Sigma, are intermediate outputs of a process, often measured at the end of process stages. The process map will capture our knowledge of what these intermediate outputs are and indicate whether these "little *y's*" are currently measured or not.

On a process map the inputs, or process "*X's*" (which include measurements made on incoming materials to the process, process methods, parameter settings, environmental factors, etc.) are categorized as controllable (*C*) or noise (*N*). Choosing to control an input and thereby labeling it with a "*C*" indicates that, given the current technology, resources, and process knowledge, these are the variables that need to be managed. Typically, these variables will have target values and requirements on their limits (possibly communicated as specifications). "Noise" refers to variables that either cannot be controlled

2 Process Maps and Statistics

Figure 1 Process map of a crimp operation

(without excessive resources and technology) or are thought to have little influence on the output, so are not controlled. Noise could be intermittent disturbances or common cause, consistent, sources of variation.

Example

A better understanding of a process map is gained by looking at an actual map of a process. The process map shown in Figure 1 was used to describe a crimp operation. It was very helpful in thinking about how the variability in the crimp could be

set to a target with minimal variation. A successful crimp required considering the incoming raw material properties, standardizing the operator procedures, and determining correct machine settings. Examples of other project work supported by a process map can be found in Leitnaker and Cooper [1].

Summary Comments

As previously discussed, a process map is an invaluable tool for directing the statistical study of a process. Some specific examples of uses of the process map are listed, and discussed, below.

1. The process map exists to document current process knowledge. As such it should serve the following purposes.
 - (a) Capture current knowledge as to which inputs need to be controlled.
 - (b) Day-to-day management of processes often focuses on a few, conveniently measured variables, but effective process management requires retaining a more comprehensive picture.
 - (c) A common failure in process improvement work is to make changes to a process without regard to what currently exists and why it is there. The process map helps direct attention to important process characteristics that must be considered when process changes are contemplated.
2. The process map will also serve to enhance improvement activities. Because of the wealth of information captured on a process map, it can be used to generate and support actionable, manageable projects.
3. Most importantly, the process map should be used to provide guidance in planning statistical studies.
 - (a) When the objective of our process study is to evaluate the consistency of process outputs, either intermediate or final, the map provides specific information about the processing conditions across which the study should occur. For example, if an incoming raw material is known to be critical to a process output, a study evaluating the behavior of that output will need to cover a sufficient time across which that material will change.
 - (b) If our process study is to include a statistically designed experiment then the process map provides immediate candidates for possible factors to be included in the designed experiment.
 - (c) A more difficult task in designing an experiment is to understand the effect that process variation will have on experimental error. The process map provides not only a list of sources of variation that affect the process, but also provides guidance about where and at what frequency this variation will occur in the process.
 - (d) By necessity, the conditions seen during any statistical study will be a subset of the conditions that will occur in the future. In the same way that it is necessary to identify the frame and population in statistical surveys, an understanding of the process being studied is necessary for making inferences based on a statistical study. The inference space of a statistical study can be better understood by the use of a process map.

Value Stream Analysis in Quality Management

Introduction

Value stream mapping first gained popularity with the book *Learning to See* [1], published in 1998. The book highlighted a technique that had become commonly used within Toyota, although Toyota does not call it value stream mapping. The technique has since been closely associated with **lean** manufacturing and the Toyota Production System. It has been used widely by those directing lean activities, but value stream mapping can also be utilized to aid in quality improvement efforts.

A value stream can be defined as the sum of all process activities needed to convert the primary product (or service) into a form ready to deliver to the customer. It includes both value-add and nonvalue-add activities. The technique of value stream mapping is a simple tool that seeks to map both material and information flow.

The technique begins (see the section titled “Creating a Current State Map”) with mapping the “current state” of a value stream. The current state map details how the value stream is operating currently. It helps visualize the overall, bigger picture of the process and thereby encourages improvements to the whole value stream, not individual processes. In addition, the technique is useful in generating discussions about how the process, or value stream, is performing.

Once the current state of the value stream is defined, plans can be developed to achieve an improved, or “future” state. This transformation from current state to future state is established by developing the improvement actions that are necessary to achieve this improved state.

In short, value stream mapping has several advantages that have contributed to its popularity and widespread use. Some of these include the following:

- **Helps identify waste** Value-add and nonvalue-add activities, or waste, within the value stream becomes apparent.
- **Helps establish a common language** Those associated with the process can use common terms and common map icons to discuss the value stream. Decisions regarding the value stream become apparent.

- **Results in an implementation plan to guide improvement activities** Activities necessary to achieve the future state become the implementation plan for the value stream improvement efforts. Specific activities can be tied directly to intended results.

- **Shows linkages** Value stream mapping uniquely links material flow to information flow. It also links the symptom of waste (e.g. excessive inventory) to the root causes (e.g., long changeover, poor process capabilities, etc.).

- **Provides data** Unlike other mapping methods, value stream maps possess considerable process data. For example, cycle times, **process yield** rates, and uptime ratios may be captured on the maps.

- **Easy to learn** The technique and an understanding of how to read maps can be taught at all levels of the organization in just a few hours.

- **A useful tool for manufacturing and non-manufacturing processes** Value stream maps can be created for many different types of processes, including manufacturing, healthcare, and transactional processes.

The technique of value stream mapping can also be used to enhance our understanding of a process and be used within **quality management** efforts. Some of the value stream wastes (e.g., excessive inventories, long lead times, etc.) may be due to process quality issues.

One initial step in process improvement is to map the process! In fact, in **Six Sigma** this is typically a recommended step in the “define”, or initial, stage of the project. Simply mapping the process, using the value stream mapping approach, can be used as one of the initial steps to improve the overall quality of the value stream. Sometimes the process quality inefficiencies become painfully obvious when just simply mapped.

In addition to helping identify improvement opportunities and projects, the value stream map aids in identifying the overall business or financial impact the improvements may have on the value stream. For example, decreasing the amount of excessive inventory may have an obvious financial impact of reduced carrying costs. Using the value stream map as an analysis tool may also note that this same project will also decrease the overall lead time to the customer

2 Value Stream Analysis in Quality Management

Figure 1 Current state map—manufacturing. This map details a manufacturing process for electrical motors. Notice the total value-add content for the value stream ranges between 657 to 683 min (approximately 10–11 h) and the nonvalue add is 21.6 days. Information flow is mapped across the top of the map

and thus could drastically influence sales. Thus, the impact from the increased sales may significantly exceed the gains from the reduced inventories. This analysis and realization may not be readily achievable without using the value stream mapping tool.

Creating a Current State Map

1. Define the scope of the map (i.e. the start and stop points for the value stream).
2. Determine the demand on the value stream (in terms of customer needs, e.g. patients seen per day).
3. Determine the operating characteristics of the value stream (e.g., how many shifts, the number of days worked each month, etc.).
4. Assemble a team of employees who know the value stream and/or know how to get to information and data concerning the value stream.
5. Walk the value stream, observing and collecting data such as cycle or process times, changeover times, yield rates, and number of operators in the process. Start the mapping process. Use paper and pencil. Stopwatch cycle times where possible. See the whole flow. Also look for waste (e.g., excess motion, transportation, scrap, etc.).

Figure 2 Operation balance chart. This diagram compares the process cycle time to *takt* time

Waste can be defined as activities the customer is not willing to pay for.

6. Gather information on inventory levels within the process. Often this is done by counting the inventory at different stages of the process (counting the inventory – if possible – is preferred to using computerized reports).
7. Determine and review the types of information obtained from the customer and how they drive activities within the value stream. Walk the information flow.
8. Reassemble the team and use the data collected to complete the current state map. Use icons to standardize and simplify the map.
9. Perform a “reality check” using observed cycle times against the calculated *takt* time for the value stream.

In most instances, the current state map can be created by the team in 4 hours or less.

Example Provided

In Figure 1 the team has created a current state map (see step 8 above). Notice the value added time (approximately 11 hours) is very small in comparison to the total non-value added time (21.6

days). This is very typical in both manufacturing and transactional processes. The value stream map should always be created in conjunction with the operation balance chart (see Figure 2). This chart compares each operation to the *takt* time.

Value Stream Mapping is also a tool that can be used in non-manufacturing too. Notice in Figure 3 a hospital has mapped an outpatient surgery process. Notice in this process too, the value-add time is low compared to the non-value add time.

Key Definitions and Calculations

Takt time.

The pace the value stream must achieve to meet customer demand. $Takt = \text{Available work time (e.g. seconds)}/\text{customer demand (units)}$.

Daily Demand Rate.

The number of units the value stream must produce each day to meet the customer demand. $\text{Daily demand rate} = \text{Monthly customer demand (e.g. units)}/\text{number of days worked per month}$.

Cycle time.

How often a part is produced (ideally timed by observation).

4 Value Stream Analysis in Quality Management

Figure 3 Current state map – healthcare process. VSM is often used to map processes other than manufacturing. This map is for an outpatient surgery process. Note again the VA time is small compared to the total time

Lead time.

The time required for one unit to move through the entire value stream. Lead time includes both value-add time and wait time.

Value-add time.

The time required to transform the product in a manner the customer is willing to pay for.

Changeover time.

The time required to change an element of the value stream (e.g. a machine tool) after one model has finished to the next model begins, “from last good piece to first good piece”.

First-pass yield rate.

The percentage of products that pass through each element of the value stream, the first time, without any type of quality problem (e.g., rework, sorting, etc.).

Uptime.

The amount of time the value stream element (e.g. machine) is available on average. Often in manufacturing this is a measure of machine reliability.

Working time.

Total planned time for work. Total seconds in a shift – any time not planned for work (e.g., breaks, shift meetings, etc.).

Pull.

Producing an item only when the next process consumes an item. A method of work that links production to the customer demand.

Push.

Producing an item without consideration of consumption from the next process. This often leads to the very common waste of overproduction.

Creativity Tools

Introduction

How do people invent? Famous scientists and engineers sharing their memories, as well as psychologists studying the creativity process describe similar situations: an individual facing a difficult problem mentally explores various approaches, persistently trying and rejecting ideas until the right one comes. Psychologists call this process the trial-and-error method (T&EM).

T&EM has a long history. It was used to create the first stone axes, bows, guns, windmills, buildings, ships, and almost everything we can see around. Some of its results are astonishing, for example, Polynesian catamarans and old Chinese, Norwegian and Russian boats. However, archaeological research has shown that even 500 years ago these vessels were rather far from perfect since the builder tried only small changes in design. Some of these changes were unsuccessful causing fatal accidents and have been forgotten while others were successful and became standard. It was a long evolutionary process similar to the evolution of life.

With the acceleration of technological evolution, T&EM became less and less acceptable as a method of innovation and design. It is unreasonable today to build thousands of samples to select the best design of a modern aircraft or a steam machine. Engineering science has stepped in offering various methods for identifying the best design. These methods include scientific research, calculations, modeling, and computer simulation. As a result, engineering design today is a rather systematic, structured, and well-controlled process. However, the creative process of searching for new ideas still lacks these features.

In the typical creative process, people start by exploring apparent conventional solutions, slowly moving to the area of “wild” ideas under the weight of *psychological inertia*.^a

This T&EM for the creative process can be effective depending on how difficult the problem is. The effectiveness of this T&EM can be measured by the number of trials that have to be made to guarantee successful results. This number can vary within a wide range – from dozens for simple problems to hundreds of thousand for difficult ones. T&EM is sufficient for problems that do not require more than

10–20 trials; however, for difficult problems that require out-of-the-box thinking, T&EM leads to an unacceptable waste of time and effort.

In addition to low efficiency, T&EM contributes to poor problem statements. Often a problem is stated in incorrect format with a lot of unnecessary information while needed information is absent.

Until recently, T&EM deficiencies has been partially compensated by increasing the number of people working on a difficult problem. Nevertheless, since the mid-1950s it had become obvious that even the best use of human resources cannot satisfy the required pace of creative invention production. Accelerating technological evolution has demanded simple and affordable creative methods. This demand has lead to hundreds of them with different efficiencies, areas of application, and practical importance.

According to Higgins [1], creativity is the process of generating something new that has value. Creativity is an absolutely necessary ingredient for innovation, problem solving, and innovative design [2].

Creativity has always attracted scientists and practitioners, who have attempted to formalize it to the extent that its output becomes predictable and controllable, like in conventional engineering tasks. The history of the development of various creative problem-solving techniques extends back to the fourth century A.D. with Papp in Alexandria, Egypt. Papp was searching for a science of invention; he even found a name for this science: *heuristics*. For centuries, however, there was no real demand for such a science – until the nineteenth century when the industrial revolution started. Moreover, it seemed fairly obvious that creativity was a product of the human brain, and thus the main approach to creativity was focused on attempts to enhance the creative process by facilitating an individual’s mental processes, that is psychology-based approaches to creativity. In summary, these efforts were aimed at the following:

- unleashing natural creativity, eliminating mental blocks
- stimulation and mobilization of resources helpful for generating ideas by a group or an individual.

Later, knowledge-based approaches have been introduced including various analytical steps to organize, restructure, and involve available knowledge

2 Creativity Tools

and experience and eventually use of specially developed and structured external knowledge (innovation knowledge bases).

Classification of Creative Techniques

Depending on the methods and means used, the following categories for creative techniques have been identified [3]:

1. Conditioning/motivating/organizing techniques

The techniques, procedures and special conditions, and means belonging to this group help create an environment that facilitates the removal of various mental blocks and the unleashing of natural creativity.

Examples: Napoleon technique, listening to music.

Other techniques from this group merely suggest the use of various helpful tools including notebooks, stickers, boards, and flip charts.

2. Randomization

Since psychological inertia usually keeps an individual “inside the box” of their paradigms/perceptions/assumptions, helping an individual make more random attempts has been found to be very beneficial in solving difficult problems. Randomization makes the search more chaotic.

Example: brainstorming.

3. Partially focusing techniques

Many people have difficulty with random idea generation when no guidelines or focusing steps or subjects are offered. Special focusing techniques are used to help an individual focus on one issue at a time and avoid frustration. Focusing elements (steps) may be presented with or without any particular order (random focusing).

Examples: attribute listing or feature transfer; various sets of control questions.

4. Process-oriented (systematic) techniques

A process containing a set of steps to be followed in a specific order.

Example: morphological analysis.

5. Targeted techniques

These techniques offer single or multistep recommendations pursuing a predetermined, promising direction. This direction may be identified

as promising based on intuition, experience, or documented knowledge.

Example: problem reversal.

6. Evolutionary directed techniques

These targeting techniques offer directions according to statistically proven fundamental patterns of evolution.

Example: use of the pattern/lines of technological evolution for prediction of new generations of technological systems.

7. Innovation knowledge-based techniques

These techniques use structured knowledge derived from past human innovation experiences.

Example: contradiction table and 40 innovation principles.

Understandably, some techniques represent combinations of the approaches described above.

Over 90 creative techniques have been classified according to these seven groups [3].

Comparative Analysis of Selected Creativity Techniques

Significant work in the direction of unleashing and mobilizing natural creativity (psychological enhancement) was done by Osborn [4] (“Osborn’s direction”). Other important techniques that followed this direction are

- Synectics (Gordon [5])
- Fundamental design method (Matchett [6])
- Complex of techniques (De Bono [7]).

Results provided by methods of psychological enhancement strongly depend on personal issues and are not repeatable. Psychological means can stimulate a person to make the best use of his or her personal knowledge or that of a group of people. Unfortunately, this knowledge represents a negligibly small part of human innovative experience. Besides, psychological means cannot help organize the process of solving inventive problems as a logical step-by-step procedure (the way that conventional technological problems are usually solved).

The most successful technique for operating with available knowledge (*systematic techniques*) was offered by Miles (value analysis and engineering [8]). Other important techniques following “Miles’ direction” are

- Morphological analysis (Zwicky [9])
- **Quality function deployment** (Akoa [10])
- System thinking (Senge [11])
- **Failure Mode** and effect analysis (FMEA) [12].

The main weakness of this approach is lack of creative methods embedded in the working process. Often, known creative techniques are hardly compatible with the process.

Theory of Inventive Problem Solving (TRIZ)^b

New knowledge-based approach to creativity

Beginning in the mid-1940s, a new knowledge-based approach to creativity was introduced. First, attempts had been made to elucidate the intuition of successful inventors in a general way (Osborn's control questions, for example). The next step was made by Genrich Altshuller who embarked on a direct analysis of inventions documented in patents and other sources of technical information with the purpose of revealing so-called patterns of invention and of technological evolution (Altshuller's direction).

The basic advantages of the innovation knowledge-based techniques are the following:

- Accumulation of the best practices in creative problem solving is possible.
- Proven knowledge can be assessed.
- Results are repeatable and do not depend on personal (psychological) issues.

The most significant result of "Altshuller's direction" is the theory of inventive problem solving (TRIZ) [13].

Classical TRIZ

TRIZ is based on *patterns of technological evolution*, which represent its theoretical foundation. Among the basic discoveries of TRIZ the most important are:

- Any technical system develops according to certain patterns.
- The patterns of evolution for different systems have much in common.
- The patterns of evolution can be unveiled by researching the evolutionary history of a system (for the area of technology, this evolutionary

history is contained in the patent library and other sources of technical information).

- *Via* application of these patterns, one could accelerate the evolution of that system to its next generation.
- On the basis of these discovered patterns of evolution, universal methods for searching for new ideas can be developed.

TRIZ tools for systematic innovation include analytical tools that help understand and if necessary to reformulate the problem, and knowledge-based tools that represent best practices in solving problems extracted from patents and other sources of information. Analytical tools include ARIZ (Russian acronym for the *algorithm of inventive problem solving*) and *substance-field (S-F) Analysis*. Knowledge-based tools include patterns/lines of technological evolution, a number of *principles* (pathways) for eliminating (resolving) contradictions, *standard solutions*, and *innovation guides*.

Ideation TRIZ

Ideation TRIZ is a natural extension of Altshuller's TRIZ and has been in development since the mid-1980s targeting and addressing the main weaknesses of classical TRIZ which are as follows:

- TRIZ development was focused on studying patents without consideration of the feasibility and usefulness of solutions. Its practical application for the first 40 years of development was limited because of specific conditions in the former Soviet Union.
- Insufficient rigorousness of TRIZ tools (i.e., many analytical skills required for successful application of TRIZ tools to practical cases had not been transformed into documented rules, algorithms, and recommendations).
- Only a limited amount of the TRIZ knowledge base had been documented and was available for study and use.
- The tools did not support all stages of the problem-solving process. For example, problems had to somehow be preformulated in TRIZ terms before the tools could be applied.

Because of the above limitations, classical TRIZ was characterized by the following:

4 Creativity Tools

- Considerable education (from 100 to 250 h) was required to effectively use TRIZ.
- Extensive practice (from 1 to 5 years) was required to become self-sufficient in applying the methodology.
- Making TRIZ available for mass use posed an insurmountable challenge.

The main objective of Ideation research was to identify the most effective techniques covering all necessary components and issues associated with creativity and successful inventive problem solving, such as mobilization of personal capabilities, problem and system analysis, and the innovation knowledge-based approach, and integrate these techniques into a single, powerful methodology capable of addressing any problem or situation. Because of this integration, the following components have been selected:

From “Osborn’s direction”:

- methods of reducing psychological inertia
- team work.

From “Miles’ direction”:

- methods of collecting and organizing knowledge about a problem and the system in which it resides (enhanced and implemented in the Ideation Innovation Situation Questionnaire®)
- functional analysis (enhanced and implemented in the technique of *problem formulation*)
- morphological approach (used to ensure the exhaustiveness of the ideas developed).

From “Altshuller’s direction”:

- evolutionary approach (*patterns and lines of technological evolution*)
- innovation knowledge-based approach (various knowledge-based tools)
- TRIZ analytical tools.

Ideation TRIZ development has resulted in the following enhancements:

- Development of a streamlined, unified, and integrated process by which all types of problems can be treated in the same way, including the following steps [14]:
 - problem definition and documentation

- problem formulation
- identification and categorization of directions for innovations (solutions)
- development of solution concepts
- evaluation and planning of implementation.
- Development of new analytical tools to support relevant process steps, as follows:
 - The Innovation Situation Questionnaire® (ISQ) is used to facilitate understanding and documentation of the problem at hand.
 - Problem Formulator® is used to analyze a problem and develop an exhaustive set of potential directions for innovation.
- Development of a new integrated knowledge-based tool called the *system of operators*.
- Development of new TRIZ-based applications within inventive problem solving and beyond as follows:
 - Anticipatory Failure Determination (AFD®) including Ideation failure analysis and Ideation failure prediction [15]
 - **Directed Evolution**® – a methodology for predicting the next generations of various systems by inventing them [16]
 - evaluation and enhancement of intellectual property.

While being originated in technology, over the decades TRIZ principles and tools have proved their applicability to any area of human activity that requires creative solutions [17].

Other versions of TRIZ

For about 40 years, TRIZ development was confined within the Soviet Union borders. Russian “perestroika” in the mid-1980s opened the borders starting the process of TRIZ penetration in the Western part of the world. The new powerful approach to creativity and inventive problem solving started attracting various individuals, companies, and other institutions; however, the complexity of classical TRIZ became a serious hindering factor in its dissemination, causing frustrations and disappointments. To accommodate the new customer base, a number of simplified versions of TRIZ were developed (with various degrees of simplification) of which the best known is

structured inventive thinking (SIT) [18] and its modifications. Other attempts at simplification involved use of selected TRIZ tools like contradiction matrix and 40 innovation principles (original [19] and enhanced [20]). In all these cases, the simplicity was achieved at the expense of a serious limitation of TRIZ's problem solving power, eventually leading to frustration and disappointments.

A different approach was applied by Ideation International involving restructuring and enhancing classical TRIZ tools, developing of new ones and embedding them into software capable of supporting all steps of the innovation process [21].

TRIZ-based software

The first attempt to automate TRIZ was made by G. Altshuller in the mid-1960s when he built an electromechanical version of the contradiction matrix with the 40 innovation principles. Since the late 1980s, various TRIZ-based software products have been developed. The most comprehensive software products are the *TRIZSoft*[®] suite [22] developed by *Ideation International* and software developed by *Invention Machine Corporation* [23] (USA). Several other software packages are also available.

Summary

1. Over centuries, the T&EM was the main creativity tool. Moreover, creativity itself was associated with the T&EM process making the words *systematic innovation* sound like an oxymoron. While resulting in an enormous amount of incredibly valuable inventions enabling human survival, T&EM became less and less acceptable as a method of design and innovation with the acceleration of technological evolution.
2. As a response to the new requirements, hundreds of creativity techniques mostly based on psychological stimulation and thus lacking a systematic approach and structure have been developed in the last century.
3. In the mid-1940s, TRIZ, a new knowledge-base approach to creativity was introduced derived from the analysis of documented technological information and unveiled patterns of inventions and of technological evolution. TRIZ is the only innovation knowledge-based and evolutionary

directed technique that can provide the user with the accumulated power of the world's best inventors and innovations and the proven processes to invent in the most systematic and expeditious way. While being originated in technology, over the decades TRIZ underlined concept and tools have proved their applicability to any area of human activity that requires creative solutions.

4. To date, an integrated approach combining the most valuable achievements of the twentieth century, including Osborns, 'Miles', and Altshuller's directions has resulted in the Ideation TRIZ methodology that offers a unified and integrated process and tools capable of guiding and supporting individual and team creativity and innovation activity from problem definition to solution implementation. The process is supported by software that embeds all necessary analytical and knowledge-based innovation tools.

Acknowledgments

The authors would like to extend our gratitude to Rod Kornienko for the comprehensive collection of various creative techniques that enabled this research and to Zion Bar-El for encouraging us to write this paper.

End Notes

- ^a Psychological inertia could be defined as a complex of perceptions based on previous experiences, including one's background, education, and expertise. While being quite useful in performing routine operations, psychological inertia is the main reason for "in-the-box thinking" and is a critical hindrance in creative thinking.
- ^b TRIZ (pronounced "trees") is a Russian acronym for the theory of inventive problem solving.

Directed Evolution®

Introduction

Ability to understand, predict, and control evolution of technology is becoming the centerpiece need of the informational era [1]. A proactive approach to all aspects of innovation requires the development of an integrated multistep process for “visualizing the future”. Directed Evolution,®^a (DE) is a technology involving systematic processes for building a sustained competitive advantage through the effective management of the evolution of various artificial (man-made) systems by utilizing evolutionary patterns for technologies, markets, business, social systems, and so on.

DE has two main roots: *technological forecasting* and the *theory of inventive problem solving*.

The first root of DE extends to the mid-1950s when technological forecasting [2, 3] – an approach for reckoning the future – was under development. From the late 1960s to the mid-1970s this resulted in the establishment of nonrelated techniques such as trend extrapolation, morphological modeling, the Delphi process, and others, all of which were based on probabilistic modeling of future characteristics of various systems. Although in the beginning much hope had been placed on the new method, most of the long-term forecasts that resulted have not proved correct, primarily due to the tools that were utilized to develop the forecasts.

The theory of inventive problem solving (TRIZ – Russian based acronym) was originated in the mid-1940s by Genrich Altshuller and represents structured systematic process for solving problem *via* unveiling and resolving contradictions (conflicts, dilemmas, creative challenges) supported by numerous tools [4]. These tools have been derived from the thorough analysis of worldwide innovative experience documented in patents and other sources of technical information. Unlike numerous methods for enhancing creativity based on trial and error and/or psychological stimulation, TRIZ is based on the assumption that inventions in technological systems appear not randomly, but rather in compliance with certain statistically proven *patterns of evolution* that could be revealed and utilized for organized and structured innovation. For example, one of the patterns states that every technological system in its

evolution becomes more dynamic, that is changeable, with higher degree of flexibility and variety. Unlike *trends* that could be short-lived (for example, the trend of increasing utilization of light metals could be in time replaced with the trend of increasing utilization of plastics), patterns of evolution reflect practically eternal customer requirements (like high performance, low cost, convenience, etc.). Typically, each pattern of evolution includes multiple *lines of evolution* – more detailed descriptions as to how this pattern could be realized step by step (for example, a mechanical system can become more dynamic *via* sequential introduction of a hinge, hinge mechanism, flexible elements, microlevel transformations, etc.). Over the years, numerous patterns and lines of technological evolution have been discovered through the analysis of hundreds of thousands of innovations spanning different areas of technology [5].

Since the mid-1970s, an entirely new approach based on utilization of predetermined patterns of evolution called *TRIZ forecasting* has been in development. Unlike traditional technological forecasting, TRIZ forecasting (as guided by patterns of evolution) offered directions together with proven standard ways on how they could be realized.

The main feature of DE is its proactive approach to the evolution of technology. Instead of making a prediction and waiting for it to be confirmed, the DE process uses numerous patterns of evolution for the purpose of identifying possible scenarios, analyzing them, selecting the most promising ones, and then planning the process of implementation. In other words, DE is a method to predict a future generation of a system by inventing it.

The DE technology was introduced in the early 1990s. Since then it has been under constant development by Ideation International’s research group and applied to various aspects of human life, including product and process development, evolution of technologies, markets, organizational development, and more [6, 7]. Later, significant progress has been made with the introduction of DE software, which incorporated powerful analytical tools and a substantial knowledge base.

Besides technological forecasting and TRIZ, other approaches and technologies were involved in the development of DE, in particular:

- methods of searching for new ideas from various modifications of the trial-and-error method to

the most recent works in the area of artificial intelligence;

- approaches and methods arising from studies in the evolution of biological and other systems (technological, social, arts, etc.) over the last two centuries;
- ideas developed within the theory of nonlinear systems and synergetics (autopoiesis); and
- ideas associated with the informational wave of modern civilization.

Directed Evolution Components

Directed evolution methodology includes the following components:

- DE forecasting – a systematic procedure for identifying all possibilities for system improvement and possible undesired events that might be associated with the system evolution and developing a comprehensive set of logically sequenced scenarios of evolution of the given system using patterns and lines of evolution.
- DE root cause analysis – a systematic procedure for identifying the root causes of any phenomenon (useful or harmful) and inventing ways to prevent harm and/or possibilities for its useful application.
- DE inventive problem solving – a systematic procedure for resolving tough technological problems, enhancing system parameters, improving quality, reducing cost, and so on, for products, processes, technologies, businesses, management, and so on.
- Evaluation and enhancement of intellectual property – a systematic procedure for unveiling and increasing IP value and strengthening IP protection against infringement and circumvention.

Directed Evolution Steps

The DE process comprises the following steps:

- analyzing the past evolution of the system of interest (whether technological, social, business, etc.) and revealing the main patterns in this evolution;
- selecting the goals for further evolution using the DE knowledge base, which incorporates information about typical needs of individuals, society,

and related environments together with basic patterns of market evolution;

- connecting the evolution of the given system with anticipated evolution of other related systems, the environment, and general technological evolution using the Ideation Bank of Evolutionary Alternatives™,b;
- defining how to pursue the selected directions and revealing evolutionary resources – i.e., the technologies, materials, products, processes, skills, knowledge, and so on, that could be utilized in the development using the DE knowledge base, which includes patterns describing the evolution of technological and social systems;
- identifying potential dangers and other undesired events, possible future problems, and so on, both in the given system and its environment, using Anticipatory Failure Determination (AFD)® and a special knowledge base of information about typical evolutionary dangers;
- revealing and solving problems, resolving contradictions, overcoming limitations, and so on, that can hinder the achievement of set goals using various instruments for problem solving including the most recent Ideation TRIZ methodology;
- developing a logically sequenced evolutionary scenarios for the given system, including a strategy for beating the competition;
- providing reliable and effective protection of intellectual property and (if necessary) eliminating possible legal obstacles, including invalidation and designing around blocking patents;
- monitoring and continuing development of the process of implementing selected evolutionary scenario(s) of the given technological or business system, utilizing feedback for prompt adjustment.

Directed Evolution Instruments

The DE process involves the utilization of a number of tools embedded in the software^c, in particular:

- DE questionnaire – a comprehensive set of questions and instructions for conducting a thorough diagnostic evaluation of the given system.
- Problem Formulator® – a software module utilizing elements of artificial intelligence for building and analyzing cause–effect diagrams describing the structure and functioning of the given system.

This tool generates lists of specific control questions for system analysis and evaluation, and then creates a set of directions for evolving the system, for revealing and solving problems, revealing the root causes of undesired events, and so on.

- A set of evolutionary patterns for artificial (man-made) systems, including over 400 patterns and lines of technological evolution and over 100 patterns and lines of marketing and social evolution.
- A comprehensive multilayer system of approximately 1000 patterns of innovation (“operators”) for:
 - solving technological problems;
 - solving nontechnological (business, marketing, logistics, etc.) problems;
 - conducting failure analysis; and
 - conducting failure prediction.

Typical Results of a Directed Evolution Project

Typical results of a DE project include:

1. A comprehensive diagnostic analysis of the DE subject, in particular:
 - (a) documenting existing problems and contradictions – and revealing hidden ones – that hinder the effective evolution of the given system,
 - (b) revealing the evolutionary potential and resources that allow for an increase in system ideality and provide new opportunities, and
 - (c) objectively evaluating the applicable intellectual property and developing suggestions for enhancing it and providing better protection.
2. Solving selected problems, generating new ideas and building alternative concepts for evolving the system, based on suggestions for selecting the most promising directions for effective strategic planning for the short, mid, and long term.
3. Predicting possible mistakes and undesired events associated with further evolving the system (for short-, mid-, and long-term planning) and developing recommendations for:
 - (a) timely prevention of potential mistakes and other undesired events;
 - (b) early diagnostics of potential undesired events;
 - (c) prompt actions capable of reducing harmful consequences from unexpected undesired events; and
 - (d) possibilities for capitalizing on undesired events such as changes in government regulations, social changes, and so on, even economical crises.
4. Providing recommendations for the effective growth of intellectual property and structuring an IP portfolio, including:
 - (a) analyzing and “sprucing up” existing ideas and inventions, including valid and expired patents; evaluating and enhancing these ideas/inventions to ensure their best utilization;
 - (b) adding new inventions to the IP portfolio; and
 - (c) ensuring effective protection of the IP portfolio, or of its most valuable elements.
5. Increasing the company’s creative potential.

To date, over 100 DE projects have been completed. The list of selected DE projects includes:

- chemical industry
 - new generation of existing chemical processing plant;
 - processing of new chemical;
 - catalysts, etc.
- heavy equipment: lifting cranes
- automotive industry
 - parking brakes;
 - doors;
 - cable applications, etc.
- medical industry: surgical instrumentation
- oil industry: control of oil production
- materials development
 - superabsorbent fibers;
 - plastics;
 - catalysts;
 - packaging, etc.
- fluid systems
 - water pumps;

4 Directed Evolution[®]

- hazardous materials pumps
- commercial products
 - sanitary products;
 - foot massagers;
 - electric shavers;
 - hair care products: combs, hair dryers, curling irons, and hair clippers, etc.
- stock/commodity exchange.

Quality Management, Overview

Introduction

Quality management (QM) is an essential feature in any organization that desires to be considered reliable by its customers – an organization that consistently keeps the promises that it makes. Reliable organizations design compelling promises for customers and consistently perform according to these promises at a high level of service thereby achieving a competitive edge over their rivals. This approach to quality requires two key elements – innovation to develop new products (whether goods or services) and customer care to effectively and efficiently deliver these products – and obtains predictable financial results for business owners. This means that the value proposition offered to consumers must deliver value that is beyond the offerings of competitors, so that consumers will consistently choose their own organization's products/services instead of the alternative offerings. QM is the approach to develop and maintain a “value edge” in competitive differentiation at a level that assures both market leadership and profitable growth. This outcome is achieved through an integrated system of business practices called *quality management* [1].

Quality Defined

To understand QM requires defining *quality* in a way that eliminates any subjective interpretation. In order to provide an operational definition of quality and illustrate how it is applied, three questions will be addressed: what is quality, how is quality created, and how is quality delivered.

First, We Must Ask What is Quality?

Quality is a comparison of expectations for performance outcomes with the perception of their achievement. Technically quality can have two meanings: it can describe either the characteristics of a product or service that give it an ability to satisfy stated or implied customer needs or it can refer to a product or service that is free of deficiencies. But, the most important aspect of quality is the one that

creates business competitiveness for an organization. To describe this perspective a theory of **attractive quality** was developed by Dr. Noriaki Kano of Tokyo Science University [2]. The Kano model of attractive quality (Figure 1) illustrates three functions that define the dimensions of competitive quality.

Kano observed that there are three functions that define how quality is perceived by customers as meeting their requirements. When customers describe their quality needs, they define their understood needs; they do not talk about unknown requirements for unanticipated needs or applications nor do they describe their assumptions regarding basic performance that is embedded within their concept of the good or service. The three curves result in different types of customer performance perceptions.

- The lowest curve represents “must be” or standard quality which is characteristic of a commodity product (for instance, there is no competitive value in the standard grade of octane in gasoline – people are likely to change brands for very marginal differences in price). These requirements are not typically described by customers as they are “expected” or “understood” to be part of the package – cars are expected to go and to stop, and most people would feel that these capabilities must not be specified, thus these features deliver no satisfaction to customers but only offer an opportunity to dissatisfy the customer through poor performance.
- The middle curve describes what Kano called *one-dimensional quality* or a product quality feature where companies compete “head to head”

Figure 1 The Kano theory of attractive quality

2 Quality Management, Overview

to win customer approval (e.g., gasoline consumption of an automobile) and value as perceived by customers is directly proportional to the performance of this feature design. In this category of product feature, quality is directly proportional to the effectiveness of the design to the customer's experience in accomplishing the job they need to accomplish [3].

- The third curve describes the type of quality that always satisfies customers or what Kano refers to as *attractive quality* – quality that anticipates customer needs before the customer knows or understands what capability or feature they are missing. This type of quality comes from innovation – knowing the customer environment and application so intimately that new technology can be applied to create new competence or capabilities in the job that the customers need to get done. This type of quality provides a disrupting influence on markets and can totally change the balance of its competitive structure.

Thus, according to Kano, quality is directly linked to the ability of a product or service to deliver perceivable value to its targeted customers.

Second, We Must Ask How is Quality Created?

Given this understanding of the importance of the customer's experience, how is this type of quality created? Consider the Watson model for value delivery for a definition of the way quality is created and delivered in the customer experience (Figure 2) [4].

Quality creation is a two-phased process: designing value into products and services and delivering

the quality of value that was designed. The design process interprets the customer experience of a Kano analysis to make a commercial promise to the market. This first stage in quality creation establishes the expectations of customers for the value they will receive and defines the offer made to customers. Not understanding or misinterpreting the best value proposition for customers thus results in suboptimization of the organization's potential competitive position. The second stage of quality delivery is in the delivery of the promise that has been defined for customers – a customer care function in which the consistency of promise delivery is evaluated by customers. Managing the daily dynamics of the customer experience must satisfy a quality entitlement – customers are entitled to consistently perceive satisfaction in the delivery of the promised performance. By aggressively executing the delivery of this quality model through an organization's business model, persistent perceptions creating long-term customer loyalty are achieved.

Third, We Must Ask How is Quality Delivered?

Sustained success and profitable growth are achieved when an organization coordinates its activities to deliver quality above its competitors, costs below its competitors, and technology ahead of its competitors. These imperatives must be constructed into a system for quality creation, which is delivered through the business processes of the organization (Figure 3 describes such a basic business model). This model characterizes the three core processes of an organization: product creation, product realization, and the process of management.

Figure 2 The Watson model for value delivery

Figure 3 Quality-driven business model

Figure 3 overlays the linkage of **Six Sigma** methodology and policy deployment on top of the business model to illustrate the linkage between change management projects (business improvement seeking *kaizen* (continuous improvement) or *hoshin kanri* (breakthrough improvement)) to the daily management system (*nichijo kanri*) represented by these core business processes. Note that two types of innovation are required to implement this change management process and that these are expressed by the two different approaches that are taken to resolve issues using Six Sigma business improvement methods:

- **DMADV** (define–measure–analyze–design–verify) is the Design for Six Sigma (DFSS) process that delivers innovation through business development processes by focusing on value delivery through product creation, service creation, or development of new value delivery work processes. This Six Sigma approach resolves issues where a current performance capability is inadequate to meet its future requirements (the designed capability is unable to meet the customer’s need).
- **DMAIC** (define–measure–analyze–improve–control) is the **lean** Six Sigma process that delivers innovation in the product realization process by improving or optimizing the performance of current products, services, and the processes that deliver products or services by applying the methods of statistical problem solving and lean production management. This Six Sigma approach resolves issues where the current level of performance is not achieving its designed capability (achieved process capability is less than the designed process capability).

Quality must be managed over the long term but it is delivered in the short-term actions of the daily management system through a disciplined work process. What is the set of specific components that are contained in a quality management system (QMS) and how do they operate?

The Elements of Quality Management

QM differs from the management of quality. QM delivers excellence through a set of good management practices while the management of quality describes the profession of managing the quality function within an organization – the first is applicable to managers in all organizational functions and at all organizational levels, while the second applies more narrowly to a specific profession and its associated disciplines.

QM is an “unnatural act” of establishing and preserving excellence – QM defies the natural law of entropy whereby everything degenerates into a state of mediocrity before it obsolesces.

Management of quality combines several specific disciplines to assure the consistent delivery of the level of service or product quality intended at the point of the customer experience. In managing quality there are five quality disciplines that have evolved over the past century. These five disciplines for managing for quality relate to practices of engineering, assurance, control, and improvement. Taken together they follow a PDCA cycle (plan–do–check–act) that is often described as the *Deming cycle*.^a

- **Quality engineering (QE)**
QE accomplishes Deming’s “plan” step for designing an enduring level of product or service

quality. QE analyzes the steps of an operational process and gives a statistical basis for measuring and managing process performance so it consistently meets outcomes for customer standards or requirements. QE delivers predictable quality outcomes by maximizing process quality to produce the required quality results in the product or service.

- **Quality control (QC)**
QC describes the methods used to address the Deming “do” step for process management. Control actions include processes for actively testing or monitoring performance, evaluating current performance results against standards for desired performance, and guiding process activities to achieve a state of statistical control by taking corrective action when performance is observed to deviate from this standard. Thus, QC consists of all operational techniques and activities used to fulfill the requirements for quality outcomes by focusing on improving process performance.
- **Quality assurance (QA)**
QA delivers the “check” step of the quality discipline. QA gives confidence that the customer requirements will be achieved by demonstrating the product or service capability to fulfill performance results as delivered to the final customer. QA is distinguished from QC in that QA focuses on the final test results or compliance with the external quality requirement while QC focuses on the interim test results or compliance with internal quality requirements, which produce final results.
- **Quality improvement (QI)**
QI executes the “act” step of the PDCA cycle. The QI process is one of continuously improving or adjusting performance to reduce the cost of poor quality, improve the cycle time of process activities, and eliminate waste from all process steps. QI seeks to obtain and sustain the “ideal” process performance that was initially designed into the process capability. QI activities include the work of both Six Sigma and *kaizen* blitz teams who seek to eliminate waste or streamline process activities.
- **Quality audit and review (QAR)**
QAR is a systematic, independent assessment of the entire quality system to determine the effectiveness of both the quality plan and its execution through application of the four disciplines of quality in the work processes of the organization.

Thus, QAR “checks” on the value of governance in the PDCA activities of an organization’s formal QMS.

When these five quality disciplines are combined into a systematic approach for the delivery of quality results, they become the cornerstones of a sound QMS. Thus, the “professional” dimension of QM may be defined as follows:

- **Quality management (QM)**
The process of designing and deploying a system for managing processes to achieve maximum customer satisfaction with product or service quality at the lowest overall cost to the organization while continuing to improve the performance outcomes of the process.

This professional dimension of QM seeks to instill a systematic way of working in the entire organization for delivering quality outcomes – achieving organization-wide practices that deliver managing for quality. What are the ingredients of this system?

Management System for Delivering Quality

The formal QMS of an organization is a documented process for managing these five dimensions of QM (described above) and QMS describes the context for the design, development, deployment, and delivery of quality activities throughout the organization. The QMS documents and executes the organization’s quality policy (strategic direction about how the organization will work to deliver quality) and it can be summarized as the PDCA of the management system: quality planning, quality standards (defines the system of work activities, controls and tests, as well as the control plan to assure that the system operates effectively despite any potential contingencies), QA, QC, and QAR, which must occur supported by the activities of an iterative process for QI. The QMS is a formal system to document the organization structure, management responsibilities, and organization-wide procedures that are required to achieve effective QM as a routine way of working. The ingredients of the QMS documentation include the following:

- *Quality policy*
An organization's general statement of its beliefs about quality, its vision of how quality will come about and what should be the expected results.
- *Quality plan*
A document or set of documents that describe the standards, quality practices, resources, and processes pertinent to the assurance of quality for a specific product, service, or project through the application of the four quality disciplines.
- *Quality standards*
The documented description of accepted way to perform work and quality operating practices so that "best practice" is applied as a discipline in the daily working environment. This documentation includes standard operating procedures as well as control plans to assure proper measurement and interpretation of the critical quality process measures and the judgments made to interpret them regarding quality performance. Standards should also exist to describe how each of the core disciplines of QM will be managed.
- *Quality systems*
The information systems that manage data for product and service performance, customer and market information about complaints, failures, warranties, and the record of responses to such claims.

The typical system for delivering quality in a modern company contains a number of proven ingredients for success: ISO 9000, business excellence criteria, and Six Sigma which can be forged into the process management architecture that is shown in Figure 4.

This integrated QMS seeks to maintain a business control system based on the ISO 9000 Quality Management Standard while encouraging the organization to aspire to apply the "best practice" principles of QM, which have been distilled into the award criteria for business excellence prizes such as the Malcolm Baldrige National Quality Award or the European Quality Award. These award criteria address a system of areas for concern in the development of a business management system that were developed as a consensus from many of the world's best companies. No company has ever scored above 800 points using these criteria as a standard, so they provide a way to challenge organizations to initiate self-improvement projects that close the gap in opportunities for improvement that are discovered when the organization conducts a self-assessment or conducts formal benchmarking with an organization that is recognized as superior by their management team. These improvement projects can be conducted using the Six Sigma DMADV or DMAIC methods.

Achievement of exceptional performance using such a management system requires that the organization develop "leadership at all levels" of its structure. What does this mean in terms of the quality actions of the organization's business leaders? We have finished discussing the key dimensions of management of quality; now let us turn back to understanding how QM can be infused into an entire organization as it integrates its QMS into its core business to manage performance in all dimensions of business excellence while ensuring successful results from the perspectives of all the organization's stakeholders (e.g., customers, employees,

Figure 4 An integrated quality system for total performance management

suppliers, investors, legal and regulatory authorities, etc.).

Pervasive Quality Leadership

It is a tall order to deliver this kind of management system. It requires, as Warren Bennis observed, the kind of situation where: “a leader is a follower is a leader” [5]. Bennis noted that we are facing a “chronic crisis of governance – that is, a pervasive organizational incapacity to cope with the expectations of their constituents – [that] is now an overwhelming factor worldwide. If there was ever a moment in history when a comprehensive strategic view of leadership was needed, not just by a few leaders in high office but by large numbers of leaders in every job, from the factory floor to the executive suite, this is certainly it” [6]. In order to have a system of sound business management there must be good role models of management quality – not just at the top of the organization, but throughout its entire structure so that the people can see this behavior is not just applicable for the “super-leaders” but that is also part of the expectation for every ordinary worker – including supervisors – and they are also capable of exhibiting the shared values and behaviors that operationally define quality actions throughout the entire organization. This consistency assures that each person understands that the vision of leadership is not about wishing, hoping, or praying: it is an act of courageous leadership that must be duplicated at all levels of the organization. What does leadership at all levels look like?

Executive Leadership

Senior managers must establish the vision and values that will guide their organization into its future state. One way executives demonstrate leadership is by establishing a framework for action through a management process for cascading values and objectives that define the way the organization will work together and the goals that it will seek to accomplish in pursuit of its long-term mission. A critical aspect of the process of management that remains the active responsibility of the top management team is conducting regular leadership reviews of the business. This activity is both a due diligence responsibility

of the business owners and a fundamental approach for exercising leadership. Leadership reviews have at least two emphases: review of the governance structure and “strategic direction of the organization” as well as review of strategic problem areas that lead to business vulnerability through challenging technologies, violation of critical assumptions, or changing “rules of competition” in the market. Leadership reviews offer the top management an opportunity for

- demonstrating personal commitment to their “philosophy of management”;
- providing visibility for their “defining moments of quality encouragement”;
- mentoring the organization to achieve desired behavioral changes;
- guiding cross-organizational efforts to achieve desired systemic change; and
- encouraging people to “build a desire to win and a will to act”.

What else can executives do personally to demonstrate “positive leadership behavior”? A few examples include the following:

- *Executive touch program*
Program for top executives to get close to the leading targeted external customers. Requires quarterly visits that are intended solely for relationship building to establish a foundation for future business discussions.
- *Executive customer advocate program*
Program for the senior management team to facilitate significant problems encountered by major customers in each of the primary lines of business.
- *Complaint listening program*
Program for all levels of management to spend a few hours monthly listening to “real” customer complaints directly on call center lines.
- *Executive escalation program*
Program for the top level of senior managers to rotate through a monthly “duty day” where they are represent formal escalation “points of last resort” for resolving all customer complaints.
- *Executive compensation program*
Change the compensation so a significant element of the “reward component” is granted for a “statistically valid” increase in customer satisfaction as measured by a valid external method.

Business leaders must exhibit consistency in all that they do. Lack of consistency is considered by employees to countermand the organizational culture and may cause deterioration in a shared system of values. It is particularly important to demonstrate consistent performance when one of the tenants of the organization is “empowerment” – the ability to make individual choices within a set of boundary conditions. An organization’s vision provides direction for empowerment, but its values provide the boundaries for making choices.

Management Leadership

Managers may also become leaders. The definitions of manager and leader are not mutually exclusive. Each person appointed to a management function should at least aspire to becoming a local leader. What can be done to demonstrate leadership at the local level? Several actions can be suggested:

- taking an active role in leading the local implementation of a major business or QI initiative that has strategic value to the organization as a whole;
- showing a personal interest in developing the next generation of leaders through the personal mentoring of high-potential employees;
- “managing by wandering around” and taking time to talk with employees about any issues or concerns they may have, providing brief words of encouragement, and taking action to apply their insights for better management of work or business processes;
- sponsoring and reviewing improvement projects that deliver on the annual continuous improvement objectives of their own management area of responsibility;
- recognizing the improvement efforts of frontline teams and individuals;
- developing the core competence of their organization through team-based on-the-job education and training programs; and
- exercising information transparency by communicating to all employees about business results and briefing them on both the strategic direction and any news that directly concerns them or their livelihood.

Frontline Leadership

Leadership is often required at the frontline in order to coordinate action and encourage common behaviors that reinforce organizational values. Each person can exhibit leadership as a means to encourage fellow employees and provide an example that reinforces the behaviors of the value system. Some of the actions that can be taken at the personal level include

- participate actively in their work group or team process management activities and continuous improvement projects;
- develop their personal problem-solving and statistical analysis skills;
- mentor new employees in the cultural values and historical accomplishments of the organization;
- pursue certification in the core skills involved in the profession and demonstrate mastery of the tools and methods of their own trade;
- provide improvement ideas and suggestions to managers whenever any opportunities for improvement are observed in the work process;
- participate on teams for conducting self-assessments, audits, and cross-functional process improvement;
- take responsibility for their personal development and pursue a combination of both internal and external courses that deliver their career objectives; and
- recognize the contributions of colleagues and team members and encourage their achievements by expressing appreciation for their positive involvement in team improvement projects or personal suggestions made for process improvement.

Personal Leadership

True leadership is not in words, but in deeds: “The authentic test for mastery of learning is not in what a manager [person] says, but in what a manager [person] does” [7]. This requires a consistent practice that is developed from the inside out and exists on both personal and interpersonal levels both within the local work experience and across the whole organization. This effort requires two key focus areas: managers must empower the workforce to exhibit the principles of total quality leadership and frontline workers must become aligned with the strategic direction, improvement objectives, and

cultural values of the leadership team. Each employee should aspire to represent a role model of the behavior desired of colleagues in the organization. This principal is also a cornerstone of the lean methods of the Toyota production system where employees are held accountable for the quality of their work and are expected to manage the quality of their work using a self-regulated QC approach. This raises an important question about the responsibility for quality and the role of quality professionals in managing to achieve quality outcomes in contrast to the responsibility of both process owners and workers for the quality of their own work output. What is the role of a quality professional in managing for quality?

Professional Leadership: The Role of a Quality Manager

Responsibility for Quality Performance

Who is responsible for the quality outcome of work? Is it the individual doing the work, the supervisor of the work effort, the owner of the work or business process owner, or the leader of the business area? There is a quandary: if everyone is responsible for the quality of work, then nobody is accountable! The resolution of this quandary lies in the multiple levels of responsibility – which fosters different types of accountability! Responsibility accumulates from bottom up; however, accountability is delegated from higher levels of authority to lower levels in the organizational structure. Thus management delegates responsibility for quality performance of work to the workers, but maintains overall responsibility and accountability. Workers can only be held responsible and accountable in the area of work that has been properly delegated to them. You cannot have accountability without responsibility! What does it take to hold someone properly accountable for executing their responsibility and then delivering the desired level of quality in their work? According to the sage advice of Peter Drucker, there are three conditions that must be satisfied to hold a worker personally accountable for the quality of their work:

1. Employees must have specific knowledge of the job they are asked to perform in terms of specifications, measurements, systems for work performance, and contingency actions that should be performed when work quality is not acceptable according to standards and they must be trained to perform to these work requirements.
2. Employees must know the standard of quality they are expected to deliver (the targets or goal of their performance expectation).
3. Employees must have the ability to monitor their work progress and be delegated the authority to make decisions that allow them to self-regulate their own performance to consistently meet the standards of performance [8, 9].

When these three conditions are not met, then the business managers retain the responsibility and accountability for all aspects of work quality. The job of a professional quality manager is to develop the QMS that assures that responsibility for execution of work practices leading to consistently sustainable quality results is achieved. What behavioral characteristics does it take to be such a “local leader” of the organization’s quality practices?

Behavioral Qualities of an Exceptional Quality Manager

On the basis of a behavioral analysis of successful and unsuccessful quality managers, there are some common traits that have been identified as distinguishing between the most successful quality managers and those who were not perceived by their bosses as being successful. Sixteen traits were identified as leading to success [10]. Interestingly, only one trait was observed to detract from managerial performance. The positive behavioral traits that were discovered in this study included customer oriented, customer advocate, organizationally astute, influencing, goal oriented, interpersonally diagnostic, persistent, organizational planning, initiating, mentoring subordinates, collaborative, professional, conceptual, innovative, communicative, and self-confident. The one negative trait that leads to loss of personal influence and ineffective personal interactions was “making fast decisions.” On the basis of these characteristics, it is clear that a “local quality leader” must behave like an internal consultant acting without the direct management authority and responsibility for line management (e.g., management of the profit and loss centers of the organization) but must convince others, through persuasive use of data, as to what is the right course to take. In an interview with Peter Drucker he was asked: how can a quality professional

convince their business leader to “do” quality? His answer was most educational. Drucker said, “It is not your job to train your CEOs. They are bright people and can understand quickly what needs to be accomplished. However, it is the job of staff to clearly report necessary information that CEOs can easily assimilate and understand, so they may draw their own conclusions” [11]. The “secret weapon” of quality professionals is the use of data as a means to convince management to act. Communicating concerns with clarity and confidence is perhaps the greatest competence that a quality professional can have.

Summary

What is quality? Quality is the never-ending pursuit of excellence in product or service performance as judged according to the standards of customers relative to alternative choices they have for selecting similar goods or services from competitors. These customer standards for quality change over time and are influenced by a wide variety of external forces such as technology and regulatory legislation. As quality improves in one area in life, it often has a positive influence by increasing the requirement for quality in other areas. Thus, managing to improve quality is an essential ingredient to continued success and QM is a business requirement that will continue to be part of the “essential work” of organizations.

End Note

^a Although PDCA is often called the *Deming cycle* it was first described by Walter Shewhart and the PDCA version was actually developed by the Union of

Japanese Scientists and Engineers (JUSE) translators of Dr Deming’s lectures under the supervision of Kaoru Ishikawa.

GREGORY H. WATSON

Benchmarking in Project Definition

Introduction

In 1990, Roger Milliken called benchmarking *the art of stealing shamelessly* and since then many have used benchmarking to generate “quick fixes” for their performance problems. However, benchmarking is not just for quick fixes, it can also provide a rigorous process that requires both “sweat equity” – learning about one’s own processes and performing the logistics of coordinating study missions to other organizations – and “analytical thoroughness” – measurement and analysis of sustained work process performance as well as the detailed mapping of processes and side-by-side evaluation of process differences. Benchmarking uses the analytical information contained in a benchmark, or a comparative measure of process or results performance to establish which organization is the candidate for a “best practice” in a specific business process. Then the business process must be specified in order to understand how the benchmark was achieved and to identify enablers of successful overall performance. Finally, a cultural adaptation of the learning must be made in order to apply this new knowledge to another organization. For benchmarking to be successful, it must heed the warning of Dr. W. Edwards Deming who said, “It is hazard to copy. One must understand the theory of what one wishes to do.” Cultural adaptation and business model adaptation are necessary to assure that the lesson observed in one organization can be successfully transferred to another organization. As Deming also cautioned, “Adapt, don’t adopt. It is error to copy.”

Benchmarking Definitions

What is benchmarking? In order to understand this methodology, it is essential that definitions be agreed upon for the meaning of some key terms. The first definitions that must be agreed upon are terms that identify the types of benchmarking studies and their operational approaches:

Process Benchmarking

The method for comparative analysis of work process performance between two unique or distinct implementations of the same fundamental process is called *process benchmarking*. It includes both the internal inspection of an organization’s own performance as well as the external study of an organization’s recognition for achieving superior performance as evidenced by objective standards of comparison (benchmarks). The objective of process benchmarking is not to calculate the quantitative gaps in performance, but to identify best practices that may be adapted for improvement of organizational performance. There are four types of process benchmarking studies: strategic, operational, performance, and perceptual benchmarking.

Strategic Benchmarking

The process benchmarking of organizational strategy or key business process performance in order to determine breakthrough opportunities for profitability and productivity improvement is called *strategic benchmarking*. This type of benchmarking focuses on those critical business areas that must change to attain or maintain the competitive advantage of a business. Strategic benchmarking studies focus on critical business assumptions, primary competence areas, core business processes, technology inflection points, or business fundamentals that define organizational purpose. The purpose of strategic benchmarking studies is to challenge the management to move from a current state to a desired state of the whole business. Examples of strategic benchmarking studies include evaluation of options for the design of an organization’s governance structure, assessment of approaches used to implement advanced technology (e.g., enterprise management software or paperless document handling), or strategic business issues that are faced by the organization (e.g., creating a web-based business capability; managing the technology transition across generations of advancement; or managing the routine work of the organization through management methods such as balanced scorecard, performance management, and business excellence assessments).

Operational Benchmarking

The process benchmarking of work processes or practices in order to discover opportunities that will

2 Benchmarking in Project Definition

provide productivity improvement in the areas of effectiveness, efficiency, or economy of the routine business operations is called *operational benchmarking*. This type of benchmarking focuses on specific work activities that need to be improved and seeks to identify the work procedures, production equipment, skills or competence training, or analytical methods that result in sustained performance improvement as indicated by objective measures of process productivity (process throughput, cost per unit, defect opportunities, cycle time, etc.). Examples of operational benchmarking studies include analysis of invoicing procedures to determine the most productive process, evaluation of production methods to determine the highest throughput methods that deliver lowest cost and least defects, and study of logistics distribution methods that result in both high-delivery service performance and low levels of finished goods inventory.

Performance Benchmarking

The process benchmarking of product or service results using a standard comparison or test under known operating conditions is called *performance benchmarking*. This type of benchmarking seeks to answer the question which product or service is better based upon rigorous assessment using objective performance criteria. Examples of performance benchmarking studies include consumer product analysis that evaluates products on a “head-to-head” basis using a fixed set of criteria for performance, evaluation of product performance using a standard test, such as operating time to run a specific application, or endurance tests that identify the ability of a product to perform over a fixed period of time under comparable operating conditions.

Perceptual Benchmarking

The process benchmarking feelings or attitudes about process, product, or service performance by the recipient of the process output is called *perceptual benchmarking*. This type of benchmarking seeks to answer the question how do you perceive the delivery of service, performance of product, or execution of process by the people who are recipients of these outputs. Perceptual benchmarking uses attribute or categorical data to quantify subjective feelings and establish relative ranking of performance based on such criteria as timeliness of performance, goodness

of knowledge transfer, soundness of information, courtesy of delivery agents, and so on. Examples of perceptual benchmarking include surveys of training satisfaction at the completion of a training event, employee satisfaction surveys to determine either the work climate or structural issues regarding compensation and benefits, or customer satisfaction with the product or service delivery to the marketplace.

The next definitions that must be agreed on are the terminologies that identify the sources of data used in conducting a specific benchmarking study. This is an older and somewhat less helpful way to identify benchmarking studies. This categorization of benchmarking practice according to the source of data leads to conclusions about the relative utility of information from these sources.

Competitive Benchmarking

An approach to benchmarking that targets specific product designs, process capabilities, or administrative methods used by one’s direct competitors (e.g., the study of performance in the laptop computer industry that features only those companies that produce these products).

Industry Benchmarking

An approach to benchmarking that seeks information from the same functional area in a particular application or industry (e.g., benchmarking the purchasing function to determine the most successful approach for managing a supplier base).

Internal Benchmarking

An approach to benchmarking where organizations learn from “sister” companies, divisions, or operating units that are part of the same operating group or company (e.g., the study of internal research and development groups to determine best practices that reduce the time to market for the new product introduction process).

Generic Benchmarking

An approach to benchmarking that seeks process performance information that is from outside one’s own industry. Enablers are translated from one organization to another through the interpretation of their

Table 1 Benefits analysis of benchmarking data sources

Source of data	Advantages	Disadvantages
Competitive benchmarking	Provides a strategic insight into marketplace competitiveness and a “wake-up” call to action	Legal issues regarding data sharing among competitors
Industry benchmarking	Takes advantage of functional and professional networks to gain study participants	Study detail may not be good enough for process diagnosis Functional concentration tends to support operational rather than strategic studies
Internal benchmarking	Provides highest degree of process detail and simplified access to process information	Does not challenge paradigm of functional thinking The internal focus tends to be operational, rather than strategic, and reinforce the organization’s cultural norms
Generic benchmarking	Has the greatest opportunity for process breakthroughs Because organizations do not compete, reliable detailed information is usually available Provides incentive for strategic change initiatives	Difficulty in developing an analogy between dissimilar businesses Difficulty in identifying the companies to benchmark Difficulty in establishing the appropriate contact for a study

analogous relationship (e.g., learning about reducing cycle time in production operations by the study of inventory management methods used in stocking fresh vegetable in grocery stores).

Comparative advantages and disadvantages of these benchmarking data sources are presented in Table 1.

The final definitions that must be agreed on are the terminologies that are used to describe the different aspects of a benchmarking study:

Benchmark

A benchmark compares performance between products, services, or processes of analogous organizations in order to establish which one is superior in its sustained performance. Note that many of the benchmarks that are publicly promoted indicate only “spot” performance at a specific point in time and do not meet the criteria of “enduring success” by failing to establish the difference in performance between a “special cause event” and a “common cause” management process. A lack of statistical discipline in the use of benchmarks threatens to diminish the perceived value of the process of benchmarking (see the section titled “Presenting Benchmarking Results”).

Best Practice

Best practice defines the set of activities, tasks, resources, training, and methods that created the observed benchmark level of performance in an observed work process. In a process benchmarking study, in order to qualify as a “best practice” the performance must be observed and mapped to assure that the work performed is properly identified and that process experts have validated and verified the distinctions between observed best practices and merely good practice. Without the objective assessment by work process experts, “best practice” becomes a subjective claim that is not verifiable.

Critical Success Factors

These are quantifiable, measurable, and auditable indicators of process performance and process capability in key business processes. They indicate in basic business terms the performance level obtained in a comparative manner using such basic building blocks of processes to describe the performance of business effectiveness (quality), efficiency (cycle time), and economy (cost). Key critical success factors are universal and may be used for cross-organizational comparisons for the same process.

4 Benchmarking in Project Definition

Enabler

The specific activity, action, method, or technique that stimulated progress in one process over the comparative processes and led to identification of a best practice (e.g., the way **quality function deployment** or **failure mode** and effects analysis was used in a product design process; a process for data presentation that more clearly indicated the action to be taken by frontline operators; or an employee training and development system that delivers the appropriate skills and competence to process workers as they require these methods to perform their work in a changing technological environment).

Entitlement

The set of work process lessons learned that are derived by examination of one's own processes and discovery of wasted activities, duplicated steps or nonvalue-added work that can be eliminated or modified solely on the basis of the self-analysis phase of benchmarking. An organization is "entitled" to make such process changes without relying on the lessons learned from external discovery. Such improvements permit the process to operate as intended and represent gap closure between original process design and current process performance. *Entitlement* also refers to the gap that may exist between the design process capability (C_p ratio) and the achieved process capability (C_{pk} ratio) as management is entitled to the performance that they purchased with their capital investment.

Gap Analysis

Gap analysis evaluates the performance difference between current internal performance and benchmark performance at the best practice organization. To be effective, a gap analysis should include both the use of statistical **confidence intervals** and the tests of difference (for both means and variance) to demonstrate that a real performance gap has been observed and not a gap due to chance observations (see **Hypothesis Testing**).

Radar Diagram

A radar diagram provides a multivariate display of comparative performance for several dimensions

of interest (e.g., cost, cycle time, quality, and productivity). These dimensions are displayed on a single chart as spokes from the center where each measure has its own unique scale; however, all indicators are shown on the same graphic to illustrate a performance profile for a specific process. The radar diagram provides a more complete benchmarking assessment than a single-point measure of performance comparison.

Baseline Analysis

At the beginning of a study a baseline analysis is conducted to compare performance data across all benchmarked processes. A common scale is used for each comparison based on the variation observed in process performance. A best process is one that has the highest average sustained performance and the lowest variation in the daily results. The performance baseline comprehends both of these factors using a standardized metric for process comparisons (e.g., process standard deviation as calculated using the defects per million opportunities as evaluated against a common customer requirement for targeted performance). The baseline analysis may be presented as an analysis of variance showing sampled performance as a function of the different process locations.

World Class

Although it is intuitively clear that there is no one world best performance that exists at a particular point in time (the enormity of analysis to support such a claim would be unmanageable), it is possible to define a category of performance as "world class" by the fact that using a standardized measurement process (e.g., the performance baseline analysis), the process was observed in the top 5% of all performance noted in the study. This indicates that there is a high confidence level that the process is in a leadership position and worthy of investigation for potential best practice areas.

Benchmarking as a Discipline of Total Quality Management

In the development of total **quality management** (TQM), benchmarking has a unique place as both a tool to stimulate improvement and a management

Table 2 Defining the scope of benchmarking

Benchmarking is	Benchmarking is not
A discovery process	A cookbook process
An improvement methodology	A panacea for problem solutions
A source of breakthrough ideas	About “business as usual”
A learning opportunity	A management fad
An objective analysis of work	A subjective “gut feeling” or opinion
A process-based learning approach	Just measurement of process performance
A means to generate ideas	Just quantitative comparisons

technique that aids in strategic positioning of an organization. Benchmarking provides opportunities for full organizational participation in business process improvement by engaging the management team in the architecture of change and choice of focus areas for study; involving the middle managers in self-assessment of the work processes that they own and in adapting the lessons learned from other organizations; and relying on the study of related processes by the organization’s frontline process experts who are charged with discovery of the significant differences that lead to performance gaps.

What is benchmarking and how is it used? Benchmarking is a structured approach for learning about process operations from other organizations and applying the knowledge gained in your own organization. It consists of dedicated work in measuring, comparing, and analyzing work processes among different organizations in order to identify causes for superior performance. Benchmarking is not complete with just the analysis, however, it must be adapted and implemented in order to have a complete cycle of learning.

The objective of benchmarking is to accelerate the process of strategic change that leads to breakthrough or continuous improvements in products, services, or processes, resulting in enhanced customer satisfaction, lower operating costs, and improved competitive advantage by adapting best practices and business process improvements of those organizations that are recognized for superior performance. Benchmarking is a method that forces organizations to look outside themselves in order to avoid myopic illusions of grandeur that come from reflecting on internal experience without external validation.

Benchmarking is not just a checklist or set of numbers that are used to make management feel better about their current performance. Benchmarking should make management uncomfortable due to

the identification of gaps in business performance. Benchmarking should challenge management due to the discovery of performance enablers that could help them to improve. Perhaps the juxtapositions shown in Table 2 can help describe this situation.

Benchmarking Logic

It is important to observe that the logic of the benchmarking process does not fail the test that was issued by Dr. Deming in the early 1980s, when he cautioned executives against deadly diseases in the management of business that were derived from setting arbitrary goals based solely on visible performance measures, without understanding the depth of profound (process-related) knowledge that lay underneath most high-level performance measures.

Dr. Deming would call “arbitrary” the use of benchmarking with the following logic:

- “Our competitor’s price is 15% lower than ours; therefore, we must lower our cost by 15%.”

The logic of benchmarking is much more process oriented and requires the development of the type of profound knowledge that Deming advocated:

- “Leading companies have operations that are 20% more effective than our operations.”
- “The reasons that their operations are more effective is because . . . ”
- “The practices that they used to improve these operations include . . . ”
- “The following enhancements to our processes are appropriate for our business model and our culture and will improve our performance: . . . ”
- “The estimate of performance gain due to implementation of these enhancements is . . . ”

The ability to apply this logic comes from developing an understanding of the root cause of process improvement at the benchmark organization and translation of their lessons learned into appropriate change for your own organization. By a process of conscientious learning and cautious adaptation, a company can learn the lessons needed to move it to the level of world-class performance.

Operational Definition of World-Class Performance

Benchmarking seeks to deliver performance that is “best of the best” (the Japanese word for this is *dantotsu*) or world-class performance. World class is an elusive performance level. To be the “best of the best” it is necessary that you have both a high level of performance (top 5%), and that this level of performance be sustainable across changes in product life cycle, underlying technology in both the product and the process, as well as successive generations of executive leadership. That is a tall order for any organization.

What does it mean to be world class? One definition [1] considers a world-class company as one that is able to achieve and sustain a leadership performance level, while at the same time exhibiting the following competitive considerations that are significant learning areas for a TQM-oriented organization. According to this definition, a *world-class organization*

- knows its processes better than its competitors know their processes,
- knows its industrial competitors business better than their competitors know them,
- knows its customers better than their competitors know their own customers,
- responds more rapidly to change in customer behavior or needs than its competitors,
- engages employees more effectively than its competitors, and
- competes for market share on a customer-by-customer basis.

Clearly this definition of world class requires both an objective performance standard as well as the profound knowledge of its business and commercial

environment in order to enjoy sustained performance at this level.

The Process of Benchmarking

Not surprisingly, there is a process for process benchmarking. Many different organizations have illustrated benchmarking processes from 4 to 42 steps [1]; however, the process that I favor has seven steps which highlight the work that must be done in a benchmarking study and which also follow a four-phase process that is generic to all benchmarking models:

1. Identify subject – choose what to benchmark
2. Plan study – identify your partners and plan your **data collection**
3. Collect information – actively collect the data and visit partners
4. Analyze data – analyze the data for performance trends and consistency over time
5. Compare performance – compare results and test differences for statistical significance
6. Adapt applications – prepare the lessons learned for transition to your own culture
7. Improve performance – implement projects to improve your processes

The generic four-phases that these steps cover roughly follow Deming’s plan–do–check–act (PDCA) process management and improvement cycle. These four process benchmarking phases are summarized as follows:

- Plan: design the study and evaluate the baseline performance.
- Collect: collect internal and external data about the process.
- Analyze: conduct a gap analysis and determine enablers of success.
- Improve: adapt the recommendations and implement the process improvements.

Each phase of this benchmarking process is described in the following sections.

Benchmarking: Plan

The steps involved in planning a benchmarking study include

- Select a process.
- Gain the owner's participation.
- Select a leader and a team.
- Identify customer expectations.
- Analyze process flow and measures.
- Define process inputs and outputs.
- Document the process.
- Identify process critical success factors.
- Determine data collection elements.
- Develop a preliminary questionnaire.

Some of the questions that must be answered during this phase of a benchmarking study include

- What process should we benchmark?
- What is our process and how does it work?
- How do we measure it?
- How well is it performing today?
- Who are the customers of our process?
- What products and services do we deliver to our customers?
- What do our customers expect from our process?
- What are the critical success factors for this process?
- What is our process performance goal?
- How did we establish that goal?
- What data should we collect for comparisons?

Notice that many of these questions are similar to the basic questions that one confronts in any TQM improvement project.

Benchmarking: Collect

The steps involved in collecting data for a benchmarking study include:

- Collect internal data.
- Perform secondary research.
- Develop partnership criteria.
- Identify benchmark partners.
- Plan data collection.
- Develop survey or interview guide.
- Solicit participation of partners.
- Collect preliminary data.
- Conduct site visits.

Some of the questions that must be answered during this phase of a benchmarking study include

- What companies perform this process better?

- Which company is best at performing this process?
- What can we learn from that company?
- Who should we contact to participate as our partners?
- What is their process?
- How representative is the process across different areas of their organization?
- How do they measure process performance?
- What is their performance goal and how was it set?
- How well does their process perform over time?
- Is there any difference in performance at different locations or based on seasonal change?
- What business practices, methods, or tasks contribute to the process performance?
- What factors could inhibit the adaptation of their process into our company?

Notice that many of these questions are the same as questions that would be addressed in any TQM-based data collection activity.

Benchmarking: Analyze

The steps involved in analyzing benchmarking study data include

- Aggregate the data across units but preserve subgroup relationships.
- Normalize performance to a common performance base (e.g., σ scale).
- Compare current performance to historical data.
- Test performance for difference in both trend of performance average and variation.
- Test differences for statistical significance.
- Identify gaps in performance and the root cause of all significant differences.
- Identify entitlement opportunities.
- Forecast performance observations to the business planning horizon.
- Develop case studies of best practice.
- Isolate process enablers.
- Assess adaptability of process enablers.

Some of the questions that must be answered during this phase of a benchmarking study include

- What is the basis for comparing our process measurements?

8 Benchmarking in Project Definition

- How does their process performance compare with our process performance?
- What is the magnitude of the performance gap?
- What is the nature or root cause of the performance gap?
- How much will their process continue to improve?
- What characteristics distinguish their process as superior?
- What activities within our process are candidates for improvement?

Note that many of the questions addressed above are the same as would be addressed in any TQM or Six Sigma improvement project.

Benchmarking: Improve

The steps involved in implementing the lessons learned from a benchmarking study include

- Set goals to close, meet, exceed the gap.
- Modify enablers for implementation.
- Gain support for change among all involved parties.
- Develop the action plan.
- Communicate the plan.
- Commit resources to achieve the plan.
- Implement the improvement plan and document the changes.
- Monitor and report progress on targeted schedule.
- Identify opportunities for further process improvement.
- Recalibrate the benchmark measure after implementation.

Some of the questions that must be answered during this phase of a benchmarking study include

- How does our knowledge of their process help us to improve our process?
- How should we forecast the future effectiveness of their process performance?
- Should we redesign our process or reset our performance goal based on this benchmark?
- What activities in their process need to be modified to adapt it into our business model?
- What have we learned during this study that will allow us to improve on “best” practice?
- What goals should we set for our own process improvement?

- How can we implement the changes in our process?
- How will other companies continue to improve this process?

Note that many of the questions addressed above are the same as would be addressed in managing implementation in any project improvement process.

Methods of Data Collection

In conducting a benchmarking study, there are several different approaches to data collection that can be pursued by a benchmarking team. Tables 3 and 4 illustrate several schemes for data collection and identify when to use each approach as well as the advantages and disadvantages associated with each of the methods.

Presenting Benchmarking Results

Some final points should be made about the process of benchmarking relative to the analysis and presentation of benchmarking data. Care must be taken in the data analysis efforts to assure that benchmarks are representative of real-world performance. Specific cautions include the following statistical problems in benchmarking:

- single data point measurements that are passed off as “benchmarks”,
- **measurement systems** not validated for sensitivity of observation or **calibration**,
- averages used to represent performance benchmarks,
- missing variation data in process characterization,
- components of variance not identified according to their source,
- comparative charts not indicating *both* mean and variance,
- process changes not correlated with performance shifts, and
- interactions not identified among the different process variables.

Clearly, there can be many issues that create problems in the measurement and analysis of results from benchmarking studies. Careful planning and solid data collection and analysis efforts can achieve the elimination of these opportunities

Table 3 Data collection methods–1

Method	Existing data review	Questionnaire/survey	Telephone survey
Definition	Analysis and interpretation of data that already exists in-house or in the public domain	Written questions sent directly to benchmarking partner – can contain any type of question: multiple choice, open-ended, forced choice, or scaled answer	A written script of questions that are used to solicit data or guide a conversation during a telephone call to gather data and information
When to use	Before conducting original research to establish what is the historical baseline	When you need to gather the same information from a large number of sources	When information is needed quickly or to conduct a fast screen of potential sources
Advantages	A large number of sources of information are available and most are accessible from your own organization	Permits extensive data gathering over time, can be analyzed by computer (if OCR form is used), and data is easy to compile	Can cover a wide range of respondents quickly, people are more candid over the phone and can also amplify answers in follow-up questions
Disadvantages	Gathering this information can be very time consuming	Response rates are low; and interpretation of questions can be subjective, creative ideas rarely surface, probing for “how to” answers is difficult	Locating the right person to answer, no exchange of process information occurs, and often requires multiple phone calls

Table 4 Data collection methods–2

Method	Interview	Focus group	Site visit
Definition	A face-to-face meeting with a benchmarking partner using questions that are prepared and distributed in advance	A panel discussion between benchmarking partners with a third-party facilitator at a neutral location	An on-premises meeting at a benchmarking partner facility that combines an interview with work process observation
When to use	When you need one-on-one interaction to probe and drive data collection to a specific objective or level of detail	When you want to gather information from more than one source or perspective at the same time – when there are diverse opinions or ways to approach an objective	When you need to observe specific work practices
Advantages	Encourages interaction, in-depth discussion and open-ended questions – a flexible style can provide unexpected information	Direct sharing of information on best practice – brings the partners together to discuss a mutually established agenda	When interpersonal or face-to-face interaction is needed to evaluate the “human aspect” of a process Can observe actual practice and verify the process capability, enablers, and assess the measurement system
Disadvantages	Takes time – the people interviewed may be reluctant to talk about sensitive issues	Logistics must be managed – result may be the “lowest common denominator” among the participating partners	Requires careful planning and preparation – who asks what of whom?

for error introduction into a benchmarking study. Whenever possible, analysts conducting benchmarking projects should have the same education as Six Sigma Black Belts in statistical analysis to assure the analytical soundness of study results.

Benefits and Pitfalls of Benchmarking

Benchmarking is a business change process that encourages managed change. It encourages an organization to take an external and objective perspective in evaluating its performance. The benefit of benchmarking comes from three specific actions:

- The gap between internal and external practices creates the need for change.
- Understanding the benchmarked best practices identifies what must change.
- Externally benchmarked practices provide a picture of the potential result from change.

However, lest benchmarking appear to be a panacea for problem resolution, the following set of potential pitfalls in conducting benchmarking studies must also be highlighted:

- selecting benchmarking partners that do not convince management (not respected);
- choosing benchmarking partners to meet popularity tests with no performance substance;
- accepting public relations claims as process performance benchmarks;
- assuming that measurements are the same in different organizations (without checking);
- identifying process measures that are not traceable from strategic to operational levels;
- conducting statistical analyses that represent surface observations – not root **causality**;
- failure to validate performance with on-site inspection to verify benchmark claims;
- enforcing implementation of a benchmarking lesson across a cultural barrier; and
- use of “benchmarks” for management decisions without recalibration over time.

Comparative Analysis and Competitive Advantage

What does an organization gain in the way of competitive advantage from benchmarking? In the long

run, competitive advantage comes from outthinking and outperforming competition. When an organization uses benchmarking effectively, they are able to think ahead of their industry and to act efficiently by adapting lessons learned from cross-industry studies to permit them to creatively imitate the best performing processes in the world. Over the long haul this can establish them as the thought-leader within their own industry. In the final analysis, it is not outthinking or prior knowledge that results in competitive advantage, it is in the excellence of execution of such new knowledge and the creative application of breakthrough insights that wins in the long term. To achieve a dominant position in a market, a company must both know and do better than its most aggressive competitors. Benchmarking can help develop the competence to achieve this position, but it must be supplemented by management will in order to make success happen.

Integrating Benchmarking with Strategic Planning

The leading organizations in the world plan to win and win by planning. Benchmarking improves performance for these organizations by providing them with a methodology to learn and challenge their critical business assumptions by thinking differently about their strategic direction. Applying benchmarking as a tool of business strategy is an effective way to evaluate options and perform an assessment of alternatives by considering the strategic implications that may be observed in other analogous situations. Such lessons reduce the likelihood of “repeating the mistakes of others”.

Conclusions

Process benchmarking is an important tool of TQM and can help to improve both the strategic direction and the operational process performance. It is a discovery methodology that is used to stimulate learning and help organizations to think about creative options for the design and implementation of its business processes. Coupled with solid statistical data analysis, best practice identification and cultural adaptation can help organizations to both “learn” and “do” their business process improvement more effectively.

GREGORY H. WATSON

Six Sigma

Introduction

There are many ways in which people try to define Six Sigma; some emphasize the philosophy, others the statistical tools, some talk about the measurements and the 3.4 parts per million defect level targets, and still others focus on the similarities and differences with **total quality management** (TQM). Perhaps the simplest and most correct way to think of Six Sigma is the current state of the art of quality management. Six Sigma is more an evolution of best practices in quality management than being something entirely new.

More than 20 years ago, when Motorola coined the term *Six Sigma*, it was after years of adding new tools, methods, and concepts to what they had learned first from the Japanese in **total quality control** and then from many leading companies in the United States, and throughout the world. Many companies follow similar paths starting with specific tools and proceeding to develop comprehensive quality systems. The normal path was as follows:

- quality circles
- statistical quality control
- ISO 9000:1987 system of quality standards
- continuous quality improvement/*Kaisen*
- reengineering
- theory of constraints
- Malcolm Baldrige National Quality Award criteria or European Foundation for Quality Management criteria
- total productive maintenance
- supply-chain management
- ISO 9000:2000 system of standards
- lean manufacturing – Toyota Production System
- Six Sigma
- Design for Six Sigma
- lean Six Sigma
- ? – we are not sure what will be next, but are sure something will be.

It is not surprising to see such a list. Companies throughout the world are in an intense competitive race. The easy communication we now have through conferences, **benchmarking** visits, and the Internet makes the spread of new ideas and best practices

faster than ever. If a method, tool, or management practice improves the performance of a company or even part of a company, it is now implemented quickly. Senior managers are not interested in the name of a program, they are simply interested in what works.

We will not try to trace the entire evolution of Six Sigma here, but just cover the most important events. Some years ago George Box presented a wonderful summary of the evolution of science. For thousands of years progress was slow. New scientific breakthroughs were often by chance, an “intelligent observer” being in the right place at the right time. A significant event occurred, someone asked why, and after some experimentation, began to understand the cause and effect. W. C. Roentgen’s discovery of X rays is a classic example.

By the late 1800s, this was beginning to change. Thomas Edison built his laboratory in 1887 to make things happen, not wait for them to occur accidentally. He ran thousands of experiments in a well-planned fashion. Throughout the twentieth century industrial, academic, and government laboratories, often employing tens of thousands of researchers, became common. The art and science of experimental design became widely used to drive improvements in products and processes and in developing entirely new products and even services. In almost every leading organization, teams of researchers well trained in statistical methods, industrial engineering, and operations research supported these researchers and operations people throughout the organization in running experiments, analyzing data, and making significant improvements.

In the latter half of the twentieth century, another phenomenon took place, first in Japan and then quickly in other parts of the world. Large numbers of employees in organizations were taught the basics of the scientific method and given a set of tools to make improvements in their part of the company, changing the process and even the product to achieve continual improved production and product performance. This basic teaching of the scientific method for quality improvement was first documented in English by Joseph M. Juran in his classic 1964 text, *Managerial Breakthrough*. The steps he laid out were straightforward:

1. breakthrough in attitudes
2. the **Pareto** principle

2 Six Sigma

3. mobilizing for breakthrough in knowledge
4. the steering arm
5. the diagnostic arm
6. breakthrough in knowledge – diagnosis
7. resistance to change – cultural patterns
8. breakthrough in performance – action
9. transition to the new level.

He then stressed the importance of control – holding the gains. The second part of the book he devoted to quality control. Later in *Quality Planning* and *Quality by Design* he added the importance of design outlining many of the tools and techniques we now widely use in the Design for Six Sigma.

Many Japanese companies had made these methods a standard practice and taught them to all employees. An example is Komatsu, the heavy equipment manufacturer. They had a small pocket book printed to easily remind each employee of the steps for improvement. An English version of this small pocket book was created by GOAL/QPC. More than 10 million copies of this small guide have been purchased by leading companies for use in training their people in the scientific method and quality improvement. The steps in the guide are the following:

1. Decide which problem will be addressed first (or next).
2. Arrive at a statement that describes the problem specifically.
3. Develop a complete picture of potential causes.
4. Agree on the basic cause(s) of the problem.
5. Develop an effective solution.
6. Implement solution and control.

Some years later these steps have evolved into the basic quality improvement methodology of Six Sigma.

- *Define* – understand what is critical to quality, the process, and define the problem and the action plan.
- *Measure* – measure all critical aspects of the process, perform the **measurement system** analyses, focus on what is important.
- *Analyze* – identify the factors that truly drive performance – the Xs.
- *Improve* – establish the optimum levels for each factor, define the functional relationship,

$$Y = f(X).$$

- *Control* – define the control plan, hold the gains.

The improvement structure of Six Sigma is not different, it is just a refinement of continuous quality improvement methods used for years by leading organizations – the scientific method widely taught with useful tools for use at each step. The question then is what is different about Six Sigma? We shall focus on seven major differences.

Philosophy

The most startling factor in Six Sigma for many is the focus on perfection. In 1994 Robert Galvin, the then chairman and chief executive officer of the Motorola Company, startled a group of executives during a dinner talk by stating, “We now believe perfection is possible.” Many writers about Six Sigma have confused Motorola’s calculation of “Six Sigma quality” as 3.4 parts per million defects with Galvin’s philosophy of perfection. The 3.4 parts per million defects are just Motorola’s practical realization that for some products perfection was quite difficult and therefore they needed, at that time, a more realizable goal. They had defined perfection as a product that was on target with respect to its specifications and had six standard deviations (Six Sigma) from the center target to both the upper specification limit and the lower specification limit. With the basic assumption of an underlying normal (Gaussian) distribution, this process is close to perfect – only two parts per billion would be out of specifications.

Someone in the company soon realized that not all processes are exactly centered; some may shift for a variety of reasons and not be exactly in the true center of the specification range. A study in one of Motorola’s plants found that their process shifted as much as 1.5 standard deviations over time thus becoming 4.5 standard deviations from one limit and 7.5 standard deviations from the other limit. A quick calculation showed that this worst-case analysis created a process with 3.4 parts per million out of specification. A Whole lot of companies have adopted this shift assumption and now consider Six Sigma quality as 3.4 parts per million defects. The true philosophy underlying Six Sigma is the relentless pursuit of perfection.

Financial Focus

A weakness in many quality initiatives in the past including the way total quality management was practiced in some organizations was a lack of hard numbers on the bottom-line results of various activities. The leading organizations practicing Six Sigma have an almost fanatical focus on quantifying actual results for every project using techniques such as “hard numbers” and “soft numbers”. The hard numbers are ones that can be proved to directly result from completed projects – reduced structural costs, reduced labor, reduced materials, decreased warranty payments, reduced machine downtimes, increased number of customers – actual savings. The soft numbers are not usually counted in terms of the actual savings but calculated as potential benefits, hard to quantify, but definitely positive results. These soft numbers often include increased customer satisfaction, reduced cycle times, improved employee morale, faster development times, and so on. Most companies now include people from the finance and/or accounting departments on project teams. Project values are estimated before projects are launched, and the teams work hard to document actual savings at each step. Return-of-investment calculations are critical for each project.

Training

For many companies the training methods now used in Six Sigma are completely different from how employees were trained in the past. People are selected for training after the leadership of the organization has selected the projects or project areas. Teams are trained together. No one comes to training without a project. During the training cycle they work on the project. The goal is to finish the project shortly after the training is complete. Tools, methods, and concepts are applied to the project as soon as they are learned. Teams present their projects during every week of training receiving valuable feedback, criticism, and ideas from the instruction team and the other participants. The goal is not to complete the training; the goal is to solve a problem with significant financial results. The emphasis is not on understanding statistical methods but to know to use sophisticated tools, statistical and nonstatistical, and to solve complex problems.

A new structure has evolved for the training. The team leaders, the fundamental building blocks of Six Sigma, are the black belts. These people receive 4–5 weeks of intense training in problem solving, statistical methods, project management, and team leadership. The companies producing significant results in Six Sigma select these people from the pool of future company leaders and make their assignments as black belts full time for several years. Some of these black belts decide to make this their company performance path and become permanent problem solvers or task force leaders, and some go on to become master black belts gaining other advanced skills and becoming trainers and consultants within the organization.

Team members are usually trained as green belts in a 2-week course again focusing on problem solving and working during training on selected projects. Green belts will often lead small project teams within the organization and work as team members under the leadership of a black belt on large projects. Many companies now have “white belt”, “yellow belt”, or even “red belt” training programs to give a basic understanding of Six Sigma methods to every member of the company. These are usually 2- or 3-day sessions focused on the basic problem-solving methodology (define–measure–analyze–improve–control (DMAIC)) and an introduction to the basic tools.

Software

One of the striking differences in the application of Six Sigma is the widespread use of sophisticated software. Several leading software companies now sell outstanding software packages directly supporting Six Sigma projects. This software makes sophisticated problem solving possible by all members of the organization. The software is not taught as a software package, it is totally integrated into the green belt, black belt, and master black belt training. As problem steps are taught, the appropriate tools are also taught. The class uses the software to solve example problems, work on complex case studies, and to work on their own problems.

Most leading companies have standardized on selected software packages to enable rapid sharing of best practices, easy understanding by all project reviewers, and enhanced support for all employees. These software packages have continued to

evolve over the past decades becoming more and more focused on the tools needed by large numbers of employees engaged in breakthrough quality projects and developing new products, services, and processes.

New Tools

For many people the most obvious new addition is the plethora of new tools—both statistical and non-statistical—introduced in Six Sigma classes and practice. Most of these tools are not truly new. The sophisticated, easy-to-use software has just made it practical to make these tools available to every level of employees in all parts of the organization. Simple “hand tools” that were taught in earlier days of continuous quality improvement, statistical quality control, or total quality management have now become practical for large datasets of thousands or even millions of data points. Other tools, for example multiple regression, that were thought to be in the purview of only advanced-degree specialists are now commonly used by people from all parts of a company. New tools are continually being added to both training classes and software as they prove useful. The problem-solving “toolbox” has been greatly expanded. A whole lot of books have been written describing these tools, giving examples of their use, and step-by-step instructions on how to use.

Structured Improvement Process and Design Process

Companies have created very structured improvement and design processes that allow much innovation and creativity but are also easy to teach and understand. Most use some form of the DMAIC process described above for improvement projects (breakthrough quality), but there seem to be slight variations in the Design for Six Sigma project steps. Some of these variations come from companies trying to match the new ideas of Six Sigma with their current design processes.

The advantages of the structured improvement and design processes are obvious. All levels of employees throughout the organization know how to lead a project from start to finish. Communication across the organization is greatly enhanced, people can

quickly learn from others working on similar issues. Managers easily review large numbers of projects, thus becoming involved in the critical implementation steps. Replication of results across many areas of the organization is facilitated.

Leadership

The driving force in successful Six Sigma implementation has not been different from the driving force in successful total quality management or other initiatives. Leadership is critical. What has been different is the amount of attention paid to senior management, executive leadership, and specific training programs developed just for the senior management team. Many companies now have 2- or 3-day special courses just for project “champions”, leaders specifically selected to oversee black belt and green belt projects. This training usually covers the basic methods (DMAIC) and introduces the statistical tools, but focuses on the actual roles of senior managers in getting the results.

This focus includes the role of senior managers in selecting the project areas and specific projects and selecting the black belts and green belts who will be involved. The senior managers understand their role in providing resources to assure that the projects are successful. They understand their roles in the implementation of the company’s organizational or process changes that will be necessary to achieve the desired results. They know to deal with the various sources of resistance to change the status quo in any organization. They become truly involved in all aspects of the Six Sigma initiative becoming major drivers in the success of projects.

Summary

In many ways Six Sigma shares most of the ideas, concepts, tools, and methods developed over the past hundred or so years in quality management. It truly is far more an evolutionary change than a revolutionary one. However, the differences discussed above have made it far more effective for a large number of organizations throughout the world than any approach to quality management or organization excellence than ever before.

A. BLANTON GODFREY

Total Quality Management (TQM)

Introduction

Many associate the philosophies of **quality management** with a number of our better-known quality gurus. And while that is certainly true to an extent, there have been many contributions to quality management philosophies, beliefs, and tested truths. These philosophies have by now also undergone evolution over long time periods, with the greatest number of additions formulated and placed in practice over the last century. In fact, the quality discipline has matured so well that there is now a large body of knowledge pertaining to associated philosophies.

The quality discipline itself has been like a “learning organization”, learning by mistakes (e.g., assigning inspection alone as a control on production, and separate from the production department, essentially removing responsibility for quality from production and applying it too late in the process stream); learning from application experiences and the sharing of these experiences in professional societies, seminars, publications, and many forms of media; formal university learning on the discipline; learning from **benchmarking** best practices; learning from other related disciplines such as leadership theories, motivation theories, organizational development, and so on; learning from the application of standards and awards such as the ISO 9000 Quality Management System, and the US Malcolm Baldrige National Quality Award for business excellence, as well as many others in Europe, Japan, and other countries. Numerous innovations of the philosophies and techniques of total quality management (TQM) have come from all parts of the world, with notable additions by the Japanese in their postwar rise to prominence.

Total Quality

Central to the term *total quality management* and to its associated philosophies is the meaning of “quality”. What is quality as it applies to the TQM philosophies? An important TQM philosophy is how we define and apply the concepts of quality. Generally, most dictionary definitions do not include sufficient

breadth of the concept as applied to the quality disciplines. Many dictionary definitions of quality do, of course, address the general subject of quality – but they lack strategic and/or operational meanings that can be used to advantage by an entrepreneur/manager in structuring products or services and processes that contribute to successful businesses. And while there are numerous contributions to defining quality in the context of the quality disciplines, this brief *exposé* cannot explore them all. One rendition of an attempt at this is by the author [1], and is expressed diagrammatically in Figure 1. The gist of this diagram is to emphasize that in the quality disciplines quality has many aspects.

The Fundamental Aspects of Quality

There is the quality of design – usually defined by way of specifications, standards (internal and/or external, company, national, regional, and/or international), grades, drawings, and so on. We refer to this as the fundamental aspects of quality and picture it as a core element in the overall definition of quality. It should be understood in this dialog that quality, in and of itself, doesn’t necessarily mean high quality to the degree of unnecessaryness; it means uniformity, consistency, and conformity to the standard or specification – a statement of what the user wants and can afford *and* what the producer can provide. Note in the fundamental aspects of quality (design quality), the reference to product “grade”. The quality statement or specification should be based on what the existing process can produce economically with reasonable controls and improvements (otherwise recognition that a new process must be designed and implemented). Hence, the producer and user must cooperate in defining a practical, reasonable, and economical specification of quality. This is, in fact, an important part of quality planning – to match the needs of the customers with the capability of the process (existing or new) and product design, taking into consideration the intended use of the product.

Two Contrasting Examples

For example, if a producer of plastic measuring and drawing rulers were to specify a requirement of ± 0.5 cm in a length of 30 cm, then even with good conformity to this requirement, the rulers would be unfit for reasonable use. Conversely, if consumers

Figure 1 Concepts and expansion of the influences and the areas of applicability of quality

were to request a 0.001-mm tolerance on the diameter of the body of ballpoint pens, their manufacture would become extremely impractical and/or uneconomical, while such a tight specification would fail to provide any extra fitness for use.

The Measurable Aspects of Quality

Next are the measurable aspects of quality, which include the concept of conformance to the standards, specifications, and requirements that are part of the fundamental aspects. Here we define important quality characteristics, often referred to as the *building blocks* of quality. In this section we address different types of characteristics such as variables, attributes, visual, sensory, and the like. And these apply to both products and processes, including management

processes. Hence, embedded in this aspect are important principles such as “fact-based” decision making as opposed to opinion-based decisions. It enhances product and process control as well as continuous improvement (CI). This aspect of quality also reaches out to bring into the TQM arena, the whole field of metrology – the science of measurement, including, across broad ranges of products and services, scientific metrology, process metrology, and legal metrology. If we are to make good and effective use of collected facts and data, they must be accurate, precise, reproducible, repeatable, and meaningful. The conformance aspect of quality was emphasized by Phil Crosby and it could represent a fairly “complete” definition of quality under the assumption that the “conformance” is to requirements that reflect sound design; customer wants, needs, and desires; and interests of other stakeholders. As we expand the diagram

of Figure 1, it needs to be pointed out that inner aspects influence outer aspects, and considerations of properties of outer aspects, in turn, influence inner aspects. This is reflected by the double directional arrows that are shown in the diagram to emphasize that each aspect is influenced and modified by the other. For example, while measuring conformance we may discover areas for which the specifications (quality of design) must be modified or improved. Measurement also touches on the broader management aspects, discussed subsequently, and includes management information systems (MIS), uses of such techniques as the balanced scorecard, the dashboard technique, the measurement of costs of poor quality (COQ), and various measures of customer and employee satisfaction.

The first two aspects of quality are particularly important for a proper understanding of the “as conceived” and “as made” quality of products and services. Concern for quality is often not exercised adequately, particularly by production and management personnel, because these two aspects of quality are not known or understood properly. In such a setting, these aspects of quality are known as “design quality” (as labeled above) and “manufactured quality”, respectively. As discussed subsequently, both should be aimed at providing quality satisfactory to the consumer – the “as delivered” and “as perceived” quality. Therefore, it can be seen that design quality is not the only aspect of quality. After a product has been designed, even to meet customer expectations and placed in manufacture, we find that the process does not always produce each unit of product (or each instance of service) in conformity to the design – defects in materials, parts, subassemblies, assemblies, and in final product arise. These defects, of course, may be related to the design of the product. The correction, reduction, improvement, and/or prevention, may call for a redesign of the product. But all too often these nonconformances are the result of incomplete, inadequate, poorly planned, and poorly controlled processes. The products or services that fail to perform as intended, most often result in customer dissatisfaction. Any defective or nonconforming materials, parts, assemblies, and finished products that are discarded or reworked during the manufacturing process, result in increased cost. And incidentally, these costs are often not identified or recognized as quality costs by owners/managers who otherwise consider “quality” too costly. The lost time and effort in

producing these defective or nonconforming parts and products, the loss of business resulting from delays in delivery, and other associated ills of poor quality products are the consequence of “manufactured quality” (i.e., the quality of conformance to the design). We will continue this discussion in still another aspect of quality subsequently.

The Consumer Aspect of Quality

We then move to the “consumer” or marketable aspects of quality. In this aspect the “customer” is king! This was emphasized by Karou Ishikawa and others. Related characteristics of this aspect are such things as “fitness for use” emphasized by Joe Juran; performance (as opposed to conformance); reliability; life; price (yes, price is a “quality”); availability; and delivery. This alludes to the philosophies of customer satisfaction, customer retention, building a base of loyal customers, making them a part of your “external sales force”, customer satisfaction/retention measurements, and tools and techniques such as focus groups, surveys, “voice of the customer” and the use of **quality function deployment (QFD)** (which also impacts other aspects of quality). Also useful here is Noriaki **Kano**’s “customer quality model” in which he emphasizes dissatisfiers, satisfiers, and excitors/delighters as well as the dynamics of these characteristics over time, requiring diligence in these efforts.

There are numerous examples of products (and services) that have been designed, specifications prepared (usually by a design engineering department), placed in production, conformance to specification checked, and confirmed – only to find that the products (or services) did not meet with customer satisfaction. Is it possible for specifications to be prepared without reflection on the needs, requirements, or desires of present, or potential customers? Consider the case of the US automobile manufacturers in the 1960s–1980s, and even beyond. Specifications do not always reflect customer needs and desires. We may have *conformance*, but do we have satisfactory *performance*?

Example

When wooden furniture is made in a tropical, humid climate for distribution to a frigid or temperate dry climate, it is the producer’s responsibility to learn

something about the effects of this climate, or for that matter, any artificially produced environment such as forced hot and dry air, on the long-term performance of the product. It may be necessary to include additional operations (e.g., kiln drying of raw materials) or controls (e.g., selection of aged raw materials) in the manufacturing process. If cracks develop in the product after some period of use and the producer is irresponsible in this regard, a decline of business after the initial orders should be expected, deservedly so. In similar situations, costly recalls, **warranty claims**, or liability judgments may be incurred, depending on the nature of the product or service.

It is one aspect of quality to establish a specification based on a quality of design. It is another aspect of quality to determine if the specification is being met – that there is conformance to the specification. It is still another aspect of quality that the specifications – as written and implemented – reflect the needs, requirements, and desires of the customers (or at least a majority of present and potential customers).

The Operational Aspects of Quality

Next we move to the operational aspects of quality. It is here that we expand well beyond the usual dictionary definitions of quality, beyond products, or entities, to the quality of management, operations, employees, systems, and the like. And it is here that our concepts of quality begin to take on a more “total”, even strategic, dimension. Characteristics of this aspect of quality include such things as maximum output (yes, productive output, throughput, cycle time, and the like are qualities!). Quantity is, in fact, a characteristic of the operational aspects of quality! A characteristic that should be monitored, controlled, and improved – an integral part of quality, as some might say, with a big “Q”, rather than with a little “q”. Other characteristics of the operational aspects of quality are minimum waste, minimum scrap, minimum repair, or rework, minimum downtime, minimum absenteeism, and certainly, minimum cost, as well as optimum delivery, and the like. Here an important philosophy is that optimum production, quality, and cost can be planned, established, improved, and achieved simultaneously. As emphasized by Deming this strikes at the core of some now (hopefully) obsolete theories of “trade-offs” of these characteristics. If quality, that includes

this aspect, is implemented properly with planning, control, and improvement, it is entirely feasible to achieve these characteristics simultaneously. And it is with respect to this aspect of quality that a great many philosophies of TQM have come to light.

If we examine these characteristics, it is not difficult to understand how quantity (e.g., maximum output) can be achieved with a correct approach to quality. Recall our earlier discussion regarding the characteristics of “manufactured quality”. When our quality orientation includes a constant effort (and associated techniques) to reduce waste, scrap, rework, downtime, absenteeism, and others, more output is a natural result at lower costs. For every defective unit prevented, another good unit is produced and available for sale. For every day of absenteeism prevented, another person-day of output is produced. Yes, our overall definition of quality must address these matters as well as those of the actual final products and/or services.

Included in this is the whole realm of variability reduction, control and improvement *via* statistical methods; statistical **quality control**, including use of **control charts**, designed experiments, and numerous such tools; process control, including concepts of **process mapping** and flowcharts, **Pareto** analysis, Ishikawa diagrams, Poka-yoke (mistake proofing), the “five-whys” technique, the “triple-role” principle, cause-and-effect analysis, and the like. The recognition that defects and/or nonconformities are caused and we can seek and find their causes is essential. And here a related quotation by Shakespeare brings this concept to the forefront from so many years ago, “*Find out the cause of this effect, or rather say, the cause of this defect, for this effect defective comes by cause*”, from Hamlet, Act ii, Sc. 2. An important philosophical understanding in this connection is the type of cause, so essential to the approach taken to locate and eliminate unwanted effects, namely, common (or chronic) causes and special (sporadic) causes, with the first set of terms used by Deming and the matching ones in parentheses used by Juran. The following quotation from Deming [2] is applicable here, “**Special causes and common causes.** A fault in the interpretation of observations, seen everywhere, is to suppose that every event (defect, mistake, and accident) is attributable to someone (usually the one nearest at hand), or is related to some special event. The fact is that most troubles with service and production lie in the system. Sometimes the fault is

indeed local, attributable to someone on the job, or not on the job when he should be. We shall speak of faults of the system as common causes of trouble, and faults from fleeting events as special causes." Further principles and disciplines involve sampling inspection, reliability, and many others. Here, we owe a great deal to pioneers and gurus such as Shewhart, Dodge, Fisher, Ishikawa, Taguchi, and others. While sampling inspection may be considered "passé" by certain elements of our profession, it is still being applied effectively in a great many enterprises to serve as a measure of control, improvement, and assurance, especially influenced by many of the regulated industries. The philosophy of CI is important here, achieved both by incremental step-by-step improvements (of the "**Kaizen**" type) as well as breakthroughs of the innovation type. **Six Sigma** programs and efforts are applicable here, including six sigma for improvement and cost reduction as well as Design for Six Sigma (DFSS). **Failure mode** and effects analysis (FMEA) to help reduce the necessity for extensive improvement efforts downstream is important, essentially moving much of process quality control and improvement upstream to the design process. Just-in-time (the JIT concept) is applicable as a production system, not just as an inventory reduction system, as many misunderstand. Juran's "Trilogy" alluded to earlier, involving planning, control, and improvement, is applicable. Elimination of the "hidden-plant" (existing to produce defective products) as emphasized by Feigenbaum is useful here. Cross-functional approaches, abetted by a "teams" approach are useful here. Deming's entire philosophy of his "profound knowledge" applies here, with emphasis on (1) appreciation for a system, (2) understanding of variation, (3) theory of knowledge, and (4) psychology, including his 14 points for management, and his seven diseases and obstacles.

As this concept of quality touches on the quality of management, employees, and systems, it includes the whole realm of managerial principles, tasks, practices, and skills as well as a "systems" approach. This includes strategic planning, including the recognition that "quality" as expounded here is a strategic element. It also includes leadership, managerial audits, system audits, and the like. It embraces the Malcolm Baldrige National Quality Award for business excellence, as well as the ISO 9000 Quality Management System procedures and requirements. It

includes the entire concept of "supply-chain" management. This involves relationships with suppliers, including the "partnership" concepts of Deming and "single-sourcing", where feasible. It includes organizational structure with a philosophy of flattening the "silo" effect of a high managerial hierarchy, in order to achieve more involvement from all levels of the organizational chain and reduce communications and errors related thereto. It also includes the philosophy of defining, communicating, and achieving for all stakeholders, the firm's vision, mission, guiding principles, and values. And while we will consider subsequently the human aspects of quality, from a management of employees point of view, this aspect of quality includes the whole realm of human resources management, recruitment of appropriate personnel, adequate training, employee involvement, suggestion systems, empowerment, fair wages, cross-functional and team deployment, recognition, awards, internal promotion, and measurement and enhancement of employee satisfaction with the additional philosophy that "a satisfied employee helps to achieve satisfied customers". It embraces the concept that quality is everyone's responsibility, not relegated to a specific function. And it emphasizes the necessity to manage quality as a shared responsibility, that every function will have various quality matters that are unique to that function.

The Conservational Aspects of Quality

The next aspect of quality from Figure 1 is that of the conservational aspects of quality. Here we are considering the optimum use of resources, including materials, machines, money, land, energy, and people. Not all waste in a business or other setting is the result of actual defective products. Materials, machine run-time and length of downtime, money, space, energy and labor of personnel can be wasted at any step in a process of production or service. How we use our resources is crucial to optimizing those resources. It is not difficult to realize that there is a strong link between this aspect of quality and the operational aspects discussed above. The same tools and philosophies of management apply. Much of this is attitudinal, but once the proper attitude toward quality has been established, actions to make optimum use of resources follow.

The Environmental Aspects of Quality

Still another part of our overall definition of quality is the environmental aspects of quality. This pertains to such things as ecology, clean air, unpolluted waters, potable water, tolerable noise levels, safe waste, open space, landscape (natural and developed), recreation, and beauty. Safety at work, home, and play is also included as an important characteristic. Therefore, our overall definition of quality includes the environmental aspects of quality as shown on Figure 1. Significant activities associated with this aspect of quality are being undertaken at the international and national levels. The International Organization for Standardization (ISO) has promulgated a series of standards on Environmental Management Systems, namely, the ISO 14000 series. These, like the ISO 9000 series on Quality Management Systems, are already generating a lot of attention and form the basis for specifying requirements, assessing compliance, and certifying satisfactory implementation.

The Human Aspects of Quality

While the quality of employees was considered as part of the operational aspects of quality in recognition that “our people are our most important asset”, the broader scope of the human aspects of quality may be considered separately. Characteristics of this aspect of quality include the quality of life, including the quality of work life, the quality of health, education, culture, society, freedom, ethical, and moral values. Therefore, our overall definition of quality includes the human aspects of quality, as shown on Figure 1 and figures significantly in the philosophies of TQM. Many of these characteristics of the human aspects can be included by forward-looking enterprises in creating an overall work environment in which employees enjoy and contribute to their productive capability and capacity. Other characteristics are challenges to larger segments of our society and emphasize that quality, indeed, is a multifaceted discipline.

The Governmental Aspects of Quality

What about the governmental aspects of quality? This aspect is shown as the last concentric ring on the diagram of Figure 1. Is the quality of how we are governed, regulated, taxed, policed, defended,

cared for, etc. of interest and importance to us? Is the “quality” of our rights and privileges of any interest to us? And these questions apply not only to the individual, but also to the corporation. Yes, the quality of our government and all of its actions and deliberations are important to us individually and collectively. The Sarbane–Oxley (SOX) act, and its implementation, is a further example of government involvement.

Total Quality Management

The preceding is the use of an extended description of “Quality” as an aid to help expose many of the philosophies of the meaning and practices of TQM. And in conclusion, quality can be seen to be a complex, multifaceted subject – not limited to a single dictionary (or other) definition. Attention to quality – in its broadest sense – and recognition that quality – as a discipline – offers sound business strategies and philosophies are evolutionary and revolutionary forces that have made (and are making) major contributions to our current way of life and progress. Managing this concept and aspects of quality is essentially what we mean by TQM. The following is one attempt to define the term.

TQM

The process that integrates fundamental management art and techniques with the principles and methodologies of total quality to develop and implement successful business strategies throughout the organization with emphasis on:

- a clear focus on customer needs, wants, desires, and specified and unspecified requirements;
- continuous planning, control, improvement, and innovation of all processes, services, and products;
- effective empowerment and recognition of individuals under a team involvement approach, including essential programs of learning, education, and training;
- sound planning for quality with fact-based decision making, variability reduction, defect prevention, and fast response systems that include recognition of the internal customer and the triple role of supplier, processor, and customer;
- integration of and mutual cooperation with suppliers based on long-term partnership relations;

- sensitivity to competitive comparisons *via*, e.g., benchmarking, including “best in class” on non-competitive but significant processes, and effective implementation of learning gained;
- productivity, cost reduction, profitability, and quality enhancements;
- strong leadership by management at all levels, sound strategic planning and deployment, and faithful dedication to ethical and moral principles and practices.

Benefits expected to be realized from TQ and TQM include the following:

- improving the quality of products and services to meet customer needs;
- increasing the productivity of manufacturing processes and commercial businesses;
- reducing manufacturing and service costs;
- determining and improving the marketability of products and services;
- reducing consumer prices of products and services;
- ensuring on-time deliveries and availability;
- assisting in the management of an enterprise.

Total quality as a strategy can bring better quality, price, delivery, sales, growth and profitability, leading to economic prosperity.

Scorecards

Introduction

Conventional wisdom in business management has long held that “what gets measured gets done”. But because conventional wisdom does not always win the competition for time and resources, business processes cycle year after year with hardly more than a wet windy finger’s worth of directional assessment. This relegates management decisions to gut instinct and to reactions to obvious stimuli. Disciplined **data collection** and scorecarding can add clarity to an organization’s direction and goal setting.

Visible performance measurement, when coupled with attention from top management and shareholders, drives a pattern of execution and improves the quality and speed of decision making. We link decision making about improvement efforts to customer expectations, which is the essence of quality. And although a rush to having good data for planning and execution is a heady stuff, the first step of robust dialog with customers about what exactly are their expectations is a moment to savor and in which to invest (Just coming to a consensus about who exactly is the customer, or about how different customers should be prioritized, is often contentious. This is particularly the case in business support organizations, e.g., human resources, information technology, and facilities management).

How to Build a Scorecard System

Build your measurement system by identifying your customers and their strategic objectives. Customer identification should start with a definition of “customer”, generally the recipient of the output of a process and/or the funder of an activity. Business support organizations are typically funded by corporate budgets. And the direct recipients of the output of their processes are the management or staff, who help in defining service expectations but do not pay from their own budgets. Business support organizations with charge-back models can drive a higher level of alignment in this regard; but the cost of charge-back models often drives firms to avoid them. This makes clear performance metrics tied to customer expectations more important, and usually leads to the

broadening of the definition of customer to include important internal stakeholder groups (we shall use “customer” and “stakeholder” interchangeably in the remaining portion of this paper).

Business support organizations never have external customers and the customer identification conversation is the first opportunity for team alignment. Once customer groups are identified through brainstorming techniques, each group’s expectations should be documented at a “financial statement” level: revenue generation, cost management, brand management, business continuity, and so on. It is important to start the conversation at this level to maintain line of sight to the real business imperatives. Next we turn to the requirements that these customer groups have for the support organization.

Customer Expectations Dialog

This dialog can be used to build a bridge between the customer group’s business expectations and an organization’s original programs. This can be a difficult task and the temptation is to go in the other direction, starting with the portfolio of the organization’s programs and justifying them by showing how they support the bigger objectives of your stakeholder groups. This bottom-up approach can often result in assumptions about the program’s impact that will not make sense to the stakeholders when presented. Common ground must be reached between stakeholders’ expectations and the organizational team’s program objectives.

Depending on the nature of the organization, customer expectations might include “supply skills to match future revenue growth demand”, “automate core tasks to reduce cost”, and “provide office locations with better adjacencies to customers for improved market coverage”. Once these objectives are brainstormed and consolidated to a working list, answering a few basic questions can provide a conceptual framework for performance metrics that will matter to stakeholders.

- How can we monitor and demonstrate that our programs, which are a priority to our customers, are achieving the desired scope?
- Are we achieving the customer-desired results on schedule?
- How do we know if these programs are being delivered cost effectively?

By now we have established a value chain showing the translation of customer business needs to expectations of our specific organization to performance metrics for those expectations. The quantified version of this chain creates an algebraic “**transfer function**” where the independent variables of our program performance drive the dependant variables of customer-required results. (In fact, we sometimes refer to this chain as “business algebra”.) This transfer function when first presented to customer groups in the form of a dashboard or scorecard must pass the customer’s test in assessing whether your cause and effect assumptions are logical. Data in this transfer function become the basis for future statistical analysis, process modeling, and graphical display, not to mention group and individual performance goal setting.

Without further development, the business transparency created by a good measurement system can align and influence behavior to focus on what customers expect. However, in people-based businesses, metrics alone are not sufficient. Management must work with their leadership teams and staff members to be explicit about how to prioritize work; inventory the programs and projects that comprise the bulk of the organization’s work and match them to the metrics defined against customer’s expectations for your group. Taking this step can – especially the first time – help an organization to see where to make investment and disinvestment decisions. Work that contributes most directly to customer expectations is resourced. Work that makes less of a contribution is eliminated. We now have a list of programs and projects that are prioritized by contribution to our customer expectations (note that a single program with a strong contribution to one customer expectation might be prioritized at the same level as a program with a lesser contribution to multiple customer expectations).

Program Prioritization

Most teams addressing the prioritization exercise for the first time start by reviewing each *program* one at a time and determining which metrics (or customer expectations) are impacted by those programs. This results in a generous assessment of program contribution because rarely will a program escape discussion without being assigned a contribution to a metric.

But these connections are less important from the customer’s point of view. The proper technique is to review each *metric* one at a time and ask, “If this metric is changing, which programs will our customer assume are performing better or worse”.

For example, if a customer expectation is to “grow profit in the Chicago region next year” and the support organization does no further translation of relevance to their group’s activities, the group might then decide that their performance should be measured by “dollars of profit change year over year”. If the support organization is the company’s real estate function and one of its programs is to “maintain the Chicago sales office”, the temptation would be to assign this program a contribution to the “dollars of profit” metric. Sales management, however, when seeing an increase in profit figures in the Chicago region, will not likely credit the result to maintenance of the office. Some interim analysis was missing in defining the transfer function.

We would drive the team to break down the customer expectation to the next level of detail. If profit is a function of revenue and cost, then the customer expectation for the real estate group could be to “reduce cost in the Chicago region next year” measured by “dollars of cost reduction year over year” or even “dollars of cost reduction per square foot year over year”. Since the program to “maintain the Chicago sales office” goes directly to cost per square foot, there should be no doubt that an increase in “dollars of cost reduction per square foot” should be credited to the performance of this program.

During the dialog to prioritize programs, it may be necessary to refine the list of metrics.

Process Mapping

Once a prioritized list of programs is defined, the focus shifts to the underlying processes. We are looking to instrument our business on the basis of a process framework. This approach allows for better continuous measurement and improvement compared to considering a business to be a portfolio of programs. Programs and projects should be positioned as process or business improvement efforts – they come and go. The customer-facing metrics and underlying processes create a stable, long-term management model.

In the above example, “maintain the Chicago sales office” is more accurately described as a program

comprising one or more processes scaled to a specific geography (Chicago) or asset type (sales office). For the sake of simplicity, let us assume that only one process is involved: facilities management. Although the facilities management process comprises a variety of subprocesses (e.g., janitorial service, heating and air conditioning, and cafeteria services), we consider this to be one process for the purposes of our scorecard. Cost per square foot is a consideration for process efficiency (less cost equals a more efficient process). But extreme cost elimination would also come with service elimination. Some measure of service quality should be assigned; in this example, we will assume that a defect-minimization metric is applied. In summary, we have at least two metrics that indicate the performance of the facilities management process: cost per square foot (\$) and service defects (#). Monitoring both metrics is required to determine if this process is meeting customer expectations.

Metric Quality

In continuing to develop the scorecard, it is important from a business standpoint to consider both the cost of data collection and the quality of component metrics in the overall deployment of a measurement system. Passive, automated systems that collect data on an entire population as work is done are easiest. Active systems like employee surveys can fatigue the audience. Managers should set expectations about how much time in a given week employees should be spending on manual reporting. This decision should balance the consequences for unforeseen process failure with the desire for complete information. Most groups overcollect data, which is costly. Sampling techniques can be used to define the data collection process. Any more than 15 min per week of data reporting for the average employee will likely be difficult to maintain.

For analysis and decision-making purposes, consider the quality of the metrics in which the team is investing. Stoplight metrics (a status of “red”, “yellow”, or “green”) provide focus on major problems at the time of review. They are common because they are easy to produce and to understand. But by themselves they provide no information about trends over time and have limited statistical analysis capability. Leading indicators allow managers and teams to take improvement action before customers experience dissatisfaction in process performance. For

example, a rolling estimate of the net present value of facilities maintenance cost, taking into account all known factors that will impact future cost, might be a more useful planning metric than simply knowing the previous month’s charge. Forward-looking metrics always have an element of uncertainty and this can require a mindset change among their users; but the value of looking forward is worth the effort. Once a business is reframed as a collection of processes, management can take advantage of some basic facts of process models. For example, every process has inputs and activity to change those inputs into an output valued by the customer. Input, activities (processes), and outputs can each be measured separately, with input and process metrics being leading indicators for the outputs that go to customers.

As statisticians, we find the use of continuous data more flexible for performance analysis. To illustrate, consider the need of a process to deliver an output to a customer on a certain day and that this process is repeated dozens or hundreds of times each month. The customer complains that the delivery is “always late”. A business might be tempted to quantify how often they are late (a laudable goal), so a “% late” metric is created, showing, on a monthly basis, what percentage of them has been late out of all the deliveries. Month after month the management can only say “Go faster!”; meanwhile, the delivery staff work to improve and feel they are making progress. But the metric shows barely a change. We would suggest that a better metric might be the “# days late” where each month the total number of days by which the delivery is late is summed and reported. When recalculated, the process showed vast improvement by driving down number of days late across all projects. Incremental progress and its causes are rewarded and investigated, leading to real improvements that are eventually felt by the customer.

Metric Management

At this point, we will likely have a dozen or so collectible, high-quality metrics for intended display on our dashboard. To put the dashboard into practice as a tool, it must be populated with data. Each metric needs a detailed set of instructions for population and management. This set of instructions should be owned by each metric owner and include the following:

- *Operational definition* of the metric. How it is to be calculated, and what system or report is the source for the data (e.g., if the data comes from a standard spreadsheet report, the operational definition must include the name of the spreadsheet and the exact cell reference for the number representing process performance).
- Clear definition for the *unit of measurement*, e.g., numbers, dollars, days, percent and so on.
- *Specification limits* allowing for calculation of a good or bad result, e.g., no more than \$35/ft² for facility maintenance cost. These limits are set with the customers' input and final approval. There are two criteria to set: the performance expectation of an individual event and the expectation for all events. For example, 90% of facilities should achieve the target square foot cost of \$35 for aggregate performance to be considered "green".
- *Frequency of data reporting*. How often will the data reasonably change based on sensitivity to process performance? We find that a monthly interval is about right for the management to review performance dashboards (unless the dashboard can be automated for real-time data on high-volume transaction processes). Thus any metric that is not meaningful on a monthly basis should be eliminated. Perhaps what is more important for performance management is that if the data are to be used to drive corrective

action then the nonmanagement review must be more frequent.

- *Performance owners*. Who will be tasked with improvement actions if the data show performance trending negatively? (This is usually a person who has a span of control over the resources doing the work and not usually the same person collecting the data.)

Conclusions

Team involvement through the dashboard development process is critical for the understanding of each individual's contribution to meeting the customer expectations. This development should not be done in a backroom by the quality manager. Now that the dashboard is live it should be used to inform customers of ongoing performance, to incent the right behavior among staff, and to identify improvement opportunities in the business. The dashboard itself becomes a focal point for management meetings where context is discussed and results are put in the spotlight.

Management's use of the dashboard in regular reviews ensures that what is getting measured is not only getting done but is adding value to its customers' operations.

MICHAEL E. JORDAN AND THOMAS MCCARTY

Theory of Constraints

Introduction

According to theory of constraints (TOC), every organization has at least one constraint (still not many – very few constraints) which prevents the system from achieving a higher performance relative to its goal (similar to Liebig’s law of the minimum – the growth of agricultural systems is controlled not by the total of resources available, but by the scarcest resource). The constraints can be broadly classified as “internal constraints” and “external constraints”. “Internal constraints” can be a physical one like a “resource constraint” or a nonphysical like a “policy constraint”. An “external constraint” can again be a physical one like “raw-material constraint” or a nonphysical one like a “market constraint”. In order to manage the performance of the system, these constraints must be identified and treated accordingly.

Background Information

The TOC was developed by Eliyahu M. Goldratt and other loosely coupled communities of practitioners around the world. Goldratt started to spread his initial ideas and thoughts in the late 1970s by first developing solutions to scheduling problems of manufacturing plants. These solutions were extended to an overall management philosophy during the years 1985–1990 immediately after the publication, in 1985, of the first edition of his best-seller book, *The Goal*. Since then additional applications of TOC were developed, and are still being developed, which enables this methodology to be applied to additional areas (business as well as others like education, health, and more). Currently, there are applications of TOC that cover most of the managerial applications. TOC is sometimes referred to as *constraint management*.

The TOCICO (Theory of Constraints International Certification Organization) is a global not-for-profit certification organization for TOC practitioners, consultants, and academics to develop and provide certification standards, and to facilitate exchange of latest developments.

A Process of Ongoing Improvement: The Five Focusing Steps

TOC is based on the premise that the rate of revenue generation is limited by at least one constraining process (i.e., a bottleneck in the case that the constraint is physical). Only by increasing throughput (flow) at the bottleneck process can overall organizational throughput be increased.

The key steps in implementing an effective TOC approach are as follows:

- Step 0: articulate the goal of the organization. Frequently, this is something like, “Make money now and in the future.”
- Step 1: *Identify* the constraint(s) – the thing that prevents the organization from obtaining more of the goal.
- Step 2: Decide how to *exploit* the constraint – e.g., make sure the constraint is doing things that the constraint uniquely does, and not doing things that it should not do.
- Step 3: *Subordinate* all other processes to the above exploitation decision – align all other processes/resources/departments to the decision made above.
- Step 4: *Elevate* the constraint – as long as the constraint is not a strategic constraint, permanently increase capacity of the constraint.
- Step 5: If, as a result of these steps, the constraint has moved, return to Step 1. Do not let *inertia* become the system’s constraint. The inertia is the tendency to continually do things the old way.

The TOC Thinking Tools

The thinking processes are a set of tools to help managers walk through the steps of initiating and implementing the TOC. When used in a logical flow, the thinking tools also help walk through the buy-in process:

1. Gain agreement on the problem.
2. Gain agreement on the direction for a solution.
3. Gain agreement that the solution actually solves the problem.
4. Agree to overcome any potential negative ramifications of the solution.
5. Agree to overcome any obstacles to implement the solution.

2 Theory of Constraints

TOC practitioners sometimes refer to these in the negative as *working through layers of resistance to a change*.

The thinking processes, as codified by Goldratt and others, are as follows:

1. Current reality tree (CRT) – evaluates the network of cause–effect relations between the undesirable effects (UDEs) in the defined system and helps to pinpoint the root cause(s) for most of them.
2. Evaporating cloud (conflict resolution diagram or CRD) – defines the conflicts that usually perpetuate the causes for an undesirable situation and helps to develop a win–win solution.
3. Core conflict cloud (CCC) – a combination of conflict clouds based on several UDEs. This is a deeper conflict that creates the undesirable effects.
4. Future reality tree (FRT) – once some actions (injections into reality) are chosen (not necessarily detailed) to solve the root cause(s) uncovered in the CRT and to resolve the conflict(s) in the CRD, the FRT shows the future states of the system as a result of implementing the changes and helps to identify possible negative outcomes of the changes (negative branches) and to prune them before implementing the changes.
5. Negative branch reservations (NBR) – identify potential negative ramifications of any action (such as an injection or a half-baked idea). The objective of the NBR is to understand the causal path between the actions and negative ramifications so that the negative effects can be “trimmed”.
6. Positive reinforcement loop (PRL) – desired effect (DE) presented in FRT amplifies intermediate objective (IO) that is earlier (lower) in the tree. Although IO is strengthened it positively affects this DE. Finding out PRLs makes FRT more sustaining.
7. Prerequisite tree (PRT) – states all of the IOs necessary to carry out an action chosen and the obstacles that will be overcome in the process.
8. Transition tree (TT) – describes in detail the action that will lead to the fulfillment of a plan to implement changes (outlined on a PRT or not).
9. Strategy and Tactics (S&T) – the overall project plan and metrics that will lead to a successful implementation and the ongoing loop through

(POOGI) (a process of ongoing improvement – the five focusing steps).

Throughput Accounting

Throughput accounting refers to a specific accounting methodology linked to the TOC. Throughput accounting suggests that one examine the impact of investments and operational changes in terms of the impact on the throughput of the business. It is an alternative accounting method to cost accounting and is very effective while making internal decisions.

Specific TOC Application Solutions

Operations

Within manufacturing operations and operations management, the solution seeks to pull materials through the system, rather than push them into the system.

Drum–buffer–rope (DBR) is a manufacturing execution methodology, named for its three components. The *drum* is either one of the two: (a) the schedule to run the physical constraint of the plant – the work center or machine or operation that limits the ability of the entire system to produce more or (b) the shipment schedule. The rest of the plant follows the beat of the drum. They make sure the drum has work and that anything the drum has processed does not get wasted.

The *buffer(s)* protects the drums, so that it always has the right work flowing to it. Buffers in DBR have time as their unit of measure, rather than quantity of material or capacity. This makes the priority system operate strictly on the basis of the time at which an order is expected to be at the buffered operation. Traditionally DBR usually calls for buffers at several points in the system: prior to the constraint, prior to the synchronization points, and at shipping. The method is known as *S-DBR*, which is a simplified form of the DBR assuming that the only real constraint of the system is the market. Consequently, it requires only a single buffer at shipping.

The *rope* is the work-release mechanism for the plant. Only a “buffer time” before an order is due (in an S-DBR environment) does it get released into the plant. Pulling work into the system earlier than a buffer time guarantees high work-in-process, reduces flexibility, and slows down the entire system.

Supply Chain/Logistics

The solution for supply chain is to move to a replenishment model, rather than a forecast model. This is based on fast replenishment capability. The two major elements in this solution are the following:

1. TOC – Distribution: enable high flexibility while using a color-based alerting system that indicates low probability to deliver on time.
2. TOC – (vendor managed inventory) VMI: Continuous and fast replenishments based on daily consumption.

Finance and Accounting

Use throughput accounting with T (throughput which is defined as revenues minus true variable costs), OE (operational expenses), and I (inventory) as the most important measures to support managers in the decision-making process.

Project Management

Critical-chain project management (CCPM) method is the derivative of TOC to project management. It is based on the realization that most of projects' tasks contain internal unseen buffers. Therefore, the "critical-chain" method suggests that these buffers be extracted from the tasks and to create well-managed buffers to the project itself. These buffers are to protect mainly (a) the completion time of the project from deviation in the critical-chain tasks (tasks with no time slack to the past and to the future) and (b) to protect the critical chain from the deviations in the noncritical tasks.

In addition, in an environment where there are more than a few projects sharing the same resources, the problem turns into one of managing the time of the most loaded resource(s), the one which is scheduled to participate in many projects. This schedule is also the basis for the synchronization between the projects and it provides the mechanism to avoid penetration of lateness from one project to other projects via the shared resource(s).

Marketing and Sales

Although originally focused on manufacturing and logistics, TOC has expanded lately into sales management. First data shows that the sales system is massively constrained and TOC offers significant opportunity to increase enterprise throughput.

The solution is based on the ability to turn the operation's superb performance (from the implementation of the above concepts in the manufacturing and project management environments) into value for the clients and, as a result, to be able to charge clients with premium prices. This will eventually increase the organizational throughput.

Buffer Management

Wherever buffers are applied, in manufacturing, in project management, in the supply chain, and so on, buffer management plays an important rule in getting significant results from the implementation of TOC. Buffer management contains three elements: (a) a well-defined color-based system to alert when probability to be on time is deteriorating; (b) dynamic modification of buffer size according to fluctuations in performance and demand; and (c) statistic analysis of reasons to penetrate into the "red" zone of the buffer providing effective information to the POOGI process.

AVRAHAM MORDOCH

Target Costing

Introduction

Target costing is a market-driven financial strategy for product and service design. Its goal is to assure profitability in the design and introduction of new products and services. Target costing was first conceived in the 1960s in Japan. It expanded the concept of value engineering to a customer-focused, profit-driven cost system that focuses on price. Target costing has been successfully adopted by most Japanese manufacturing firms including, among others, Sony and Toyota. More recently, it has begun to gain acceptance among US companies, as well.

Traditional “cost plus” reasoning sets the price of a product or service by starting with anticipated costs, and adding the desired profit margin. In competitive markets, the “cost plus” approach often leads to producers setting an “asking price” that customers are unwilling to pay. The result is a failure of the new product or service to achieve market acceptance, with an accompanying substandard return on the producer’s investment, or, in the worst case, a partial or total loss of the capital invested in product development.

Target costing, on the other hand, starts with the price that market conditions warrant, and then factors in required profitability to yield a “target cost” that must be met in the design and delivery of a product or service. To assure sound financial decision-making, target costing can and should be applied from the very start of the concept phase. As design and development progress, updated information permits continuous reassessment of whether costs are on track to provide a feasible return on investment (ROI). Through this process, target costing can be integrated with – and provide critical information to – corporate investment decision tollgates, which exist to provide go/no go decisions on funding of the development project. Target costing thereby provides a realistic and rational discipline that places the focus squarely on profitability throughout. Moreover, it provides a financial management discipline that is consistent with, and a valuable addition to, other related best practices such as **Six Sigma** and Design for Six Sigma.

Methodology

The concept of target costing is simple; however, achieving the benefits of the approach requires business commitment and discipline throughout the organization. The following example illustrates the requirements and challenges that companies face along the path to success.

Consider the definition of target cost:

$$\text{Target cost} = \text{Market price} - \text{Profit} \quad (1)$$

Then the current shortfall relative to target costing requirements is

$$\text{Cost gap} = \text{Target cost} - \text{Current expected cost} \quad (2)$$

The cost gap can be further detailed by attribution to specific design components or activities.

Consider a company that determines, through competitive analysis and customer feedback, that the market-driven price that a product will sell at is \$100. Leadership decides that for a sustainable ROI, the contribution margin must be 30%, and hence the target cost is \$70.

On the surface, this sounds simple. However, implementation of the target costing plan requires considerable thought and planning. At the outset, successful target costing requires an accurate and comprehensive assessment of market price. While gathering competitive analysis is straightforward in theory, and often will be even in practice for a commodity, for most products this exercise can pose quite a challenge. Often the sale of one product is bundled with others, or there will be warranties and services attached, which impose additional costs on the producer. So the price of an individual product may not be obvious. The target costing team will be required to work closely with marketing, sales, and service functions, and to look as well for confirmation of pricing projections from industry trade data. It should be evident that considerable expertise is required to confidently project the \$100 starting point for our hypothetical target costing analysis.

Similarly, a cross-functional effort will be required for identifying the impact on profitability of the many aspects of the company’s performance, which will in turn impact the required \$70 target cost. These include not only variable costs of production, but also manufacturing yield losses, scheduling and utilization

2 Target Costing

efficiencies, distribution, warranty and service costs, and many others. For realistically projecting these costs, expertise in finance, operations and supply-chain management, product life and warranty cost estimation, procurement, supplier quality, and statistical quality control are required.

Cost management entails trading off wins in cost reduction in some of the above areas against challenges in others to assure that the “cost gap” is closed. Effective use of target costing promotes resource reallocation, as needed, to assure success. In instances where best practices are being applied for the first time, “low-hanging fruit” will often account for a significant component of cost reduction; but it will seldom close the gap by itself. The engineering, design, service, and finance functions – and perhaps others – will be asked to turn the *status quo* on its head to achieve the remaining gains.

In addition, while traditional methods typically ignore trends of key financial characteristics over the life of the product – including, for example, price erosion, productivity increases, share gain/loss, and so on – a long-term focus on target costing can estimate these items from the outset and update them on a continuing basis. This activity can continue even after product introduction, to update profitability projections or run “what if” scenarios to determine the potential impact of market developments.

Application Issues

Target costing offers a wide array of advantages and best practices for promoting profitable introduction of new products and services. It promotes cross-functional awareness and cooperation, supports an expansive long-term view of product/service profitability, and can be implemented in a manner consistent with a variety of corporate financial metrics (e.g., ROI, internal rate of return (IRR), and others).

At the same time, as evidenced by the foregoing example, a company’s target costing success requires strong management coordination. In addition, a comprehensive long-term approach to target costing may require estimates of factors that are difficult to predict – for example, price erosion, share gain/loss, and demographic shifts. However, target costing tech-

niques compensate for this uncertainty by offering management the opportunity to specify alternative scenarios, and to run “what if” analyses across an array of potential market developments.

Software for implementing target costing requires substantial financial modeling skill, and represents a nontrivial development effort. Partly for that reason, most companies which have adopted target costing have implemented a form which is built around the more commonly estimated aspects of new product development, such as variable costs, manufacturing quality, and perhaps warranty/service costs. Incorporating additional factors such as R&D investment, time to market, and sales and distribution costs entails significant additional complexity.

Conclusion

Given financial expertise, cross-functional cooperation, and effective management support, target costing can provide an unprecedented means for assuring new product/service profitability. Target costing provides extraordinary information quality in support of capital expenditure planning, investment decision tollgates, and related corporate financial practices. By starting from market realities and explicitly accounting for business needs, target costing makes business success a design requirement, and helps avoid costly financial disasters in new product or service introduction.

Lean Accounting

Introduction

The Association for Operations Management, also known as *APICS*, defines a **lean** enterprise as one with a continuous focus on (a) waste elimination and (b) the customers' needs in all parts of its operations, manufacturing, and administration. Emphasis is given to lean structures and processes, flexibility of response, and methods and techniques to continually seize new opportunities as they arise.

Achieving a lean enterprise requires a culture built on a foundation of lean thinking, which is a continuous process of eliminating wasteful activities while increasing the value of a process or function. By creating visibility into operations and processes – no matter what industry or function – management gains the ability to analyze the elements of a process, thus allowing the enterprise to eliminate unnecessary activities and create more time for additional value-added activities.

Lean accounting focuses on accounting for activities in such a way that it allows for an understanding and measuring of the value created for the customers, and uses this information to enhance customer relationships, product design, product pricing, and continuous lean improvement. A successful lean accounting implementation enables a company to take advantage of benefits such as providing accurate, timely, and understandable information to motivate the lean transformation throughout the organization, and for decision-making leading to increased customer value, growth, profitability, and cash flow. It also facilitates the use of lean tools to eliminate waste from the accounting processes while maintaining sound financial control. It can support a lean culture by motivating investment in people, providing information that is relevant and actionable, and empowering continuous improvement at every level of the organization.

The DMAIC Framework

An example of a DMAIC framework can be found in Figure 1.

Every process within an organization has inputs and outputs, suppliers and customers, and beginning and ending boundaries. Under DMAIC, we start

with defining the process we want to analyze, measure, improve, and control. Developing a SIPOC (supplier, inputs, process, outputs, and customer) diagram provides a high-level understanding of process stakeholders, contributors, and customers. A critical component to the success of the initiative is capturing the voice of the customer (VOC). Understanding the customers' needs and continually soliciting their feedback will drive the analysis and improvement components. Most businesses that we know exist for one sole reason: to make money. In order to maximize their profitability, businesses must assure that they are always working on delivering a product and/or service that continually meets their respective marketplace requirements. One key element to understanding a businesses marketplace is to capture the voice of the external customer. There are many tools to do so, with the most common method being to conduct a **Kano** analysis. By stratifying collected customer data, the business may get to know its customers better. By capturing the VOC, the business may identify current functional business to customer as well as learn where their customer's strategic direction is heading. This is important when considering a new product or service design. The Kano analysis chart in Figure 2 depicts the relationship between product performance and customer satisfaction.

A cross-functional **process map** for the “as is” state is then developed to provide visibility into the components and their respective relationships within the process to be analyzed and improved.

Knowing the VOC allows the business to understand what is important. This dictates what needs to be measured from the customer's viewpoint; after all, the customer is the final judge of product and service.

We then define the measurements by which to monitor our progress as we make improvements and implement controls. During this phase, we will develop a baseline **value stream map** (VSM), and collect some baseline data as to the performance of the process. Some noteworthy process performance indicators include but are not limited to the following:

- *Process cycle efficiency (PCE)*, which is calculated by value-added time (VAT) divided by the total elapsed time (TET) of the process.

$$PCE = VAT / TET \quad (1)$$

2 Lean Accounting

Figure 1 DMAIC framework for lean accounting

Figure 2 Classifying customer needs by Kano analysis

Processes that are benchmarked as being lean are processes whose $PCE \geq 25\%$. The typical Pareto principle applies where 20% of the investigated

process steps are responsible for 80% of the process bottlenecks. This finding typically serves both service and manufacturing environment processes.

- *Defect per million opportunities (DPMO)* displays the average number of defects per unit of measure observed during average process throughput

$$DPMO = M \times \frac{D}{N \times O} \quad (2)$$

D = total number of defects counted in the sample

N = number of units of product or service

O = number of opportunities per unit measured of process product or service to have the defect occur

M = one million (1 000 000)

- *Rolled throughput yield (RTY)* is the likelihood that a single unit can pass through the series of required process steps free of defects. This measure considers “rework” as often witnessed in accounting reconciliation. To calculate RTY, one must consider the defect rate at each subprocess step. If we consider a process to have four subprocess steps, P1, P2, P3, and P4 with each delivering 80% usable output per process step criteria, the RTY would equate to 0.4096

$$\begin{aligned} RTY &= P1 \times P2 \times P3 \times P4 \\ &= 0.8 \times 0.8 \times 0.8 \times 0.8 \\ &= 41\% \end{aligned} \quad (3)$$

Consequently, the defect rate for each subprocess is 20% and the defect rate on the final product or service from this process is 59%.

Essentially, a value stream encompasses all the activities performed to create value for a customer that can be associated with that product or service. Remember, value is defined as a product or service that a customer is willing to pay for, and must be balanced with what it takes a company to deliver that product or service to the customer’s satisfaction. A company cannot just decide that it believes engineering is a nonvalue adding function. Without the engineering expertise of the company, the product or service could not be developed to meet customer specifications. Some of the activities within a value stream might include marketing, selling, estimating, pricing, designing, purchasing, engineering, production, warehousing, delivery, customer service, and

collection. A value stream blends costing principles with value principles, since both are necessary to derive a true picture of customer profitability.

With this VSM and baseline data, we can then begin to analyze ways to eliminate waste and increase value within the process. Some examples of types of lean waste include overproduction, motion, inventory, transportation, waiting, underutilized people, defects, and overprocessing. The analysis of the process will involve techniques such as **cause and effect**, and the identification of activities that are value adding, nonvalue adding, unnecessary, or are considered to be rework that should be avoided.

Once this visibility into the process has been created, we can begin to identify ways to improve the process, which includes methods for gaining buy-in from the constituencies. Unless the affected parties are on board, a successful implementation is at risk.

Finally, we want to be sure that our improvements are lasting and that we have created an environment of continuous improvement. Most changes take place at a point in time and reflect marginal improvements. A continuous improvement program (Figure 3) ensures that processes will perform at peak efficiency into the future. Today, businesses draw benefits from continuous improvement programs by endorsing the resource development in both soft project skills (people and general **project management**) and hard skills (analytical and quantitative). There is usually a good blend of both types of skills within an organization, but it is critical for any continuous improvement effort to address optimization of team talent as well as to foster a culture for skill development.

Utilizing an overview of the elements of lean accounting as provided by the American Institute of Certified Public Accountants (AICPA), we can classify lean accounting components into four levels to demonstrate the progression of the use of financial and accounting data within an organization, from basic transaction recording to use of the information in strategy development. The levels are defined as follows:

- Level 1: lean financial accounting, which includes items such as procurement and payment, order fulfillment and receivables, and month-end closings.
- Level 2: lean operational accounting, which includes items such as materials cost, labor and

Figure 3 Hierarchy for Lean Accounting's Continuous Improvement

- overhead cost, direct cost, and inventory tracking.
- Level 3: lean business management which includes items such as organization of the value stream, customer value and **target costing**, and rewards and recognition.
- Level 4: lean management accounting, which includes items such as alignment of organizational strategy with lean goals, budgeting and planning, managing service line or product profitability, and performance management.

Example Applying the DMAIC Framework

Let us look at an example of how a multinational communications company implemented lean accounting within its organization utilizing the DMAIC framework. The company began the lean implementation initiative by defining the Level 1 financial accounting processes to be analyzed, where the accounting transactions were processed and recorded. Those processes included billing, revenue recognition, cash management, accounts payable, fixed asset accounting, and subsidiary accounting. We will use the billing process in this example.

Once SIPOC and functional deployment maps were created for the billing process, management had a baseline to begin analysis. One of the issues that became apparent was the amount of time and resources involved in pricing products and preparing

invoices. The first step was to identify wasteful activities in the process. The measurements they used included task time for the process, percentage of rework, number of price quotes, time to prepare a price quote, number of invoices processed, time to process an invoice, PCE, and number of customer inquiries on invoices. The process included some significant rework and unnecessary activities because the people performing the billing function thought it was their job to fix other people's errors. Management's challenge was to identify ways to prevent those errors upstream of the data.

Once nonvalue activities were identified and eliminated and a future VSM was created, the company realized significant benefits. One improvement was to change its billing methods from the traditional bundled service to a more customer-oriented breakdown of value components. This helped customer and product profitability to be measured more accurately. The timeline for pricing and billing activities decreased, and management had greater visibility into the value stream. Customer service was better equipped to anticipate and address customer value issues. They had laid the foundation for a continuous improvement program.

Discussion and Summary

There is a saying that we frequently hear from successful business leaders: you cannot manage what you cannot see or control. Implementing lean

accounting using the DMAIC framework provides both the intelligence and visibility necessary to see how the company is servicing the customer, managing operations, and meeting expectations. Once management has a view as to what is value adding and what is unnecessary, it can refocus efforts toward adding value to the customer experience, maintaining a lean operation, and improving profitability. The key to a successful lean accounting

implementation utilizing the DMAIC framework is commitment from management, clear direction, and involvement of the constituents. Once the team is on board and the culture is established, the company should have the fuel to maintain a continuous improvement program, thereby improving its profitability and value.

Organizational Assessment Models

The Quality Assurance Models

The seeds of organizational assessment models can be traced back to the period between the 1930s and 50s, when leading companies operating in strategic sectors started to elaborate the quality assurance (QA) concept. The concept was based on the definition of system requirements (QA standards) and on independent assessments (audits) aimed at checking compliance of the involved organization with such requirements. The purpose of QA was to give executives confidence that the audited organization was capable to meet the quality targets and all the relevant activities (planning, execution, measurement, review) had been put in place. The first structured QA standards appeared in the 1950s/1960s, in the wake of the progresses made in the definition of the “product development cycle”.

QA extended rapidly to all sectors where defect prevention was a strategic issue (defense, aerospace, nuclear), and then to commercial sectors. Geographic diffusion was also rapid. But companies using QA soon realized that the next logical step was to extend the concept to their suppliers and to assess them for compliance (second-party audits). *External* QA standards were created. Proprietary at the beginning – being derived by the customer internal standards – external standards could not obviously enter into the same details as internal standards. External QA standards soon took the lead over internal standards. In B2B and B2A (Business to Business and Business to Administration) relations, earlier system assessments were seen as an important means to save time and money with respect to the traditional product testing procedures [1].

The need to reduce the burden, for both the suppliers and customers, coming from multiple standards and audits, fostered joint definition of sector standards (e.g., automotive). Increased awareness of the commonalities among production systems – whatever the product – led some supply-intensive administrations (typically defense) to create a wide scope of general standards. The next step was the creation of national QA standards, and finally, in 1987, of the ISO 9000 quality system standards [2]. Such

international standards marked the decisive turn from second- to third-party audits, conducted by independent, recognized bodies (certifications).

Total Quality Management Models and Awards

The 1980s showed the limits of a standard-based quality vision. The new customer- focused quality approach inaugurated by the Japanese was winning out over the inward- focused approach induced by standards. The Western “quality prophets” (Deming, Juran, Feigenbaum), unheard at home in the past, were rediscovered. New quality models – called *total quality management (TQM) models* – proliferated, rotating around the concepts of customer focus, process-based management, employee involvement, and continuous improvement (see **Total Quality Management (TQM)**). Proliferation dwindled sharply when some highly respected quality organizations thought of creating national and international quality awards, as a means to diffuse the new quality culture. To that purpose, experts were gathered to review and consolidate the findings of the period and define, through a consensus process, the relevant award assessment model and process. The American Malcolm Baldrige (MB) National Quality Award [3] was issued in 1987, followed, in 1991, by the European Foundation for Quality Management’s (EFQM) European Quality Award [4]. Figures 1 and 2 represent the block diagram of the two models.

The two models brought forth significant changes with respect to QA standards. First, they do not look for compliance with minimum requirements but define methods to measure performance and capabilities, based on a number of factors (the blocks in the figures) and subfactors that are considered critical in relation to excellence. The award assessment is based on the analysis of an application report presented by the candidate and a site visit. Scores are assigned according to defined measurement rules. Second change: results appear on the assessment scene – *perceived results* (or outcome) in particular. That means recognition that *compliance* with a model is not sufficient for a quality judgment; *effectiveness*, measured by results, completes the assessment scenario. Finally, the subdivision between *results* and *enablers*, introduced by the EFQM model, starts to shape a real organizational model, where management can identify – and test – the links between

2 Organizational Assessment Models

Figure 1 The Malcolm Baldrige model [Source: The National Institute for Standards and Technology – <http://www.quality.nist.gov>.]

Figure 2 The EFQM excellence model, 2007 [Source: European Foundation for Quality Management – <http://www.efqm.org>. © EFQM. 1999–2003.]

organizational causes and their effects. That helps to understand the underlying dynamics of TQM models: continuous improvement.

Models for Continuous Improvement

The narrower the scope of a model, the better it works. Award models are conceived to measure, compare, and publicly recognize organizational excellence, and to that purpose they need rigorously defined standards. Is it correct to use the same standardized models and processes for performance improvement also? Arbitrarily enlarging the scope of a model is risky; better to reshape it. Unfortunately, the award models and processes have become, in the last 20 years, the normal choice for self-assessment. An acceptable choice when seeking for comparable quantitative measurements of performance; less acceptable when the aim is organizational diagnosis, to identify areas that need improvement (we use this term here both for incremental and quantum leap improvement). Experience shows that focus on scoring is often at odds with focus on diagnosis.

The dominance of award models in TQM – combined with the dominance of ISO 9000 in QA – created a kind of conformism that somehow hampered the development of free, improvement-oriented models. In fact, diagnostic effectiveness is enhanced by the use of *contingency* models (that is, models that fit the organization's specific characters). Standardized models and procedures, necessary for the awards, turn out to be a burden.

The Present Situation

In the area of QA and certification, ISO 9000 is the reference worldwide. In the area of TQM, the MB and EFQM are the most popular models in the West, the Deming Prize Model [5] in Japan. Recognition that the more the model fits the organizations' characters the better it performs, has led to the development of sector TQM models (e.g., education, public administration).

Several TQM/excellence models have been developed by companies, consultant organizations, and experts, often merging TQM concepts with other

successful approaches, such as the *balanced scorecards* [6]. They can be divided into two categories.

1. Models aimed at measuring organizational performance and capabilities

Similar in principle to the award models, they are however – usually – more inward than outward directed. The aim is to endow management with a set of high-level indicators to measure the state of the organization from a plurality of perspectives. Indicators are chosen from among those factors that are considered critical for excellence (critical success factors, CSF). The literature provides many examples of CSF [7–10]. Albeit experts agree on comprehensive lists of CSF, differences arise when a short list (typically, 7–10 elements) is pursued to get to a manageable model. CSFs are normally high-level, abstract constructs (e.g., leadership, organizational learning) that require careful declination into assessable elements. Separation of results and enablers helps, since it confines the more intangible evaluation to the enabler side. Inconsistencies between enablers and results turn out to be important symptoms for further investigation. For these models, tests and validation of the chosen CSFs, taking into account interdependence, is important, as well as measurement reliability. Structural equation modeling is often used for the purpose.

2. Models aimed at organizational diagnosis and improvement

These too imply performance and capability measurements. But the role of measurement is secondary, in relation to results. Measurement is mainly used to identify performance gaps (the starting point for diagnosis); in relation to enablers, it serves to quantify weaknesses and then define priorities of intervention. Possible errors are controllable, since the normally used heuristic cycle “plan/execute/test” evidences them. Diagnostic models tend to overcome the use of abstract constructs, like the critical success factors, as basic elements of the model. Given their purpose, the use of elements that are more directly linked to the reality of the organization is recommended. They can be called *critical systemic factors*, since they are normally subsystems or important elements in the systems perspective. The critical systemic

factor constructs are normally deployed to lower level elements and questions, to the point that the critical organizational causes of problems (very often interdependent) can be addressed. Diagnostic models, albeit focused on assessment, have shown the potential to be also used in planning and execution, that is, in all phases of the organization PDCA (plan/do/check/act) cycle [11].

Development Trends: The Systems View

The evolution from organizational assessment models to organizational improvement models seems the most promising trend. However, progress is slow. What is the reason? Why do not managers generally recognize TQM models as management tools, useful to keep their organizations fit. Probably one of the answers (possibly the most relevant) is lack of systems perspective. One could object that all TQM/excellence models claim the systems view. Declarations of interdependence between the components of the system are made, but little is said on how to enhance value generation capabilities through relations – and how to assess consistency of relation maps with strategies. In fact, by developing appropriate relations within a system, unique properties can emerge (the so-called emergent properties) – and organizational excellence is a unique property, that cannot be reached through technology or individual excellence alone.

Separation of enablers from results is a first step toward integration of the systems concepts into the model. Enablers in fact represent the components of the systems (elements, subsystems, and throughput processes) that are critical in relation to the purpose (Figure 3). The purpose is to be found mainly outside the system, in the environment, where customers and stakeholders are located. In the figure, internal stakeholders (like managers and employees) are placed across the border, since they are independent as persons but part of the system in relation to their role. The environment (that represents the suprasystems where the examined system lives and operates) is divided into two parts: the transactional environment (that the organization can influence) and the independent environment, that the organization is bound to understand as well as possible.

A challenge today seems to be developing organizational models that merge quality thinking and

Figure 3 A systemic model of the organization highlighting the main relations within the system and between the system and its environment. It can be used as the basis for building TQM models [12]

systems thinking – and making them acceptable to managers [12].

Assessment of Experimental Designs

Introduction

When we collect data with a designed experiment, we gain the advantage of being able to control the input factors and determine not just a **correlation** between the input factors, also called *explanatory factors*, and the response of interest, but also a causal connection between inputs and output. This more powerful conclusion comes with the additional advantages of being able to specify the region of interest for studying this relationship between factors and response, and to select which data should be gathered during the experiment. In this article, a number of different criteria are presented for consideration when deciding what combinations of input factors to select.

To help frame our discussion and to make some of the trade-offs to be weighed more concrete, we consider an experiment to understand what factors affect the strength of a part being produced during manufacturing.

Some of the preliminaries to consider before selecting a particular design, include how many and which factors to consider. Choose too few, and the possible interrelationships (*see* **Interactions**) between the explanatory variables can never be studied; choose too many, and budgetary or logistical constraints may not allow adequate information to be gathered about each of the factors. In many cases it makes sense to prioritize factors based on current knowledge, and then select designs with potential follow-up designs being possible under a sequential learning and experimenting framework. It is common during the exploratory phases of experimentation to start with a screening design (*see* **Screening Designs**) such as a factorial or fractional factorial design (*see* **Factorial Experiments; Fractional Factorial Designs**) which focuses on estimating major trends in the relationship between the inputs and the response (*see* **Main Effects; Main Effect Designs**). Later when we have gained an understanding of the key inputs on which to focus, a more detailed study of the form of the relationship can be achieved with a response surface design (*see* **Response Surface Methodology**). For our example, determining which factors to include in the experiment will depend

on what is already known about the manufacturing process. If we are just beginning our study, then including many factors (such as temperature, speed of the production line, proportion of various ingredients, type of machines, setup of the machine, suppliers, etc.) of potential interest using a screening design is recommended. If we already have a good understanding of the key factors influencing the process (say, temperature, setup of the machine, and speed of production line), then a response surface design will help with more precise **estimation** of the underlying relationship, and allow us to explore how to optimize the strength of the part within the allowable ranges of our key factors.

Once the factors of interest for the current experiment have been identified, it is important to specify an assumed model for the relationship between the inputs and response, and a range of values for each of the input factors. The assumed model most typically has a parametric form, although nonparametric models are also possible. The form of the model indicates our assumptions about the shape of the underlying relationship to be studied, with more complex relationships requiring bigger models involving more parameters to be estimated. For our part production example, during initial exploration for determining key factors with the screening design, a simple form of the model will allow us to more efficiently gather data on all possible explanatory variables; once we have narrowed our focus to a smaller number of factors, a higher-order model will allow for more flexible underlying relationships to be considered. The designs considered should be matched to the assumed model that we would like to be able to estimate.

The range of input values for the input factors can be independent of each other, which will yield a rectangular region of the appropriate dimension, or constraints on the values of the factors conditional on each other can lead to spherical or oddly shaped regions. For an interesting discussion about the relative merits of different shaped design regions, see Voelkel [1].

There may also be restrictions on how many observations can be collected while experimental conditions are thought to be similar. Hence, choosing a designed experiment which can be implemented in blocks of an appropriate size will yield better consistency of information and unbiased estimation of parameter estimates (*see* **Blocking**). Sometimes if some factors cost more to adjust than others or if there

are restrictions on what randomizations are possible (see **Randomization in Experimental Designs**), a split-plot design (see **Split-Plot Designs**) may be a suitable choice to consider in order to maximize the information gained per unit of cost. For the response surface design of the part production example, it may be the case that altering the setup of the machine takes considerably longer and is more expensive than changing the temperature or the speed of the production line. In this case, the best designs to consider will be split-plot designs with the setup of the machine as a whole-plot factor, and temperature and speed as subplot factors. By not changing the setup of the machine for each observation collected, we can potentially afford to collect more data, and maximize the information gained per unit cost.

Once a model and region of interest have been specified, we can begin to consider choosing a “best” design. We can think of this as a collection of points in the region of interest that allows us to maximize the information gained once the data have been collected, while still being convenient to gather the data. We can think of considering the aspects of a “best” design by looking at several categories of criteria:

1. The ability to estimate well model parameters and make new predictions in the region of interest.
2. Robustness of the design to our choice of model, problems with running the experiment or the quality of the collected data.
3. Qualitative aspects including cost effectiveness, ease of implementation subject to constraints in **data collection**, symmetry across input factors, and inclusion of some data combinations representing best known settings.

These categories with particular characteristics are presented in Box and Draper [2] and Myers and Montgomery [3, p. 304]. In the discussion that follows, some of the trade-offs between different characteristics are considered in more detail.

Estimation and Prediction

Historically, good estimation of the model parameters and prediction for new locations in the design region have been a primary focus when selecting from among candidate designs. Several single-number summaries for the “goodness of the design”

exist and are known as *optimality criteria* (see **Optimal Design**). D- and A-optimality focus on measures of the variance of the model parameters as summarized by the moment matrix, $\mathbf{M} = \mathbf{X}'\mathbf{X}/N$, which is related to the variances and covariances of the regression coefficients of the selected model. G- and I-optimality (also known as *Q*-, *V*-, and *IV*-optimality in the literature) focus on the quality of prediction as a function of the scaled prediction variance of the form

$$SPV = N\mathbf{x}^m'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{x}^m \quad (1)$$

for a completely randomized design, where N is the total number of observations in the design, $\mathbf{X}$ is the matrix for the design, and $\mathbf{x}^m$ is a location in the design region coded to match the selected model.

While these single-number summaries are helpful for making coarse comparisons between designs, often a single number may be too simplistic to capture the differences between two designs. Alternative measures may also be helpful. For example, if we wish to focus on good estimation of model parameters for the screening design to model strength in our part production example, some parameters may be of greater interest than others. For example, consider an experiment involving p factors ($X_1, X_2, \dots, X_p$) in a cuboidal region $[-1, 1]^p$ where a first-order model with two-factor interactions

$$Y = \beta_0 + \sum \beta_i X_i + \sum \sum \beta_{ij} X_i X_j + \varepsilon \quad (2)$$

is thought to be appropriate for summarizing the underlying relationship. Perhaps in some previous experiments, the main effects for each factor may have been studied quite thoroughly, and so focusing on the good estimation of the interaction terms, $\beta'_{ij}s$, is of primary interest. D_s -optimality allows for a single-number summary for the quality of estimation of a subset of the model parameters. In the part production example, if we are in the screening phase of experimentation, we are likely primarily interested in estimating the effects of our many potential factors of interest. This would enable us to discern which factors are most influential on the strength of the part, and hence focusing on D-efficiency can be advantageous.

If the focus of the experiment is to provide good prediction in the design region, G- or I-optimality, which focus on minimizing the worst-case or average scaled prediction variance values, respectively, may not be adequate to summarize all of the important

characteristics of the performance of the design. This focus is typically more common during the response surface design phases of experimentation, where optimizing the process or understanding the underlying relationship between the select few explanatory variables and the response are the key objectives. Various graphical summaries of the prediction properties have been suggested to allow for a more comprehensive look. Variance dispersion graphs (VDGs) proposed by Giovannitti-Jensen and Myers [4] and fraction of design space (FDS) plots by Zahran *et al.* [5] provide complementary two-dimensional summaries of scaled prediction variance throughout the design region. VDGs show the minimum, maximum, and average scaled prediction variance values at different distances from the center of the design space, with three separate curves. FDS plots summarize the range of scaled prediction variance values throughout the region with a single line, and are likely best for making direct comparisons between competing designs. In the FDS plot, prediction variance values are plotted versus the fraction of the design space that has prediction variance at or below the given value. Samples of VDG and FDS plots are shown in Figures 1 and 2, respectively for three designs for a second-order model for two factors on a spherical design space. The three designs – hexagonal or **central composite** designs – are common choices for a response surface methodology design, which involve either six or eight equally spaced points around the circumference of the design space with one or three center runs. All three designs are rotatable (*see Rotatable Designs and Rotatability*), which means that for the VDG, the minimum, maximum, and average scaled prediction variance values are all the same at a given radius. Notice how the VDG shows where good and bad prediction occurs, while the FDS plot allows for direct comparisons between the different designs. In this case, the central composite design with three center runs has uniformly the best proportion of the design space at any scaled prediction variance value.

Adaptations of these graphical methods have been suggested for various specialized situations when there are several groups of factors, each with distinct properties (*see Goldfarb et al.* [6, 7] and Liang *et al.* [8] for more details). Quantile plots [9] also provide another alternative to understand the characteristics of prediction variance.

In addition to considering good estimation of the model parameters and good prediction in the design

Figure 1 Variance dispersion graph to compare three rotatable designs for a second-order model with two factors on a circular design region. The designs compared are the hexagonal design with one center run, and the central composite design with one and three center runs

space, choosing a design that allows for estimation of pure experimental error, through the inclusion of some replicated design points, is advantageous. This may frequently be implemented with the inclusion of center points (*see Center Points*) in the design. This allows for a measure of the natural variability of the response around the modeled surface that is not dependent on the choice of model or the estimation procedure used. Allocating some observations for replication at one or more locations in the design space can help with the estimation of the experimental error.

Typically, estimation and prediction are considered of primary importance when selecting between competing designs, but as we will see in the following sections some additional aspects of the designs should also be considered.

Robustness of the Design

Because things often do not go exactly as planned, including considerations of robustness can be important to salvaging the results of the experiment if things do go wrong. Recall, that as we began the process of selecting a good design, we specified an

Figure 2 Fraction of design space plot to compare three rotatable designs for a second-order model with two factors on a circular design region. The designs compared are the hexagonal design with one center run, and the central composite design with one and three center runs

assumed model, which summarized the relationship between the input factors and the response. The quality of our estimation and prediction is dependent on the correctness of our assumed model. A good design will allow us to test whether our model is adequate for the observed relationship, or whether additional parameters may be needed to capture its complexity. Typically, the designs which perform best for good estimation or prediction (D-, G-, and I-optimal designs) do not have adequate ability to test for **lack of fit** of the model, and are highly nonrobust to model misspecification. So if the experimenter selects an **optimal design** for a particular model, which later turns out to be incorrect, the design may perform very poorly. Hence allocating some observations to check for the adequacy of the model is also an important consideration. DuMouchel and Jones [10] suggest a Bayesian approach for design selection that allows for the designation of both necessary and “if possible” terms in the model, which offers some protection for assessing the adequacy of the model. Alternately, we may have specified too complex a model for the underlying relationship, and exploring how well the design performs for a number of simpler forms of the model may be beneficial. Ozol-Godfrey *et al.* [11] present an adaptation of the FDS plot that allows

for comparisons of different designs for a variety of nested models. In addition, we can consider the projection properties of the design (*see Projectivity in Experimental Designs*) to assess how well we can expect the design to perform if we subsequently discover that fewer factors than originally assumed are active. For the part production example, exploring the approaches suggested by DuMouchel and Jones [10] and Ozol-Godfrey *et al.* [11] would be most helpful during the response surface methodology phase of experimentation, to protect against the second-order model being insufficiently complex or too complex, respectively, for the actual underlying relationship between temperature, setup of the machine, speed of production line and part strength.

After the data are collected, we may end up with a reduced model with fewer active input factors than initially incorporated; therefore choosing a design that has good projection properties into lower dimensions can be a helpful consideration as well. For example, if it later turns out that speed of the production line is not influential on the response, selecting a good design that has good projection properties in the temperature and setup of machinery design space would be beneficial.

A common additional assumption of the model is that the variance is homogeneous throughout the design region. If this assumption is not correct, then the quality of the estimation can suffer and lead to incorrect inference. Also, prediction precision will not be appropriately characterized. Hence, it is sometimes desirable to allocate some observations to determine the adequacy of this assumption.

Aside from assumptions made about the model, there can be difficulties during the running of the experiment. A good design can help to minimize the impact of these on results. There may be problems in setting the levels of the input factors, for example, the desired level may require a temperature set at 300 °C, but when the experiment is run, the actual temperature is 292 °C. If the experiment is run in a way that the temperature is reset multiple times, then the chance of systematic errors in the factor levels may be reduced. When the response is observed, there may be **outliers** in the response, which a well-designed experiment can help to compensate for with replicates at some or all of the locations. In addition, it may be possible that some run combinations will turn out to be impossible to run or obtain a response value. A good design should be able to cope with

some or all of these problems. It is important to consider carefully which of the above problems are most likely to be an issue in a particular experiment and then allow for additional runs to be allocated to help compensate for potential practical difficulties.

While typically secondary in importance to good estimation and prediction, considering the robustness of the design to model assumptions and the difficulties in running the experiment can help make the results obtained informative, even if everything does not turn out exactly as planned.

Qualitative Aspects of a Good Design

A number of other important aspects of a good design should also be considered. One of the most important considerations that enters into the decision process of choosing a designed experiment is its cost. We can think of cost in terms of two natural metrics, monetary or time, since these are common constraints on our ability to collect data. In many situations, we may have a fixed budget (dollar amount or time with access to the equipment needed to gather the data), and hence we choose a design that maximizes the quality of information we obtain, subject to it being within our budget requirements. For the example considered earlier with a cuboidal region for p factors and an assumed first-order model with interaction terms, we may be able to collect 28 observations. In this case, we would like to find the best design of this size that balances the important subset of the multiple criteria listed in the previous sections.

A second possible scenario for incorporating cost for choosing a best design might be to have an objective of maximizing the quality of information on a per unit cost basis. In this situation, we may choose to run an experiment of size 35 over an experiment of size 28, if we get a proportional improvement in the quality of our estimation or prediction that is greater than the 25% increase in the number of observations. It is not uncommon for the quality of the design to increase nonlinearly with the addition of extra observations, so a small increase in design size can sometimes yield a disproportionate improvement in quality. Scaled prediction variance is an example of how cost, here assumed to be proportional to the number of observations collected, is incorporated into comparisons of designs.

Increasingly, cost considerations are being included in design selection, with Bisgaard [12] and

Liang *et al.* [13] exploring how cost can be appropriately incorporated in split-plot experiments (*see Split-Plot Designs*) with different costs for the setup of whole-plot and subplot factors. There may also be different costs associated with different regions in the design space, and hence design selection may wish to reflect this consideration as well.

Another qualitative aspect of the design that may be considered is the ability to run the experiment subject to constraints on experimental conditions. For example, there may be practical limitations on the number of levels of each factor that we are able to consider. Choosing a design with a moderate number of different levels for each factor can provide cost savings. For our part production example, restricting the number of levels considered to three for each factor will considerably reduce the cost of the experiment and make it easier to run. Since a single experiment will rarely teach us everything that we need to know about the process of interest, it is often beneficial to proceed sequentially by running a series of experiments (*see Sequential Experimentation*). In this case, choosing a design in the early stages that allows for follow-up experiments that incorporate understanding gained from a previous experiment can make for more efficient data collection approaches.

Trade-Offs Between Objectives

Given the extensive list of criteria of a good design that have been outlined above, it makes sense to choose an appropriate subset of these objectives on which to focus for a particular study, based on the goal of the experiment. Many of the objectives require that the locations of observations in the design be selected specifically for that objective. Hence, a design that is D-optimal for a first-order model will likely not have the ability to test whether higher-order terms are needed, to estimate pure experimental error, or protect against difficulties with running the experiment. For our part production example, a D-optimal design might be a fractional factorial design, which will do very well for estimation of the model parameters. We may be well advised to augment the design with some center runs or additional replicates, to allow for not only good estimation but also to enhance our ability to assess various types of robustness.

In particular, many of the objectives require a larger design size, so cost effectiveness is likely at cross-purposes with most of the other criteria. Depending on the nature of the cost constraints of the experiment, working with a fixed **sample size** and looking to maximize several other objectives can be an appropriate strategy. Alternately, exploring different sized designs and determining the quality of information on a per unit cost basis may lead to desirable results.

Since good estimation or prediction are typically the dominant concerns when selecting from competing designs, it may be best to focus on this consideration initially, while reserving some additional observations to augment an optimal design to offer good performance on some of the other criteria. For example, we may construct a D-optimal design and then supplement it with additional observations to allow for estimation of pure experimental error and to assess lack of fit. For our part production example, a D-optimal design might be a fractional factorial design, which will do very well for estimation of the model parameters. A good augmentation to the design would be a number of center runs, to allow for estimation of pure error and a preliminary test of curvature. This approach of selecting a good base design with ideal properties for the primary objective, and then expanding the design to incorporate other measures of a good design can yield some excellent choices. For some situations, a design that estimates the model parameters well may not be best for prediction of new observations. Hence if only one of these objectives is of interest, then choosing a starting design based on an optimality criterion based specifically on that objective may be advantageous.

Conclusions

When selecting a design for an experiment, there are many competing objectives to consider. By prioritizing which of these aspects are important for our particular study, and then strategically choosing a design that performs well for these objectives, we can maximize the quality of information gained during the experiment. Choosing a design that is optimal for a single objective may lead to substantially less than desirable performance with respect to many other

objectives, and hence a conscious balancing on multiple objectives is likely to yield a better overall design.

Multivariate Stochastic Orders and Aging

Dynamic Multivariate IFR Notions

A random vector $\mathbf{X} = (X_1, X_2, \dots, X_n)$ is said to be smaller than the random vector $\mathbf{Y} = (Y_1, Y_2, \dots, Y_n)$ in the *multivariate ordinary stochastic order* (denoted by $\mathbf{X} \leq_{\text{st}} \mathbf{Y}$) if $E[\phi(\mathbf{X})] \leq E[\phi(\mathbf{Y})]$ for every function ϕ that is increasing with respect to the coordinate-wise order in $\mathbb{R}^n$, such that the expectations above are well defined. See Shaked and Shanthikumar [1] or Müller and Stoyan [2] for detailed studies of this order.

Let $\mathbf{X} = (X_1, X_2, \dots, X_n)$ be a nonnegative random vector with an absolutely continuous distribution function. Here it is helpful to think about $X_1, X_2, \dots, X_n$ as the lifetimes of n components $1, 2, \dots, n$ that make up some system. Suppose that an observer observes the system continuously in time and records the failure times and the identities of the components that fail as time passes. Thus, a typical “history” that the observer has observed by time $t \geq 0$ is of the form

$$h_t = \{X_I = \mathbf{x}_I, X_{\bar{I}} > t\mathbf{e}\}, \quad 0\mathbf{e} \leq \mathbf{x}_I \leq t\mathbf{e},$$

$$I \subseteq \{1, 2, \dots, n\} \quad (1)$$

(Here, for every n -dimensional vector $\mathbf{x}$ and for any set $I \subseteq \{1, 2, \dots, n\}$, $\mathbf{x}_I$ denotes the vector of the x_i 's such that $i \in I$. Also, here $\bar{I}$ denotes the complement of I in $\{1, 2, \dots, n\}$, and $\mathbf{e}$ denotes the vector of 1's.) In equation (1) I is the set of components that have already failed by time t (with failure times $\mathbf{x}_I$) and $\bar{I}$ is the set of components that are still alive at time t .

Let

$$h'_s = \{X_J = \mathbf{y}_J, X_{\bar{J}} > s\mathbf{e}\}, \quad 0\mathbf{e} \leq \mathbf{y}_J \leq s\mathbf{e},$$

$$J \subseteq \{1, 2, \dots, n\} \quad (2)$$

be another history. If $t \leq s$ and the histories h_t and h'_s are such that each component that failed in h_t also failed in h'_s , and, for components that failed in both histories, the failures in h'_s are earlier than the failures in h_t , then we say that the history h_t is *less severe* or *more pleasant* than the history h'_s and we denote it by $h_t \leq h'_s$. Note that if h_t and h'_s are as

in equations (1) and (2), then $h_t \leq h'_s$ if, and only if, $I \subseteq J$ and $\mathbf{y}_I \leq \mathbf{x}_I$.

Recall that a univariate nonnegative random variable X has the increasing failure rate (IFR) aging property if, and only if, $[X - t | X > t] \geq_{\text{st}} [X - t' | X > t']$ whenever $t \leq t'$ (see **Stochastic Orders and Aging**).

For every vector $\mathbf{a} = (a_1, a_2, \dots, a_n)$ denote by $\mathbf{a}_+$ the vector $(\max\{a_1, 0\}, \max\{a_2, 0\}, \dots, \max\{a_n, 0\})$. Generalizing the univariate IFR characterization mentioned above, we can define a nonnegative random vector $\mathbf{X}$ as multivariate increasing failure rate (MIFR) if for $t \leq s$ we have

$$[(\mathbf{X} - t\mathbf{e})_+ | h_t] \geq_{\text{st}} [(\mathbf{X} - s\mathbf{e})_+ | h'_s]$$

whenever $h_t \leq h'_s$ (3)

Another possibility is to call the nonnegative random vector $\mathbf{X}$ MIFR if for $t \leq s$ we have

$$[(\mathbf{X} - t\mathbf{e})_+ | h_t] \geq_{\text{st}} [(\mathbf{X} - s\mathbf{e})_+ | h'_s]$$

whenever h_t and h'_s coincide on $[0, t]$ (4)

The latter definition is the MIFR $|\mathcal{F}_t$ definition of Arjas [3] where $\mathcal{F}_t$ is the minimal σ field generated by $\mathbf{X}$; see Arjas [3] for more details. Obviously the two MIFR notions, defined by equations (3) and (4), satisfy

$$\text{MIFR}(3) \implies \text{MIFR}(4)$$

The two *different* definitions of MIFR, given in equations (3) and (4), have some desirable properties. For example, a vector consisting of independent IFR random variables is MIFR according to either one of these two definitions. However, perhaps the most important feature of these kinds of definitions is their intuitive interpretation. In the univariate case these two definitions coincide with the univariate definition of IFR. More properties of these MIFR notions can be found in Arjas [3] and in Shaked and Shanthikumar [4].

Let us now recall another characterization of the univariate IFR aging notion, that is, a nonnegative random variable X has the IFR aging property if, and only if, one of the following equivalent conditions hold:

$$[X - t | X > t] \geq_{\text{hr}} [X - t' | X > t'] \quad \text{whenever } t \leq t' \quad (5)$$

2 Multivariate Stochastic Orders and Aging

or

$$X \geq_{\text{hr}} [X - t | X > t] \quad \text{for all } t \geq 0 \quad (6)$$

where $\leq_{\text{hr}}$ denotes the univariate hazard rate stochastic order (see **Stochastic Orders and Aging**). Generalizing these univariate characterizations to the multivariate case we obtain other MIFR notions as described next.

Consider a typical “history” of X as in equation (1). Let $i \in \bar{I}$ be a component that is still alive at time t . Its multivariate conditional hazard rate, at time t , is defined as follows:

$$\begin{aligned} \lambda_{i|I}(t | \mathbf{x}_I) &= \lim_{\Delta t \downarrow 0} \frac{1}{\Delta t} P \{t < X_i \leq t + \Delta t | \mathbf{X}_I \\ &= \mathbf{x}_I, \mathbf{X}_{\bar{I}} > t\mathbf{e}\} \end{aligned} \quad (7)$$

where, of course, $0\mathbf{e} \leq \mathbf{x}_I \leq t\mathbf{e}$, and $I \subseteq \{1, 2, \dots, n\}$. Let $\mathbf{Y} = (Y_1, Y_2, \dots, Y_n)$ be another nonnegative random vector with an absolutely continuous distribution function. Denote its multivariate conditional hazard rate functions by $\eta_{i|I}(\cdot | \cdot)$, where the η ’s are defined analogously to the λ ’s in equation (7). Suppose that

$$\begin{aligned} \eta_{i|I \cup J}(u | \mathbf{y}_I, \mathbf{y}_J) &\geq \lambda_{i|I}(u | \mathbf{x}_I) \quad \text{whenever } J \cap I = \emptyset, \\ \mathbf{y}_I &\leq \mathbf{x}_I \leq u\mathbf{e}, \text{ and } \mathbf{y}_J \leq u\mathbf{e} \end{aligned}$$

where $i \in \overline{I \cup J}$. Then $\mathbf{Y}$ is said to be *smaller than $\mathbf{X}$ in the dynamic multivariate hazard rate order* (denoted as $\mathbf{Y} \leq_{\text{dyn-hr}} \mathbf{X}$); see Shaked and Shanthikumar [1] for more details about this multivariate stochastic order. Recalling the univariate characterization (equation (5)) of the IFR aging notion, one may define a multivariate aging property of $\mathbf{X}$ by requiring $\mathbf{X}$ to satisfy, for $t \leq s$ and histories h_t and h'_s ,

$$\begin{aligned} [(X - t\mathbf{e})_+ | h_t] &\geq_{\text{dyn-hr}} [(X - s\mathbf{e})_+ | h'_s] \\ \text{whenever } h_t &\leq h'_s \end{aligned} \quad (8)$$

Yet another possible multivariate analog of the characterization (equation (5)) is to require $\mathbf{X}$ to satisfy, for $t \leq s$,

$$\begin{aligned} [(X - t\mathbf{e})_+ | h_t] &\geq_{\text{dyn-hr}} [(X - t\mathbf{e})_+ | h'_s] \\ \text{whenever } h_t &\text{ and } h'_s \text{ coincide on } [0, t] \end{aligned} \quad (9)$$

An analog of the characterization (equation (6)) is to require $\mathbf{X}$ to satisfy equations (8) or (9) with $t = 0$; that is,

$$\begin{aligned} \mathbf{X} &\geq_{\text{dyn-hr}} [(X - s\mathbf{e})_+ | h'_s] \\ \text{for any history } h'_s, \quad s &\geq 0 \end{aligned} \quad (10)$$

It turns out that the three conditions, defined in equations (8), (9), and (10), are equivalent:

$$\text{MIFR}(8) \iff \text{MIFR}(9) \iff \text{MIFR}(10)$$

and as such they define a notion of MIFR property. Since the order $\leq_{\text{dyn-hr}}$ is stronger than the order $\leq_{\text{st}}$ (see Shaked and Shanthikumar [1]), this notion is stronger than the MIFR notions defined by equations (3) and (4), that is,

$$\text{MIFR}(8) \implies \text{MIFR}(3)$$

See more details in Shaked and Shanthikumar [4].

Arjas [3] also defined a multivariate notion of decreasing failure rate (DFR). This definition is a version of equation (4) in which the inequality is reversed, but some care is needed for such a definition – only the lifetimes of components that are alive at time s are compared.

A Dynamic Multivariate NBU Notion

Recall that a univariate nonnegative random variable X has the new better than used (NBU) aging property if, and only if, $X \geq_{\text{st}} [X - t | X > t]$ whenever $t \geq 0$ (see **Stochastic Orders and Aging**). Following the idea that led to the MIFR aging notion given in equation (4), one can define a multivariate new better than used (MNBU) aging notion. Explicitly, one can call the nonnegative random vector $\mathbf{X}$ MNBU if

$$\mathbf{X} \geq_{\text{st}} [(X - t\mathbf{e})_+ | h_t] \quad \text{for all } t \geq 0 \quad (11)$$

This is the MNBU $|\mathcal{F}_t$ definition of Arjas [3] where $\mathcal{F}_t$ is the minimal σ field generated by $\mathbf{X}$; see Arjas [3] for more details. Obviously the MIFR notion in equation (4) implies this NBU notion.

Arjas [3] also defined a multivariate notion of new worse than used (NWU). This definition is a version of equation (11) in which the inequality is reversed, but some care is needed for such a definition – only

the lifetimes of components that are alive at time t are compared.

Multivariate Aging Notions Based on Comparisons with Multivariate Exponential Distributions

The univariate aging notions of IFR, IFRA (increasing failure rate average), and NBU, can be characterized, respectively, by the univariate convex transform order $\leq_c$, by the univariate star order $\leq_*$, and by the univariate superadditive order $\leq_{su}$ (see **Stochastic Orders and Aging**). Explicitly, if X is a nonnegative random variable, and Exp denotes an exponential random variable (no matter what the mean is) then

$$X \text{ is IFR} \iff X \leq_c \text{Exp} \quad (12)$$

$$X \text{ is IFRA} \iff X \leq_* \text{Exp} \quad (13)$$

$$X \text{ is NBU} \iff X \leq_{su} \text{Exp} \quad (14)$$

Motivated by equations (12–14), one may define MIFR, multivariate increasing failure rate average (MIFRA), and MNBU aging notions. In order to do that one needs multivariate analogs of the univariate stochastic orders $\leq_c$, $\leq_*$, and $\leq_{su}$, and one needs to choose a suitable multivariate exponential distribution to replace Exp in equations (12–14). Below we first describe multivariate analogs of the orders $\leq_c$, $\leq_*$, and $\leq_{su}$.

Roy [5] considered the following multivariate extensions of the univariate stochastic orders $\leq_c$, $\leq_*$, and $\leq_{su}$. Let $\mathbf{X} = (X_1, X_2, \dots, X_n)$ and $\mathbf{Y} = (Y_1, Y_2, \dots, Y_n)$ be two nonnegative random vectors, with survival functions $\bar{F}$ and $\bar{G}$, respectively; that is, $\bar{F}(\mathbf{x}) = P\{\mathbf{X} > \mathbf{x}\}$ and $\bar{G}(\mathbf{x}) = P\{\mathbf{Y} > \mathbf{x}\}$ for $\mathbf{x} = (x_1, x_2, \dots, x_n) \in \mathbb{R}_+^n$. For $i = 1, 2, \dots, n$, and $\mathbf{x} \in \mathbb{R}_+^n$, denote by $\bar{G}_i^{-1}$ the inverse of $\bar{G}(\mathbf{x})/\bar{G}(x_1, \dots, x_{i-1}, 0, x_{i+1}, \dots, x_n)$ as a function of x_i , and also denote $\bar{F}_i(\mathbf{x}) = \bar{F}(\mathbf{x})/\bar{F}(x_1, \dots, x_{i-1}, 0, x_{i+1}, \dots, x_n)$. Then $\mathbf{X}$ is said to be less than $\mathbf{Y}$ in the multivariate convex transform (star, superadditive) order (denoted by $\mathbf{X} \leq_c$ ($\leq_*$, $\leq_{su}$) $\mathbf{Y}$) if for each $i = 1, 2, \dots, n$, it holds that $\bar{G}_i^{-1}(\bar{F}_i(x_1, x_2, \dots, x_n))$ is convex (star-shaped, superadditive) in x_i for any given $x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_n$.

Next, let **Exp** denote any random vector that has a multivariate Gumbel exponential distribution with

the survival function

$$\begin{aligned} \bar{G}(x_1, x_2, \dots, x_n) = \exp & \left[- \sum_i \lambda_i x_i \right. \\ & \left. - \sum_{i < j} \lambda_{ij} x_i x_j \cdots - \lambda_{1,2,\dots,n} x_1 x_2 \cdots x_n \right], \\ (x_1, x_2, \dots, x_n) \in \mathbb{R}_+^n \end{aligned} \quad (15)$$

where $\lambda_{i_1, i_2, \dots, i_k} > 0$ for each $\{i_1, i_2, \dots, i_k\} \subseteq \{1, 2, \dots, n\}$; see Kotz *et al.* [6, p. 406].

Now one can define MIFR, MIFRA, and MNBU aging notions for a random vector $\mathbf{X}$ by replacing Exp in equations (12–14) by **Exp**, using the multivariate stochastic orders $\leq_c$, $\leq_*$, and $\leq_{su}$ described above. However, historically, proper definitions of MIFR, MIFRA, and MNBU aging notions were introduced first, and then analogs of equations (12–14) were obtained. So this is the way we will proceed here.

Roy [7] proposed multivariate extensions of the IFR, IFRA, and NBU notions as described below. Let $\mathbf{X} = (X_1, X_2, \dots, X_n)$ be an absolutely continuous nonnegative random vector with survival function $\bar{F}$. For $i = 1, 2, \dots, n$, denote by $r_i(\mathbf{x})$ and $A_i(\mathbf{x})$ the failure rate and the failure rate average of the random variable $[X_i | \bigcap_{j \neq i} X_j > x_j]$ at the point x_i , where $\mathbf{x} = (x_1, x_2, \dots, x_n) \in \mathbb{R}_+^n$; that is, writing $R(\mathbf{x}) = -\log \bar{F}(\mathbf{x})$, we have

$$r_i(\mathbf{x}) = \frac{\partial}{\partial x_i} R(\mathbf{x})$$

and

$$A_i(\mathbf{x}) = \frac{1}{x_i} \int_0^{x_i} r_i(x_1, \dots, x_{i-1}, y, x_{i+1}, \dots, x_n) dy$$

According to Roy [7], $\mathbf{X}$ has the

1. MIFR property if $r_i(\mathbf{x})$ is increasing in x_i for all $(x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_n) \in \mathbb{R}_+^{n-1}$ and each i .
2. MIFRA property if $A_i(\mathbf{x})$ is increasing in x_i for all $(x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_n) \in \mathbb{R}_+^{n-1}$ and each i ,
3. MNBU property if

$$\begin{aligned} & \bar{F}(x_1, \dots, x_{i-1}, x_i + y, x_{i+1}, \dots, x_n) \\ & \times \bar{F}(x_1, \dots, x_{i-1}, 0, x_{i+1}, \dots, x_n) \end{aligned}$$

4 Multivariate Stochastic Orders and Aging

$$\begin{aligned} &\leq \bar{F}(x_1, \dots, x_{i-1}, x_i, x_{i+1}, \dots, x_n) \\ &\times \bar{F}(x_1, \dots, x_{i-1}, y, x_{i+1}, \dots, x_n), \end{aligned}$$

for all $y \geq 0$ and for all $\mathbf{x} \in \mathbb{R}_+^n$ and each i .

Roy [5] provided the following characterizations

$$X \text{ is MIFR} \iff X \leq_c \mathbf{Exp} \quad (16)$$

$$X \text{ is MIFRA} \iff X \leq_* \mathbf{Exp} \quad (17)$$

$$X \text{ is MNBU} \iff X \leq_{su} \mathbf{Exp} \quad (18)$$

where $\mathbf{Exp}$ denotes any random vector with survival function given in equation (15). Roy [5] also noted that equations (16–18) hold if $\mathbf{Exp}$ is replaced by a vector of independent exponential random variables.

Scan Statistics

Introduction

Scan statistics have been used extensively in several areas of science and technology to test for occurrences of clusters of rare events. In this article, we survey results in the area of scan statistics that are applicable to **quality control** and reliability theory. In reliability theory, scan statistics have been used in the analysis and design of a k -within-consecutive- m -out-of- n : F system of n components arranged in a linear or circular fashion. This system fails if k components fail within any segment of m consecutive components. In the section titled “ k -within-Consecutive- m -out-of- n : F Systems”, we survey results for approximations and bounds for the system reliability of such systems. Two-dimensional scan statistics have been used in the analysis and design of a k -within-consecutive- (m_1, m_2) -out-of- (n_1, n_2) : F system of $n_1 n_2$ components arranged in a rectangular or cylindrical lattice. This system fails if k components fail within any m_1 by m_2 rectangular subregion. In the section titled “ k -within-Consecutive- (m_1, m_2) -out-of- (n_1, n_2) : F Systems” of this article, we survey results for the approximations and bounds for the system reliability of these two-dimensional systems. In quality control, scan statistics have been used in the design and analysis of **acceptance sampling** schemes. In the section titled “Quality Control and Acceptance Sampling Plans”, we survey results that are useful in evaluating the operating characteristics of these acceptance sampling schemes. In material science, reliability of certain materials can be compromised by the appearance of a large number of microcracks in a small area or volume. In the section titled “Reliability of Materials”, we present a survey of two- and three-dimensional scan statistics that have been used to analyze the occurrences of such microcracks. References include related results and references that are not discussed in this article.

k -within-Consecutive- m -out-of- n : F Systems

A k -within-consecutive- m -out-of- n : F system is defined as a system of n components arranged in

a linear or circular sequence. The system fails if and only if k components fail in any consecutive segment of m components [1–5]. Let $X_1, \dots, X_n$ be a sequence of n 0–1 Bernoulli trials, with $P(X_i = 1) = p_i$ and $P(X_i = 0) = 1 - p_i$, $0 < p_i < 1$. If $X_i = 1$ we say that the i th component has failed and if $X_i = 0$ we say that it is functioning. We review here recent results for discrete scan statistics that are relevant to evaluating the reliability of consecutive k -within- m -out-of- n : F systems. We first discuss the linear system. For integers $2 \leq m < n$ and $k \geq 2$ a linear discrete scan statistic is given by:

$$S_m = \max\{X_i + \dots + X_{i+m-1}; 1 \leq i \leq n - m + 1\} \quad (1)$$

We are interested in evaluating $R(k; m, n, p) = P(S_m \leq k - 1)$, the reliability of a k -within-consecutive- m -out-of- n : F system. Most of the research has been focused on the case of independent and identically distributed (i.i.d.) Bernoulli trials with $p_i = p$, $1 \leq i \leq n$. Approximations and inequalities for $P(S_m \leq k - 1)$ are discussed in [6–8; 9, Chapter 13; 10, Chapter 9; 11, Chapter 5]. Exact results for $P(S_m \leq k - 1)$ for restricted values of the parameters have been derived using a combinatorial approach in [12, 13]. Recently, in [14], using a finite Markov chain imbedding method, an exact formula for evaluating $P(S_m \leq k - 1)$ has been derived for a wide range of the parameters. This Markov chain approach for studying reliability systems has been introduced by Chao and Fu [15, 16]. Additional applications of this method are presented in [10, 11, 17, 18].

For the case of independent nonidentically distributed Bernoulli trials and Markov-dependent Bernoulli trials, evaluation of $P(S_m \leq k - 1)$ has been discussed in [10, 19–21].

The following related problem in system reliability is of interest as well. Suppose $P(X_i = 1) = p$ is unknown and we have observed that a components, in the linear system discussed above, have failed and $n - a$ components are functioning. We seek to approximate

$$\begin{aligned} R^*(k; m, n, a) &= P\left(S_m \leq k - 1 \mid \sum_{i=1}^n X_i = a\right) \\ &= P(S_m(a) \leq k - 1) \end{aligned} \quad (2)$$

the reliability of a k -within-consecutive- m -out-of- n : F linear system with a failed components, where

2 Scan Statistics

S_m is defined in equation (1). $S_m(a)$ is called a *conditional scan statistic*.

For integers $k, m, l \geq 2$ and $n = ml$ an exact formula for $R^*(k; m, n, a)$ has been derived in [13, Theorem 1]. If n, m, l are large and $k < a/2$, computing $R^*(k; m, n, a)$ using [13, Theorem 1] becomes impractical. Moreover, the finite Markov chain approach in [14] or the martingale method in [21] cannot be extended to evaluate $R^*(k; m, n, a)$. Approximations for $R^*(k; m, n, a)$ have been investigated in [7].

We now survey relevant results on scan statistics that are applicable for the circular system. For integers $2 \leq m < n$ and $k \geq 2$ a circular discrete scan statistic is given by:

$$S_m^c = \max\{X_i + \dots + X_{i+m-1}; 1 \leq i \leq n\} \quad (3)$$

For the circular system one is interested in evaluating $R^c(k; m, n, p) = P(S_m^c \leq k - 1)$. Accurate approximations for $P(S_m^c \leq k - 1)$ have been derived in [22]. Tight bounds for the system reliability $R^c(k; m, n, p)$ can be obtained from the bounds for the circular discrete scan statistic in [8].

If a components in the circular system discussed above have failed and $n - a$ components are functioning, then one is interested in evaluating

$$R^{*c}(k; m, n, a) = P\left(S_m^c \leq k - 1 \mid \sum_{i=1}^n X_i = a\right) \quad (4)$$

the reliability of a k -within-consecutive- m -out-of- n : F circular system with a failed components. For this system, [8, 22] provide accurate approximations and inequalities, respectively, for $R^{*c}(k; m, n, a)$.

k -within-Consecutive- (m_1, m_2) -out-of- (n_1, n_2) : F Systems

A k -within-consecutive- (m_1, m_2) -out-of- (n_1, n_1) : F system is a system of $n_1 n_2$ components arranged in a rectangular or cylindrical fashion. A k -within-consecutive- (m_1, m_2) -out-of- (n_1, n_2) : F system fails if and only if k or more components fail within any rectangular grid of size m_1 by m_2 within the n_1 by n_2 rectangular or cylindrical lattice of components [1, 23–30]. We first discuss the system with a rectangular arrangement for its $n_1 n_2$ components. We assume that the system consists of identical components and the failure of one or more components does

not affect the failures of other components in the system. The following probability model has been employed for this system. Let $X_{i,j}$, $i = 1, \dots, n_1$ and $j = 1, \dots, n_2$, be i.i.d 0–1 Bernoulli trials with $P(X_{i,j} = 1) = p$, $0 < p < 1$, and $P(X_{i,j} = 0) = 1 - p$. The event $X_{i,j} = 1$ denotes that the i, j component is functioning, while $X_{i,j} = 0$ denotes that the i, j component has failed. Let

$$Y_{i_1, i_2} = \sum_{j=i_2}^{i_2+m_2-1} \sum_{i=i_1}^{i_1+m_1-1} X_{i,j} \quad (5)$$

where $1 \leq i_1 \leq n_1 - m_1 + 1$ and $1 \leq i_2 \leq n_2 - m_2 + 1$, denote the number of components that have failed in the m_1 by m_2 rectangular region with a southwest corner located at (i_1, i_2) . A two-dimensional scan statistic is defined as:

$$S_{m_1, m_2} = \max\{Y_{i_1, i_2}; 1 \leq i_1 \leq n_1 - m_1 + 1, 1 \leq i_2 \leq n_2 - m_2 + 1\} \quad (6)$$

Approximations and bounds for $R(k; m, m, n, n, p) = P(S_{m, m} \leq k - 1)$ have been derived in [28–34].

We now discuss a scan statistic that is relevant for the two-dimensional cylindrical system. For integers $i = 1, 2$, $2 \leq m_i < n_i$ and $k \geq 2$ a cylindrical two-dimensional discrete scan statistic is defined as follows:

$$S_{m_1, m_2}^c = \max\{Y_{i_1, i_2}; 1 \leq i_1 \leq n_1, 1 \leq i_2 \leq n_2\} \quad (7)$$

where Y_{i_1, i_2} is given in equation (5). For the cylindrical system with $n_1 = n_2 = n$ and $m_1 = m_2 = m$, one is interested in evaluating $R^c(k; m, m, n, n, p) = P(S_{m, m}^c \leq k - 1)$. The methods used in evaluating the reliability of the rectangular system can be extended to the cylindrical system.

Suppose that, p the probability of a failure of a component in the system is unknown and the entire system contains a failed components. Then, the reliability of the two-dimensional rectangular lattice system is given by

$$\begin{aligned} R(k; m, m, n, n, a) &= P\left(S_{m, m} \leq k - 1 \mid \sum_{j=1}^{n_2} \sum_{i=1}^{n_1} X_{i,j} = a\right) \\ &= P(S_{m, m}(a) \leq k - 1) \end{aligned} \quad (8)$$

where $S_{m,m}$ is defined in equation (6). Algorithms for evaluating quite accurate approximations for $P(S_{m,m}(a) \leq k-1)$ have been derived in [35]. Similar approximations for a two-dimensional cylindrical system, with a failed components, can be derived using the approach in [35].

Approximation for the rectangular and cylindrical two-dimensional systems discussed above can be extended to the case where $n_1 \neq n_2$ and $m_1 \neq m_2$. Extending these approximations for systems with nonidentical components is computationally complex. Approximations for reliability of two-dimensional systems with nonindependent components is an open problem.

Quality Control and Acceptance Sampling Plans

The use of scan statistics in quality control and acceptance sampling plans has been reported in the statistical literature since 1958 [36], where an i.i.d. Bernoulli trial model is employed. Let $X_1, \dots, X_n, \dots$ be a sequence of 0–1 i.i.d. Bernoulli trials, with $P(X_i = 1) = p$ and $P(X_i = 0) = 1 - p$, $0 < p < 1$. The event $X_i = 1$ denotes that the i th inspected item is defective, while $X_i = 0$ denotes that the i th inspected item is nondefective. Acceptance sampling plans have been designed in which inspection is suspended when k or more defective items are observed in m consecutive inspected items [37]. Let

$$W_{k,m} = \inf \left\{ n \geq m; \sum_{i=n-m+1}^n X_i \geq k \right\} \quad (9)$$

be the waiting time until k or more defective items are observed in m consecutive inspected items. The expected waiting time for $W_{k,m}$, denoted by $E(W_{k,m})$, is called the **average run length** of this inspection plan until suspension. For this model, Troxell [37] developed acceptance sampling plans and evaluated their average run length and the operating characteristic curve for $k = 2$ and 3 and $3 \leq m \leq 11$. Additional results for this model have been derived in [12, 13, 38]. Note that

$$P(W_{k,m} \geq n) = P(S_m \leq k-1) \quad (10)$$

where S_m is defined in equation (1). References for evaluating $P(S_m \leq k-1)$ and deriving accurate approximations and bounds have been given in

the section titled “ k -within-Consecutive- m -out-of- n : F Systems”.

In [37], a sample inspection suspension rule is designated as (k, m) , if k lots are rejected in m or less consecutive inspected lots. Binomial and Poisson models can be used for the numbers of defective items in each of the lots. A more general acceptance sampling rule can be developed on the basis of exceeding a preassigned number of defective items in m or less consecutive inspected lots. In this case, a binomial or a Poisson model is used for the X_i 's in equation (9). Glaz and Naus [6], Chen and Glaz [7], and Karwe and Naus [39] discuss approximations and inequalities for evaluating $P(W_{k,m} \geq n)$ and $E(W_{k,m})$.

Recently, Lachenbruch *et al.* [40] investigated a potential use of the scan statistic defined in equation (1), in a quality control scheme for monitoring blood product manufacturing. Both Bernoulli and binomial models, as well as their conditional counterparts (when the parameter p is unknown and the numbers of defective samples has been recorded), can be utilized in this important application.

Control charts based on scan statistics or moving sums of i.i.d. normal random variables have been discussed in [41–44]. Asymptotic approximations and bounds for $P(W_{k,m} \geq n)$ and $E(W_{k,m})$ have been derived for $m = 2, 3$. In [43, 44], $P(W_{k,m} \geq n)$ and $E(W_{k,m})$ are evaluated *via* simulation. Accurate approximations and bounds for moderate or large values of m have not been developed yet.

Reliability of Materials

In certain materials microcracks develop, on the surface or within the material, at random *via* a **Poisson process** with some intensity λ [45–47]. A large number of microcracks in a small area (volume) on the surface (in the body) of the material can develop into a crack, resulting in deterioration of the material. The following two- and three-dimensional scan statistics play an important role in detecting material fatigue *via* analyses of occurrences of such microcracks.

Let $\mathbf{X}$ be a two-dimensional Poisson process with intensity λ . Following [47], the two-dimensional scan statistic is defined as

$$S_W = S_W(\lambda, A) = \max\{\mathbf{X}(W(\mathbf{x}) \cap A); \mathbf{x} \in R^2\} \quad (11)$$

where $A = [0, T_1] \times [0, T_2]$ is the entire scanned region, W is the scanning set and $W(x)$ is the translate of W by a point $x \in R^2$. For a rectangular scanning set $W = [0, w_1] \times [0, w_2]$, the scan statistic given in equation (11) is given by

$$S_W = \max\{\mathbf{X}([t_1, t_1 + w_1] \times [t_2, t_2 + w_2]); \\ 0 \leq t_i \leq T_i - w_i, i = 1, 2\} \quad (12)$$

In [45–47], accurate approximations for $P(S_W \geq k)$ have been derived for rectangular, circular, and triangular scanning sets. Approximations for the following three-dimensional scan statistic with a rectangular scanning set are derived in [47]:

$$S_W = \max\{\mathbf{X}([t_1, t_1 + w_1] \times [t_2, t_2 + w_2] \\ \times [t_3, t_3 + w_3]); 0 \leq t_i \leq T_i - w_i, \\ i = 1, 2, 3\} \quad (13)$$

where $\mathbf{X}$ is a three-dimensional Poisson process with intensity λ .

If the **intensity** of a Poisson process is unknown, then conditional on the number of observed events, these events are uniformly distributed in the scanning region A . For the two-dimensional case with a rectangular scanning set, Loader [48] derives approximations for $P(S_W \geq k)$. These approximations have not been extended to the three-dimensional case.

Causality

On the Causality Concept

Notions about causes and effects, or causality, must have been around as long as human beings have lived on earth. If human beings, when they came into existence, had not perceived physical dangers as potential causes of harm and death, humanity would not have survived. It seems obvious that when human beings started to construct tools and other equipment, notions of causes and effects had influenced the ideas behind the working mechanisms of these things. In prehistoric time, notions of causes and effects probably ranged from superstitious ones to rational ones, as we know they have in historic time. Even the great Greek philosopher and scientist Aristotle (384–322 B.C.) had superstitious causal ideas. He claimed among other things that the suction pump worked because of *horror vacui*, that is, nature's fear of empty space. This notion was dominating in science until Blaise Pascal (1623–1662) in 1647 performed experiments that provided convincing evidence that the suction pump worked because of the atmospheric pressure.

There is no widely accepted definition of causality, neither a general one nor one in relation to statistics. In spite of this, there is a vast literature on causality, also in relation to statistics (see e.g., the references [1–4]). In [1, p. 97], is given a list of some different ways in which the cause concept has been understood:

- as some essential aspect of a prior state that jointly determines an event, the *effect*, and without which the effect would not occur;
- as any condition tending to increase the probability of the effect;
- as any quantity whose prior variation would result in the subsequent variation of another quantity; and
- almost universally, in connection with the idea that feasible or imaginable interventions in natural systems change, or would change, the distribution features in populations of those features – were the sun to vanish, the planets would go off in nearly straight lines, were drinking water purified, people would live longer.

Causal relationships range from very simple to extremely complicated. A simple example is putting

up some dominoes in a row such that when the first is tilted so that it falls against the second, then all the dominoes are tilted in turn, without further intervention. A complicated example is what happens when a drug cures an illness. The cause-and-effect mechanisms involved in drug treatments are usually only partially understood, so that causal models are insufficient or impossible. This is one reason why it is compulsory to perform **clinical trials** to collect empirical evidence regarding effects of the drug on the illness in question, and on unwanted side effects and often on interactions with other drugs, before the drug is possibly registered for regular use.

There are still difficult and unsolved philosophical problems related to the concept of causality, some of which may well remain unsolved. One such problem is whether everything in the universe is subject to causal laws. Views on causality in science have ranged between extremes. One extreme is the so-called deterministic worldview, stating that everything that will happen in the future in the universe, down to the least detail, is predetermined for all future, owing to causal effects. On the other extreme is the view, based on results in quantum mechanics, that there is no cause for an individual quantum event, and that the universe is fundamentally unpredictable. This view is discussed in [5, p. 743]. Going into the important epistemological and philosophical problems related to the above views on causality is however far beyond the scope of this article.

It should be noted that in spite of the vast literature that exists on causality, causality is usually not an explicit part of the syllabus in science and technological studies at universities. It seems that an intuitive and pragmatic attitude to the concept is usual in such studies, where it is understated as obvious what causal mechanisms mean in different contexts. This seems to be the case also in research in the same areas. Nevertheless, causal thinking has been necessary for the development of natural science and technology. Scientific knowledge consists, to a large extent, of causal explanations and models, often in the form of mathematical or statistical models.

On Establishing Causal Relationships

The assumption that causal relationships exist in nature and that many such relationships can be revealed by human effort, either fully or partly, is

a central part of the basis for natural science and technology.

On Causality and Statistics

In statistical literature it is frequently emphasized that one cannot just from statistical association between phenomena found by **observational studies**, validly conclude that a causal relationship is present. This emphasizing is well founded. A classical example is that only from the fact that lung cancer is more widespread among smokers than nonsmokers, one cannot validly conclude that smoking causes lung cancer. In [6, p. 387], it is stated that: “It may be that persons whose genetic constitution predisposes them to smoke, also predisposes them to lung cancer or even that incipient lung cancer causes people to smoke.” The first possibility corresponds to the classical case of a “third variable” which influences the two variables among which an association is observed. The second possibility implies that the “causal direction” is opposite to what is intuitively reasonable to believe. In [6, p. 388], it is stated that: “The fact that a clear concept of causation requires widely applicable models of a class of phenomena implies that by far the surest, if not the only way to establish (non-spurious) **correlation** is by a series of experiments in which situations to which the model is supposed to apply are set up, and the relevant input variables are deliberately modified by the experimenter. If over a long series of repetitions under widely different circumstances, changes in the input variables are found to be associated with changes in the output variables, then causal relations can be said to be established.” The view that causal relations can be established by experiments as described is widely accepted in science. According to [2, p. v], Albert Einstein (1879–1955) has stated: “Development of Western science is based on two great achievements: the invention of the formal logical system (in Euclidian geometry) by the Greek philosophers and the discovery of the possibility to find out causal relationships by systematic experiment (during the Renaissance).” Accordingly, a reliable way to find out if smoking causes lung cancer would be to perform a randomized trial involving a large group of young people, where half of them commit themselves to smoke at least a certain amount per day for a large number of years, and the other half commit themselves not to smoke during the same period. Such

an experiment would however be neither ethically acceptable nor practically possible.

There is a high degree of general agreement that the existence of a causal relationship often can be concluded from results of experiments, including statistical association, while this is not so for observational studies. However, statistical association found by observational studies can often be used as a clue to a possible causal relation, which has to be investigated closer by additional means.

Empirical versus Mechanistic Causal Models

Regarding causal relationships in science and technology, the ideal is a detailed, subject matter-based understanding and description. Such understanding is termed *mechanistic*, whether mechanical devices are involved or not. Mechanistic understanding of a causal relationship gives deeper insight than a purely empirically based causal relationship established through experiments. In [7] the differences between empirical (causal) models and mechanistic (causal) models are discussed. An example of a type of empirical causal model can be, linear or nonlinear, regression models with one or more explanatory variables that are used for prediction purposes. A necessary presumption for a regression model to be classified as a causal model is that the data on which it is based stem from experiments, with deliberate interventions in the phenomenon, or system, which is modeled. In accordance with the discussion in the section titled “On Causality and Statistics”, a regression model based on data from an observational study should not be considered a causal model. An example of a mechanistic causal model, as opposed to an empirical causal model, is Newton’s law of movement, $f = ma$. This law expresses that when a body of mass m is exposed to a net force of size f , then the body is subject to an acceleration of size a . This model is also an example of a deterministic model, i.e. a model containing no stochastic elements, as opposed to for example a regression model. However, compilation of statistical data was part of Newton’s work when he established the law. According to [8, p. 80], Isaac Newton (1643–1727) was “a master at manipulating observations so that they exactly fitted his calculations” and according to [9], he often reported data with a precision, which was unlikely to be achieved with observational techniques at his time. So, it seems likely that Newton arrived at the law of

movement by means of manipulated data, which fitted the law much better than his actually observed data. However, for all practical purposes, the law can be considered as exactly valid except for elementary particles, which are accelerated up to velocities so large that their mass is noticeably increased according to the theory of relativity. This happens when a body attains a velocity that is not negligible compared to the velocity of light. The above mentioned is related to two interesting perspectives, which are accounted for shortly in the sections titled “Agreement within Acceptable Margins of Error” and “Karl Popper’s Concept of Falsifiability”.

Agreement within Acceptable Margins of Error

It is known for certain that Newton and many other world famous scientists during the history have manipulated experimental data to fit the causal laws they reported (see e.g., [10], especially page 23). According to [8, pp. 81–82], “The concept of agreement within acceptable margins of error did not exist until statistical theory of testing of hypothesis was developed. It was thought that a closer agreement with data implied a more accurate theory and a more convincing evidence for acceptance by the peers. We are now aware – due to the emergence of statistical ideas – that too close an agreement with data might imply a spurious theory!” Researchers nowadays who want to manipulate, or fabricate, data to fit a theory, sometimes put constructed variation into their faked data in order to disguise the faking. This can be designated *second-order faking*. It is, however, often difficult to fabricate realistic variation in data and in many situations, statistical methods for detecting such fabrication exist or they can be constructed. Faking of data, and how to reveal it, is treated briefly in [8, Section 2.3], with references to more comprehensive treatments.

Karl Popper’s Concept of Falsifiability

The science theorist Karl Popper (1902–1994) advocates an interesting point of view on the possibility of establishing scientific laws, including causal laws. He claims that a scientific law cannot be verified, only falsified. This implies that if predictions are made by means of a hypothesized law, and experiments are performed in order to check if the predictions are correct (within acceptable error margins), the

law cannot be verified no matter under how many different conditions predictions and experiments are done without deviations from the predictions. The law is however falsified when the experimental results do not agree with predictions, provided no failures have been done. Popper claims however that one has more reason to have faith in a potential law the more efforts are made to falsify it without succeeding. The concept of falsifiability is central in his teaching. He claims that if a statement cannot be made subject to falsifiability, then it is not a scientific statement. For an account of these ideas, see [11, Chapter 1].

The fact that the mass of a body increases with increased velocity is a consequence of the theory of relativity, which was established more than 230 years after Newton’s law of movement. This new knowledge implied that Newton’s law of movement had to be modified for large velocities. This need for modification indicates that Popper’s skepticism of the possibility of final verification of scientific laws, including causal laws, is sound. Popper’s view is in accordance with the following statement by Einstein: “No amount of experiments can ever prove me right; a single experiment may at any time prove me wrong” (quoted from [12, p. 715]).

Empirical Causal Relationships May Turn Mechanistic with New Knowledge

According to [2, p. 335], “Snell’s law, Hooke’s law, Ohm’s law, and Joule’s law are examples of purely empirical generalizations that were discovered and used much before they were explained by more fundamental principles.” Thus these laws were changed from empirical causal relationships to mechanistic ones by new knowledge. A situation between a purely empirically based causal relationship and a full mechanistic understanding is common, especially when the causal relationship is complicated and entangled. An example: In 1747, James Lind discovered by experiment that oranges and lemons prevented ship passengers from developing scurvy. This led the British Admiralty to mandate the provision of lime juice to all sailors, thereby eliminating scurvy from the navy (described in [13, p. 44]). At that time, the causal relationship in question was purely empirical. Now we know that the working agent in question is vitamin C, which gives some mechanistic understanding. However, a total mechanistic

understanding of why vitamin C effectively prevents against scurvy has not yet been reached, and will possibly never be. It is however likely that a deeper understanding will be reached than what physiology provides today. In [3, p. 156], it is stated that "... even today our mechanistic knowledge is very limited or even nonexistent in many fields. Typically, it is quite good in physics, quite limited in biology, and almost nonexistent in the social sciences." In the next paragraph, it is stated that "Statistics plays its most important role in connection with experience-based causality. In fact, much modern use of statistics may be seen as an extensive, formalized collection and analysis of experience, where mechanistic understanding often plays little role." The authors of [3] use the term *black-box causality* in relation to (purely) experience-based causal relations, and the term *mechanistic causality* in relation to understanding of causal mechanisms. Gaining more mechanistic understanding corresponds to revealing some of the content in the black box.

A Little on Causes and Effects in Quality and Reliability

It is well known among quality experts that variation in production processes, and the implied variation in output from such processes, is a usual and very important cause of reduced quality and reliability of products. This is easy to explain to people with no formal background in quality improvement. For example, almost everybody can easily imagine that if the parts going into a car motor do not have dimensions that are close to their nominal values, this will cause the motor to be subject to fast wear and low reliability, and thus low quality. It is therefore important to keep the variation of the part dimensions small. Statistical process control (SPC) is an important tool for controlling and reducing variation in, among other things, production processes, and thus output from such processes. The concepts *common causes of variation* and *special causes of variation* are important in SPC, and constitute part of the standard terminology. These concepts, and their use related to reduction of variation in processes and products are explained in the chapter on SPC.

Another quality tool where the term *cause* is used is the cause-and-effect diagram. Other names for the diagram are fishbone diagram and Ishikawa diagram.

This diagram is mainly used by competent people in a subject matter area to map perceived causes of unwanted circumstances, and relations/interactions between such causes, in a visual and clearly setup way. It can be used as an idea generating tool, as well as a diagnostic and preventive tool, and is well suited for discussions also.

Reference [14] is an expository paper outlining a Bayesian approach to reliability analysis of network systems comprising a web of interconnected components, which are subject to interacting (or dependent) failures like the power grid and other infrastructure systems. Such systems are often prone to paralyzing collapse caused by a succession of rapid failures, a phenomenon referred to as *cascading failures*. The purpose of the paper is to articulate on aspects of infrastructure reliability, in particular in relation to the notions of chance, cause, interaction, and cascading. It is emphasized that assessing the reliability of an infrastructure system is a key step in its design. Some additional aspects of the concept of cascading failures are treated in [15] in Section 4.8, titled "Causality and models for cascading failures".

Generally, there seems to exist little literature on causality related to statistics in quality and reliability, and on causality related to statistics in technology.

Further Reading – Especially on Newer Treatments of Causality and Statistics

At the beginning of modern statistics, around 1900, the prevailing attitude was that causality should not be treated in relation to statistics. According to [2, pp. 338–339], the seminal reason for this was the discovery of correlation at that time, and that correlation need not imply causality. The strong reluctance of statisticians to concern themselves with the concept of causality has changed gradually, but slowly, over time. There have however been considerable differences among statisticians in attitude toward causality. An interesting discussion of the development of causality in statistics is found in [2, pp. 338–342].

Dawid [16] gives an overview of different ways the concepts of probability and causality have been perceived and treated in the statistical literature and gives a synthesis of some of these ways. The article is highly philosophical, rather theoretical and parts of it are relatively mathematically advanced.

During the past few decades, quite a lot of literature on new theory on causality and statistics has emerged. The treatment is far more formal, even mathematical, than the informal discussion common earlier. Different types of problems, arising in different subject matter areas, have been attacked with different types of models, though without defining causality explicitly. The book by Pearl [2] is considered an authoritative source. Articles by Aalen and Frigessi [3] and Cox and Wermuth [4] are good overview articles on modern approaches to causality and statistics. Glymour's article [1] is also a good source of such information.

Three major formal approaches in the new area are counterfactual models, graphical models and the so-called Granger causality.

Counterfactual models are, to state simply, concerned with analysis of what would have been observed under other circumstances than those which actually were present in a statistical investigation; e.g., what would have been observed in a randomized trial with a treatment group and a control group if the two groups had been exchanged, and what conclusions can be drawn from such analysis. Counterfactual thinking is fundamental in causality.

Graphical models have a long history, beginning in 1921 (see [17]). Important treatments of modern graphical models are given in, among other sources, [2] and [18–22].

Counterfactual modeling started as early as 1923 (see [23]). Important treatments are found in, among other sources, [2] and [24–26].

The seminal paper on Granger causality is from 1969 (see [27]). (Granger shared the Nobel prize in economics in 2003, mainly for other ideas.) Granger causality is defined for two **time series**, $X(t)$ and $Y(t)$. One says that X does not Granger cause Y if prediction of Y based on all predictors is no better than prediction based on all predictors with X omitted. Further developments of Granger causality, with references, are described in [3, pp. 159–162].

ØYSTEIN EVANDT

Process Capability Indices, Alternatives to

Introduction

The entire issue of the journal of quality technology (JQT) in October 1992 JQT was devoted to the topic of process capability indices (PCIs). The five articles covered recent developments of PCIs, confidence bounds on PCIs, relationships to squared error loss, and the distributional and inferential properties of PCIs [4–8]. Additionally, the editor, Peter Nelson discussed the various problems with PCIs and further stated the reason for the publication was “to give those unfortunate enough to have to use capability indices a clear understanding of the assumptions involved and of what the indices are actually measuring” [9]. Finally, with the publication of that issue of JQT, *everything* you ever wanted to know about PCIs had been discussed and PCIs would no longer be abused. Unfortunately, the articles were probably too heavily involved mathematically and the messages contained in the JQT issue were not fully appreciated. Many companies still rely on PCIs to measure and compare the quality of their vendors’ processes without understanding the underlying assumptions of PCIs and the properties of the *estimators* of these indices.

Preceding the JQT issue, the topic of capability indices had been a source of much interest and debate from their popularization in the early 1980s. The indices C_p and C_{pk} were regularly taught in most introductory statistical process control (SPC) classes and usually without caveats about their shortcomings. Efforts to improve PCIs continue as evidenced by the fact that in a recent issue of JQT [10], an article by Wang *et al.* compared three multivariate PCIs.

A multitude of indices exist and C_p , C_{pk} , C_{pm} , C_{pmk} , C_{psk} , C_{pw} , P_p , P_{pk} , $C_p M$, MC_{pM} , and so on, are a few examples. Many improvements have been proposed such as the use of **confidence intervals** to show the uncertainties in the calculated estimates of the indices. Unfortunately, these are not practical for large sets of indices and the widths of these intervals increase as the estimate increases. It is not clear how to demonstrate that a required index has been met. Must the required value exceed the lower confidence limit or is it sufficient to be contained

in the interval? Another suggestion has been to use tolerance regions (see Wang [10]), but how can these be used in a practical way for large sets of indices? In addition, there is some difficulty in interpretation of these regions.

The purpose of this paper is to introduce a basic approach to meet most of the goals of PCIs that are presently being used without some of the associated problems that have been addressed in the previous literature. The intention is to create a foundation and direction for future expansion rather than to formulate a total solution. In cases where simple assumptions (normality and symmetric specifications) are not justified, the usual modifications can easily be introduced to meet the requirements of the application.

Specification Limits and Process Capability Indices

PCIs are often used in two specific phases. In phase I, the capability of a process to meet required specifications is determined. Three approaches are often used and are explained below.

The first approach is to determine the process specifications by needs (product performance, process optimization, customer requirements, etc.). A technology development group then determines the process distribution. The PCIs are calculated and if they are not met, the process is returned to the development group for the needed improvement to meet the required PCIs.

The second alternative is to determine the process specifications by needs as in the initial approach. A set of PCIs is specified and the technology group determines the process distribution. If the process does not meet the PCIs, a new set of indices is calculated that can be met.

The third technique always works the first time. The technology group determines the process distribution. A set of PCIs are specified and then the process specifications are determined from the combination of the process distribution and the PCIs. Unfortunately, this method is used more often than expected particularly when the specifications are on intermediate process steps and not on final product parameters.

In phase II, the goal is to measure changes in the process (either degradations or improvements) over time.

2 Process Capability Indices, Alternatives to

Before continuing, perhaps a few comments on how specification limits might best be determined are worthwhile. When the limits are determined for process and product development, the following ideas are often utilized. The design requirements of the product are determined, simulation models are run, engineering judgment is factored into the picture, and last, but not least, customer agreement is needed. These limits are then validated by data from product or process window characterizations and/or by historical data if it exists. Specifications used in manufacturing are often obtained by this data validation approach.

An Alternative Approach to Process Capability Indices in Phase I

The alternative is to measure whether the process distribution meets the required specifications by matching the mean (or a measure of the center) and the variance (or a measure of the spread) against those values assumed by the specifications. The criteria for the matching of the mean and standard deviation will be based on ratios that encompass both the sample size of the data set as well as a level of confidence associated with the ratio. Consequently, it would be feasible, if desired, to make comparisons between requirements, time periods, processes, and so on, in a statistically meaningful procedure. The usual caveats applied to PCIs must still hold. The process must be stable and the specifications must be technically based. In addition, a set of initial assumptions will be made. For this discussion it will be assumed that the process is normally distributed with mean μ and variance σ^2 . The specifications will be assumed to be symmetric about the mean and the specification width reflects $k\sigma$. These assumptions can be modified for future work. The matching of the variance will be addressed first.

Let $x_1, x_2, \dots, x_n$ represent a sample of n data points from the normal distributed process under study with $\bar{X}$ and S^2 the unbiased estimators of the mean and variance. Thus,

$$\frac{(n-1)S^2}{\sigma^2} \sim (\chi_{n-1}^2) \text{ so that} \quad (1)$$

$$\Pr \left[\frac{(n-1)S^2}{\sigma^2} < \chi_{1-\alpha, n-1}^2 \right] = 1 - \alpha \text{ and} \quad (2)$$

$$\Pr \left[S^2 < \frac{(\chi_{1-\alpha, n-1}^2)\sigma^2}{n-1} \right] = 1 - \alpha \quad (3)$$

Hence,

$$\Pr \left[S < \sigma \sqrt{\frac{(\chi_{1-\alpha, n-1}^2)}{n-1}} \right] = 1 - \alpha \quad (4)$$

Similarly, at the lower tail of the distribution,

$$\Pr \left[\sigma \sqrt{\frac{(\chi_{\alpha, n-1}^2)}{n-1}} < S \right] = 1 - \alpha \quad (5)$$

Denote σ_{upper} and σ_{lower} as follows:

$$\sigma_{\text{upper}} = \sigma \sqrt{\frac{(\chi_{1-\alpha, n-1}^2)}{n-1}} \quad (6)$$

and

$$\sigma_{\text{lower}} = \sigma \sqrt{\frac{(\chi_{\alpha, n-1}^2)}{n-1}} \quad (7)$$

Using the sample size of the data set, a predetermined probability level α , and the value of σ reflected by the specification, the values of σ_{lower} and σ_{upper} can be determined. From process data, an unbiased estimate of σ^2, s^2 , may be obtained.

Now define the ratios:

$$S_{\text{ru}} = -\frac{s}{\sigma_{\text{upper}}} \quad (8)$$

and

$$S_{\text{rl}} = \frac{\sigma_{\text{lower}}}{s} \quad (9)$$

With these definitions,

$$\Pr[S_{\text{ru}} < -1] = \alpha \text{ and } \Pr[S_{\text{rl}} > 1] = \alpha \quad (10)$$

If $S_{\text{ru}} < -1, s > \sigma$ with α significance (based on the sample size) then the process needs improvement with respect to σ .

If $S_{\text{rl}} > 1, s < \sigma$ with α significance (based on the sample size) then the process is performing better than expected and is clearly capable with respect to σ .

If neither condition exists, the difference between s and σ is not statistically significant and no action is necessary.

A similar approach may be used for matching the mean of the process distribution. However, with large sample sizes, a statistical significance may not reflect the practical or engineering significance. Therefore, it is necessary to define a “minimum engineering significant difference” (MESD) that is of real importance.

As stated earlier, $\bar{X}$ and S^2 are the unbiased estimators of the mean and variance. Thus,

$$\sqrt{n} \frac{\bar{X} - \mu}{S} \sim (t_{n-1}) \quad (11)$$

so that

$$\Pr \left[-t_{\alpha/2, n-1} < \sqrt{n} \frac{\bar{X} - \mu}{S} < t_{\alpha/2, n-1} \right] = 1 - \alpha \quad (12)$$

and

$$\Pr \left[-1 < \sqrt{n} \frac{\bar{X} - \mu}{t_{\alpha/2, n-1} S} < 1 \right] = 1 - \alpha \quad (13)$$

Define the mean ratio (MR) as

$$\sqrt{n} \frac{\bar{X} - \mu}{t_{\alpha/2, n-1} S} \quad (14)$$

Hence,

If $MR > 1$ and $(\bar{X} - \mu) > MESD$, then $\bar{X} > \mu$, with significance α .

If $MR < -1$ and $(\bar{X} - \mu) < -MESD$, then $\bar{X} < \mu$, with significance α .

Otherwise, no significant difference exists.

Phase II – Measure Changes in the Process Over Time

The approach to measure changes over time uses the two-sample analogs of phase I, which are to test the significance of the differences in the variance (spread) and the mean (center) from the previous time period. The initial assumptions are similar to those of the one-sample case with respect to symmetry, spec width, and the underlying distributions for the present (new) and the past (old) time periods. Additionally, assume no change has taken place between the period so that $\sigma_{old} = \sigma_{new}$ and $\mu_{old} = \mu_{new}$. As in the earlier case the comparison of variances will be addressed first.

Now,

$$\left(\frac{S_{new}^2}{S_{old}^2} \right) \sim (Fn_{new} - 1, n_{old} - 1) \quad (15)$$

so that

$$\Pr \left[\left(\frac{S_{new}^2}{S_{old}^2} \right) < (F_{1-\alpha}, n_{new} - 1, n_{old} - 1) \right] = 1 - \alpha \quad (16)$$

This leads to

$$\Pr[S_{new}^2 > (S_{old}^2)(F_{1-\alpha}, n_{new} - 1, n_{old} - 1)] = \alpha \quad (17)$$

and

$$\Pr[S_{new}^2 < (S_{old}^2)(F_{\alpha}, n_{new} - 1, n_{old} - 1)] = \alpha \quad (18)$$

As with the one-sample case, denote S_{upper} and S_{lower} as follows:

$$S_{upper} = (S_{old})\sqrt{(F_{1-\alpha}, n_{new} - 1, n_{old} - 1)} \quad (19)$$

and

$$S_{lower} = (S_{old})\sqrt{(F_{\alpha}, n_{new} - 1, n_{old} - 1)} \quad (20)$$

From the past and present process data calculate s_{old}^2 and s_{new}^2 . Using the sample sizes of the two sets of data and a predetermined probability level, α , S_{lower} , and S_{upper} can be determined.

Now define the ratios:

$$S_{cru} = -\frac{s_{new}}{s_{upper}} \quad (21)$$

and

$$S_{crl} = \frac{s_{lower}}{s_{new}} \quad (22)$$

With these definitions,

$$\Pr[S_{cru} < -1] = \alpha \text{ and } \Pr[S_{crl} > 1] = \alpha \quad (23)$$

If $S_{cru} < -1$, $s_{new} > s_{old}$ with α significance based on the sample sizes then the process needs improvement with respect to s_{old} .

If $S_{crl} > 1$, $s_{new} < s_{old}$ with α significance based on the sample sizes then the process is performing better than expected and is clearly capable with respect to s_{old} .

If neither condition exists, the difference between s_{old} and s_{new} is not statistically significant and no action is necessary.

4 Process Capability Indices, Alternatives to

Continuing with the same assumptions previously stated and using an analog to the one-sample case, define the comparative mean ratio (CMR) as follows:

$$\frac{(\bar{X}_{\text{new}} - \bar{X}_{\text{old}})}{(s^*)(t_{\alpha/2, \nu})} \quad (24)$$

where s^* is the appropriate **standard error** of the estimate determined after the variances have been tested, using a pooled estimate of σ if no change is indicated and the calculated values of s_{old}^2 and s_{new}^2 if a change is indicated, and ν is the **degrees of freedom** for the combined sample.

Hence,

If $CMR > 1$ and $(\bar{X}_{\text{new}} - \bar{X}_{\text{old}}) > MESD$, then $\bar{X}_{\text{new}} > \bar{X}_{\text{old}}$ with significance α .

If $CMR < -1$ and $(\bar{X}_{\text{new}} - \bar{X}_{\text{old}}) < -MESD$, then $\bar{X}_{\text{new}} < \bar{X}_{\text{old}}$ with significance α .

Otherwise, no significant difference exists.

Example

The example is discussed in Spiring's article in JQT 29 [11]. The process is a blow-molding procedure for plastic bottles where the outside lip diameter is the measure under study. He states that the upper specification limit (USL) is 0.846, lower specification limit (LSL) is 0.814, and the target is 0.830. A sample of 100 observations were collected with $\bar{X} = 0.8254$ and $\hat{\sigma}$ (m.l.e.) = 0.005. The author then calculates the following estimates and 95% confidence intervals:

$$\hat{C}_p = 1.067 \text{ (0.914, 1.209)} \quad (25)$$

$$\hat{C}_{pk}^* = 0.760 \text{ (0.688, 0.881)} \quad (26)$$

$$\hat{C}_{pm} = 0.785 \text{ (0.686, 0.836)} \quad (27)$$

What has changed? Does a problem exist with this process? The first index confirms that the process spread is not a problem, but does not address the possibility that it is better than the specification suggests. The second and third indices and their confidence intervals point to a problem in the mean of the process.

Assuming that the process is normally distributed and that the specification is defined as $\mu \pm 3\sigma$, then $\mu = 0.830$ and $\sigma = 0.016/3 = 0.0053$.

Since $\hat{\sigma}$ (m.l.e.) = 0.005, then $s = 0.005025$ which is less than the hypothesized σ . Therefore,

$S_{\text{rl}} = \frac{\sigma_{\text{lower}}}{s}$ is the appropriate statistic to evaluate. For this example,

$$\begin{aligned} \sigma_{\text{lower}} &= \sigma \sqrt{\frac{(\chi^2_{\alpha, n-1})}{n-1}} \\ &= (0.0053) \sqrt{\frac{77.046}{99}} = 0.0047 \end{aligned} \quad (28)$$

and $S_{\text{rl}} = 0.9353 < 1$. Consequently, based on the sample size of 100 and the one-sided 95% confidence interval, there is no significant difference in the standard deviation of the process.

Looking at the $MR = \sqrt{n} \frac{\bar{X} - \mu}{t_{\alpha/2, n-1} s}$ and assuming the MESD is approximately one σ , the

$$MR = \sqrt{100} \left(\frac{0.8254 - 0.830}{(1.98422)(0.005025)} \right) = -4.614 \quad (29)$$

Now, $MR = -4.614 < -1$, but since $(\bar{X} - \mu) = -0.0046$ and the MESD was assumed to be $\sigma = 0.0053$, no action would be taken despite the statistical significance of the result. However, if the MESD was less than 0.0046, the statistical significance would also be of engineering significance.

Other Issues

This paper has addressed only the relatively simple case in which the specifications are two-sided symmetrical and the process is assumed to be normally distributed. However, because the technique uses the distribution parameters in the metric, it may easily be adapted to applications involving other assumed distributions and their parameters such as discrete and nonsymmetric distributions without an intermediate transformation or fitting to a **normal distribution**.

In cases where these conditions are not true, the use of medians, interquartile ranges, and other standard robust procedures may be used in a similar manner.

Comments and Conclusions

The advantages of this technique include the following:

1. Since the sample size and confidence levels are built directly into the ratios, they may be sorted to

- prioritize improvement efforts unlike the present PCIs.
2. The ratios can be used to measure changes over time.
3. The concepts can be expanded to other distributions in a direct manner.
4. The ratios add statistical thinking to the measurement processes so that meaningful changes are recognized.
5. Many of the problems associated with the traditional PCIs have been eliminated.

Although the advantages are clear, the implementation of this procedure to the areas where PCIs are presently used will be difficult to accomplish. A great deal of effort will be required to change the mindset with respect to the *status quo* and this must occur at all levels within a company from top management to the worker on the factory floor.

RICHARD I. POST

Statistics in Data and Information Quality

Introduction

This article discusses statistical issues and opportunities in data and information quality. Just as managing and improving the quality of manufactured goods depends on statistics for its foundations and makes ample use of statistical methods, so too for data and information. But data and information differ from manufactured products in some critical respects. We focus on these differences and their implications for **quality management**.

After providing a brief historical perspective and describing what we mean by data and information, we focus on the following topics:

- Measurement issues, which stem from the fact that, unlike manufactured products, data and information are intangible.
- Opportunities to automatically correct data errors, which stem from the fact that most data are highly redundant.
- Statistical control issues, which stem from the fact that “interesting” data differ from one another.
- Inconsistency issues, which stem from the fact that data and information can be copied so easily. But it is very difficult to ensure that subsequent changes in one copy are reflected in all other copies.
- Matching issues, which stem from the fact that real-world entities may be identified in different ways.
- Privacy and security issues, which stem, in part, from the fact that “stolen data” are not actually missing.

High-Quality Data and Information Are Increasingly Important

Quality professionals have always depended on measurement data and information to bring manufactured goods into closer conformance to requirements, to identify and eliminate root causes, to improve customer satisfaction, and to drive business results. Similarly, generals, managers, scientists, and professionals

have always depended on data and information to craft strategy, to keep operations humming along, to test and advance theory, and to develop new insights. So, data and information have always been important, at least to an elite few.

However, a number of trends are conspiring to make data and information more and more important to virtually everyone. First is the spectacular and sustained development of information technologies that create, store, process, and communicate data and information. Second is the spectacular and sustained growth in the sheer quantity, variety, and complexity of new data and information. Third is the penetration of data, information, and the associated information technologies into virtually all human endeavors, be they public, private, or personal (in the developed world certainly and more slowly in the developing world). From a quality standpoint, this means more customers, with more needs, more diverse needs, and, in many cases, little training on what data mean, their nuances, or proper ways to interpret them.

Fourth and not surprisingly, data and information are responsible for an increasing share of the economy and especially new economic growth. For example, in the shipping industry it is estimated that, by the year 2010, half the value associated with delivering a container halfway around the world will stem from the data and information associated with the container (Taggart [1]). Fifth and unfortunately, recent data and information quality “disasters”, from the disputed year 2000 presidential election, to the corporate collapses brought on by misstated financial results, to the case for the Iraq War, to privacy breaches have raised the importance of data and information quality in the eye of public.

All of these underlying trends appear to be accelerating, so we should expect data and information quality to grow even more important.

Data and Information Defined

We noted above that practitioners are familiar with “data” and “information” in the context of quality management and experimentation. But since data and information are important in so many settings, we will first define these two terms.

Importantly, “data” is a multifaceted notion, and philosophers, computer scientists, and information systems engineers have proposed many competing

approaches to defining the term. We have selected the definition used herein (Fox *et al.* [2], Tsichritzis and Lochovsky [3]) because it best exposes how data are created and used in organizations, which is essential if they are to be managed effectively.

Thus, data (or a data collection, dataset, etc.) consist of two related components: a *data model* and *data values*. Data models are abstractions of the real world that define what the data are all about. Models define entity classes, the collections of things (physical or ideal) of interest, and attributes and relationships, which specify pertinent features of the entities. For example, the reader is an entity. His or her employer is interested in the entity class “EMPLOYEES” and attributes such as NAME, DEPARTMENT, SALARY, and MANAGER. Each attribute must have a well-defined domain of possible values. For example in the United States, all possible nine-digit numbers define the domain of possible values for SOCIAL SECURITY NUMBER (SSN). Data values are to be drawn from the domain and assigned to attributes for specific entities. A single datum is thus a triple:

Datum = <Entity, ATTRIBUTE, value>

An example datum is

<John Q., Public, SSN = 123-45-6789>

Note that data, as defined above are abstract. One never actually sees data. Instead, what we actually see (and computers process) are *data records* on paper, *via* computer applications, in tables or charts, and so on. Finally, note that the same datum may be recorded and presented in a virtually unlimited number of formats.

For the purposes of this entry, we will define information as “the portion of a collection of data (or, more generally a ‘signal’) used in a specific decision-making process”. As an example, when the datum

<Consumer Price Index, 4th QUARTER 2006,
0.7%>

is used (with other data) to adjust social security payments, it is information. In other contexts it is not. This definition adheres closely enough to the formal approaches used in communications, thermodynamics, and statistics (Resnikoff [4]) and to the

less formal way in which many business people use the term.

Measurement

Every quality practitioner knows that one cannot manage what one cannot measure. One can measure the length of a manufactured product, the viscosity of a liquid, the impedance of an electrical component, and so forth. “Length”, “viscosity”, and “impedance” are all physical properties and all can be measured directly. But data and information are intangible, so they have no physical properties. Hence, no direct measurement.

There are quite literally, hundreds of “dimensions” of data and information quality (Wang and Strong [5]) ranging from relevancy to comprehensiveness, to ease of interpretation. Here, we will focus on *accuracy* because it is critical to almost all data customers and because it illustrates the approaches to dealing with the lack of physical properties. We define accuracy as “the degree to which data and information agree with a standard (usually but not always the real world) assumed to be correct” [2].

Thus, even though direct measurement of accuracy is impossible (i.e., there is no “accurometer”), practitioners have devised a number of ways to get around this problem (Redman [6]). The first involves comparing data to their real-world counterparts. For example, a company may contact customers to check that the addresses in its database are correct. This approach is powerful, but comparing data to the real world is time consuming and expensive. So sampling must be employed to make the job manageable.

The second method is called *data tracking*. It involves “tracking” a sample of data as the selected records wind their way across a process, and noting unexpected changes in data values or formats. Figure 1 below is an example of a tracked record. The Figure also features several such unexpected changes, which usually correspond to data errors. “Counts” of the fraction of records make it across the process correctly and types of errors advise the process owner how well the process is performing and point out the likely sources of error.

The most popular method to measure accuracy takes advantage of the aforementioned domain of allowed values. Properly defined, a data value may only take on certain values. For example, there are

Figure 1 The matching process

only a few possible values of the attribute SEX. Values outside the domain of allowed values cannot be correct. Importantly, the domain of allowed values may be large and complex, but virtually all properly defined data are so constrained.

This point extends to multiple data elements. Consider the pair

<STREET ADDRESS = 12Main Street>
<CITY = Any town>

Not every town has a Main Street, so offending pairs are easy to identify. Adding STATE, POSTAL CODE, and other data elements increases the potential for error detection.

So-called business rules (sometimes called *edits*) specify the domains of allowed data values and failures of business rules that correspond to erred data. Counting the failures often leads to useful measurements of accuracy. The method has two important advantages: first, there are a whole host of good business rules and methods for developing new ones (Ross [8] and Olson [9]). Second, there are plenty of good off-the-shelf software programs to execute them. The principal shortcomings are that erred data need not fail a business rule and that additional work is needed to determine which data elements are erred.

Error Correction

Another way of looking at business rules is that they stem from redundancies that occur in even the

simplest collection of data. As noted above, this redundancy makes it easier to find errors and in many cases, to fix them. As an example, there is no place with the address

<12 Monmouth Ave., Rumson, NJ, USA, 07706>

so the record will fail good business rules. But there is a

<12 Monmouth Avenue, Rumson, NJ, USA, 07760>

Note two differences: first, Ave. and Avenue. While “Ave.” is not really incorrect, changing it to “Avenue”, is an example of “data standardization”. The second difference is that the last two digits in the POSTAL CODE are transposed. It is the likely error. Of course, other attributes, even the entire record, may be erred. So error correction is essentially a probabilistic exercise.

Data standardization and error correction can be quite sophisticated when there are lots of data and good business rules. ADDRESS is probably the best example. Generally though, business rules are not defined clearly and one must resort to the real world to determine the correct data values.

Interestingly, in telecommunications, algorithms that digitize and transmit data (including voice conversations) use parity bits to ensure faithful end-to-end transmission. More sophisticated error-correcting algorithms take the concept a step further. They “build-in” redundancy to provide error correction (Pierce and Noll [10]). Except in the design of some

identifiers (attributes used to uniquely identify individuals), these concepts are yet to be fully exploited in data and information quality.

Statistical Control

The twin notions of interchangeable parts and reducing variation are the heart and soul of the industrial revolutions and quality management. Further, since its discovery by Shewhart [11], statistical control has proved unmatched in helping reduce variation by helping sort out sources of variation:

- inherent to the process (common causes)
- external to it (special causes).

But the notion of interchangeable parts simply does not apply to data. Quite the opposite. “Interesting” data are novel and different. No one bothers to include an attribute PLANET OF RESIDENCE in a customer database, as the value will be the same for each individual (today at least). So it is not at all clear whether statistical control will apply.

Three insights help resolve the problem. First, the insight that a more constructive way to view data is not “as the stuff stored away in corporate and other databases”, but as “organic”, coming into existence, moving around the organization and being modified as it goes, being stored and processed, and, from time to time being put to some value-creating use (Levitin and Redman [12]). Second, the insight that “control” is best applied to *process*, and it matters not whether a process produces components, final assemblies, or data. And finally, the insight that accuracy measurements, made in-process, lend themselves beautifully to so-called *p* charts (see **Control Charts, Overview; Control Charts for the Mean**).

Inconsistency in Data and Information

Data are inconsistent when two or more sets of data do not agree. For example if Sally Jones’ primary residence is given as

<STREET ADDRESS = 10 Main Street>
in one database and
<STREET ADDRESS = 14 Maple Avenue>

in a second, these data are inconsistent. Both cannot be correct. This issue is exactly the same as noted above in which a pair of attributes within a data record could not simultaneously be correct.

Inconsistencies arise for many reasons. One is that it is easy to copy data from one place to another, but very difficult to synchronize the copies when changes occur. A second is that each department (even person!) can develop its own database, for its own reasons and processes for keeping up with changes. Synchronization is near impossible!

Note that there is no analog to data inconsistency in manufacturing, and it is an important and expensive problem. Billions are wasted sorting out inconsistencies. And everyone can cite examples where important decisions were delayed because the “facts” did not agree.

Of course, good process design to keep data values current helps. So does “concurrency control”, an important technique in database management systems (Date [13]). Also, data tracking, as described, has proved effective at sniffing out inconsistencies as data wind their way across processes, but overall, the body of theory and technique for addressing inconsistency is neither powerful enough nor consistently applied.

Unique Identification and Matching

One of the most important dimensions of data quality and principles of database design is “identifiability”, the notion that each entity should be uniquely labeled. EMPLOYEE ID and SOCIAL SECURITY NUMBER represent attempts to establish unique identifiers. An especially virulent form of inconsistency arises when identifiability is not met. It is sometimes called the *matching problem*.

The problem arises in many ways. Determining whether a person is on any “terrorist watch lists” is one example. Another involves the sequential mergers of four companies into one. The new company needs to understand the totality of its relationships with customers and so wants to merge the contents of customer databases in the former companies. As an example, four customer names are:

Former company 1: IBM
Former company 2: Intl Bus Mach
Former company 3: International Business Machines

Former company 4: Intergalactic Bell Modules.

The question is “Which of these records indicate the same customer?”

Statisticians have worked on this problem for decades and, as computing power has grown, there have been many improvements (Bishop *et al.* [14], Winkler and Thibaudeau [15], and Loshin [16]). Methods for answering the question proceed as in Figure 2.

Step 1: Assemble relevant attributes: For matching people, HOME ADDRESS, AGE, and SEX are useful. None applies for matching companies, though TAX ID and CEO may prove useful.

Step 2: Standardize/correct: To the degree possible, standardize data values and make corrections, as described above.

Step 3: Assemble a comparison vector. Determine the degree to which attributes match. Exact matches are easy. One may assign a “partial match” to values that are close, but not exact matches, such as <LAST NAME = Shackelford > and <LAST NAME = Shackleford>.

Step 4: Score the comparison vector. Doing so usually involves assigning weights to each attribute and summing to obtain an overall “score”.

Step 5: Make matches/assign new entities/human

investigation. On the basis of the scores, one now matches data records with a high enough score. Similarly, unmatched records are recognized as unique entities. Finally, some data records may fall into a middle area, where further investigation by human beings is warranted.

Privacy and Security

The last couple of years have witnessed a spate of “data breaches”, in which personal and other private data have been compromised [17]. While protecting physical assets is tough enough, protecting data and information may be even more problematic. For, as we noted above, since data can be digitized they can be easily copied. This means that, for example, people can put copies on their laptops and take them home. It also means that to “steal data”, criminals need not actually take the data. They can make a copy and take it instead. And those in charge of protecting the data will not detect any change.

Final Remarks

The statistical foundations of quality management have proved remarkably fungible to data and information quality, but not without effort. For data

Figure 2 An example of a tracked record. Each of the shaded pairs of attributes highlights a change in the tracked record as it winds its way through the process. From Redman [7]

and information have no physical properties, complicating measurement; the most important data are novel and unique, complicating statistical control; it is extremely difficult to properly identify “entities” uniquely, complicating management, and a “bad guy” need not physically remove data and information to steal them, complicating privacy and security. On the other hand, data and information are often highly redundant, making it easier to identify, and sometimes correct errors.

Acknowledgments

The author would like to thank Frank Guess of the University of Tennessee and David Loshin of Knowledge Integrity for discussions that improved this article.

THOMAS C. REDMAN

Interlaboratory Comparisons

Introduction

An interlaboratory comparison for a measurement procedure is an exercise carried out by a group of laboratories to compare their performance or assess a measurement standard. The basic approach for carrying out this type of comparison, also commonly referred to as a round-robin comparison, is to circulate an artifact to be measured among the laboratories, collect the results from each laboratory, compare the results from the group of laboratories, and report the results to the participants. As usual, however, there are many important details to be considered when planning an interlaboratory comparison or analyzing interlaboratory data.

The details to be considered start with the exact goals of the comparison. Interlaboratory comparisons are typically used for one of three main purposes:

1. to assess the random variation in measurement results across a population of laboratories,
2. to determine the systematic differences in results among a fixed set of laboratories, or
3. to determine the value of a physical property of an artifact or a population of artifacts.

On the basis of the purpose and results of the comparison, different conclusions or actions may be taken. For example, if the primary goal is to assess the variation in the results of a standard measurement procedure and the variation is found to be reasonably low, then the results may be used to establish an uncertainty statement that will become part of the published measurement procedure. If, on the other hand, the variation between laboratories is higher than acceptable, the details of the measurement standard or the individual measurement processes used at each laboratory may be revisited to learn how they can be improved.

Design of Interlaboratory Comparisons

Naturally, the goals of an interlaboratory comparison will impact its design. For example, if the goal is to assess the between-laboratory variation in a

population of laboratories, then a random sample of laboratories from the relevant population will be needed. When a random sample of laboratories is not available, a representative sample that can be treated as random is often used as a surrogate. When the differences in the results from a fixed set of laboratories are of interest then there is no need to randomly select which laboratories will participate in the comparison.

In a study whose goal is to determine the value of a physical property of an artifact, a randomly selected or fixed set of laboratories may be used. For example, in the production of reference materials for measurement assurance or **calibration** or in the analysis of environmental samples a random sample of typical laboratories may be selected to determine a consensus value and associated uncertainty for the artifact property [1, 2]. Alternatively, two or three laboratories that use measurement methods based on different underlying scientific principles that have biases that can be bounded [3] or can be assumed to bracket the artifact value [4] may be chosen.

The cost and stability of the artifacts and the time frame for the comparison will also affect the design. In a simple, circular design a single artifact is circulated, as illustrated in Figure 1(a). This design has the advantage that the results from each laboratory are directly comparable, but requires a stable artifact whose value will not change as it travels. Use of a circular design is also relatively time consuming since the laboratories cannot make measurements in parallel.

If the stability of the artifact is a concern, a variation on a figure-eight design, shown in Figure 1(b), can be used. This design still uses one artifact, but it is remeasured by the organizing laboratory (Lab 1 in this case) about halfway through the exercise to check for drift or other changes to the artifact's value. Depending on how much the value of the artifact has changed, the design of the comparison can be modified or appropriate corrections can be made in the analysis of the data.

If the use of multiple artifacts is feasible, then the figure-eight design can be run in parallel, as demonstrated in Figure 1(c) for artifacts A1 and A2. This design can be used to assess artifact drift like the single-artifact figure-eight design, but may require the use of the results from Lab 1 to make comparisons among labs that measured different artifacts, if the artifacts cannot be assumed to be identical. The

2 Interlaboratory Comparisons

Figure 1 High-level experiment designs for interlaboratory comparisons. (a) A circular design, (b) a figure-eight design with one artifact, (c) a figure-eight design with artifacts A1 and A2, (d) a star design that requires an artifact for each participant

figure-eight design can be extended to include more loops to assess artifact drift more frequently or shorten the study by increasing parallelism. In the limit, each laboratory may receive its own artifact to measure, as shown in the star-shaped design in Figure 1(d). This design is used frequently in comparisons of chemical properties of solutions, where a master solution can easily be divided into aliquots with essentially identical properties.

Finally, as for most experiment designs, the models hypothesized to describe the data and the properties of the analysis methods will also have a major impact. For example, a very simple and useful graphical analysis of interlaboratory data is described in a group of papers published by Youden starting in the 1950s [5–8]. For this analysis two artifacts with similar, but not identical, values are circulated. Each laboratory measures each artifact once, or provides a prespecified number of measurements for each that can be summarized by the organizer to obtain a pair of results. The decision to use a pair of artifacts is convenient for the graphical analysis of the data (discussed in the next section), provides data that can

be used to assess the random variation within and between laboratories, and also provides a reasonable level of blinding to reduce screening of the results prior to reporting.

A data set for the residual cement caught in a 45- μm sieve using Youden's two-artifact design is given in Table 1. The proportion of fine particles in a cement formulation is an important parameter that affects its physical properties and is monitored for quality control. ASTM standard test method C430 [9] is used for the determination of this cement property.

As for the graphical analysis, to use a hierarchical, analysis of variance (**ANOVA**)-like model to describe the data the design of the comparison must incorporate the necessary features. In particular, replicate measurements at each laboratory are likely to be needed and it is desirable to have each laboratory make an equal number of measurements. If additional sources of variation other than between- and within-laboratory sources are important then each laboratory may need to make measurements on a prescribed number of days, with a particular number of operators, and so on.

Table 1 Data from an interlaboratory comparison to assess the performance of ASTM test method C430 for the residual cement left on a 45- μm sieve

Lab	Residue mass fraction (%)	
	Cement 1	Cement 2
1	8.838	7.039
2	7.574	5.927
3	8.677	7.254
4	8.494	7.047
5	6.760	5.191
6	7.545	6.209
7	8.434	6.749
8	7.985	6.401
9	9.365	7.871
10	8.351	6.870
11	9.639	7.806

13	8.065	6.603
14	8.119	6.449

Of course, while it is natural, and potentially necessary, to pin down these design details when planning an interlaboratory study, it is also important to keep in mind their impact on the scope of the results. One of the goals of most comparisons is to reflect typical conditions, thus a good design must accommodate trade-offs between ideal statistical properties and realistic day-to-day testing practices.

Analysis of Interlaboratory Data

As mentioned above, Youden's graphical analysis [5–8] of artifact pairs is easy to implement, intuitive, and often successfully communicates the essential information in the data for comparisons designed to assess the variation between laboratories. The graphical analysis is carried out by simply making a scatter plot of the pairs of results for each laboratory, using the means of the measurements on each artifact if replicate measurements were made. The plot is then augmented with median lines for each artifact and a 45° reference line (relative to the intersection of the median lines) to help the analyst interpret how well the results from different laboratories agree. In some cases a circle whose radius is chosen to encompass a specified fraction of laboratories on average, under the assumption that there is no between-laboratory variation, is also added to the plot to aid interpretation

of the results. Figure 2 shows a Youden plot for the cement data from Table 1 with a circle sized to encompass about 95% of the laboratories, if there were no significant variation between laboratories.

Although Youden's analysis does not rely on many formal statistical inferences, there is a wealth of information in this simple plot about how well the laboratories agree and how their performance can be improved. For example, points that are arrayed together in an elliptical pattern along the 45° line rather than being randomly scattered inside the circle, as in Figure 2, indicate the presence of systematic differences in how the laboratories are implementing the measurement procedure. Points along the 45° line that are well away from their peers, like the lower left point in Figure 2, indicate laboratories that may not understand the standard procedure or have serious difficulties with its implementation. Points that fall well outside the circle but away from the 45° line identify laboratories that may have larger within-laboratory variation than their peers or may not be in statistical control.

The results obtained from random-effects hierarchical models, fit using ANOVA or Bayesian methods, allow the analyst to assess the between-laboratory, within-laboratory, and potentially other,

Figure 2 A Youden plot of the cement data from Table 1 showing large variation between laboratories relative to the within-laboratory variation

4 Interlaboratory Comparisons

sources of random variation associated with a particular test method. In addition to standard statistics texts that discuss these types of analyses, a description of a one-way, random-effects ANOVA specific to interlaboratory comparisons is given in ASTM standard practice E691 [10]. Approximate **confidence intervals** for the between-laboratory and within-laboratory **variance components** and their sum can also be obtained by building on basic ANOVA results or *via* maximum likelihood [11, 12].

Other more specialized models and methods extend the results of these workhorse analysis methods. These include the use of robust statistical methods to better handle data that contains **outliers** [13, 14] and models to simultaneously assess a measurement method over a range of analyte levels [2, 15, 16].

Probabilistic intervals for pairwise differences of between laboratories are often used to assess the agreement among a specific set of laboratories. In many cases, when the difference between one specific pair of laboratories is of interest, use of a simple confidence interval based on Student's *t* distribution (or other analogous probabilistic interval) is often most appropriate. When the goal is to make several simultaneous comparisons between laboratories with a stated error rate, however, procedures for multiple comparisons must be used [17].

When analyzing data from an interlaboratory comparison with a random-effects model to determine a consensus mean for the value of an artifact, there are many possible methods ranging from simple to complex. For example, in cases in which the data comes from a random sample of laboratories each with the same level of within-laboratory measurement variation and each about the same number of results, the consensus value and its uncertainty can simply be based on a standard Student's *t* distribution confidence interval computed using the laboratory means. This simple interval will also work well when the results from each laboratory are not equally precise as long as the between-laboratory variation dominates the within-laboratory variation in the least precise result. When the individual laboratory results do not all have the same level of within-laboratory variation and the between-laboratory variation does not dominate, however, other methods will give better results. As long as results are available from a relatively large number of laboratories, the maximum-likelihood methods described in [18–20] work well.

Iyer, Wang, and Mathew present a **Monte Carlo** method using generalized pivot quantities that gives results similar to the maximum-likelihood results and works reasonably well even for small numbers of laboratories [21]. The same general method can be used to estimate artifact values in comparisons based on fixed sets of laboratories as well. The authors compare confidence intervals based on generalized pivot quantities with those based on the minimax approach in [3] that uses known bounds on the laboratory biases. They also comment on the intervals used in [4] that assume the laboratory biases bound the true artifact value.

WILLIAM F. GUTHRIE

Quadrature and Numerical Integration

Introduction

A numerical integration technique is an algorithm to calculate the numerical value of a definite integral,

$$\int_a^b f(x) dx \quad (1)$$

Numerical integration problems go back at least to Greek antiquity when e.g. the area of a circle was obtained by successively increasing the number of sides of an inscribed polygon. In the seventeenth century, the invention of calculus resulted in a new development of the subject, leading to the basic numerical integration rules. In the following centuries, the field became more sophisticated and, with the introduction of computers in the recent past, many classical and new algorithms have been implemented, leading to very fast and accurate results. Consequently, there is a vast amount of relevant literature on solving numerical integration problems consisting of books, articles, software packages, etc. Some essential references are [1–6].

Numerical integration is sometimes called *quadrature*. A quadrature rule is a numerical approximation of an integral using a weighted sum of some values of the integrand,

$$\int_a^b f(x) dx \approx \sum_{i=1}^n \omega_i f(x_i) \quad (2)$$

where $x_1, \dots, x_n$ are the points or abscissas, usually chosen to be in the interval of integration, and $\omega_1, \dots, \omega_n$ are the weights associated to these points.

The simplest quadrature rules are the Riemann sums. Given a set of ordered abscissas, $a = x_1 < x_2 < \dots < x_n = b$, the left-handed Riemann sum is obtained with,

$$\int_a^b f(x) dx \approx \sum_{i=1}^{n-1} h_i f(x_i) \quad (3)$$

where $h_i = (x_{i+1} - x_i)$, the length of the i th interval between points. Observe that the area under the curve in the i th interval is approximated by a rectangle

of width h_i and height $f(x_i)$. Analogously, one can define the right-handed and midpoint Riemann sums by evaluating the function on the maximum or midpoint value, respectively, of each i th interval. The Riemann sums are also known as *rectangular rules* because of the use of rectangles to approximate the integral.

The rest of this paper is organized as follows. The section titled “Newton–Cotes Formulas” describes the Newton–Cotes formulas which are based on evaluating the integrand at a number of equally spaced points. The section titled “Gaussian Quadrature” introduces the Gaussian quadrature rules where the abscissas are chosen optimally to give the most accurate approximations possible. This section also includes a numerical example comparing different approaches. Some comments on the extensions of the Gaussian quadrature are also included. The section titled “Discussion and Remarks” concludes with some discussion and remarks.

Newton–Cotes Formulas

Assume that we divide the interval $[a, b]$ into n equally spaced points such that,

$$x_i = x_1 + ih, \quad \text{for } i = 0, 1, \dots, n-1 \quad (4)$$

where $x_1 = a$, $x_n = b$ and $h = (b - a)/n$. Let us denote $f_i = f(x_i)$, for $i = 1, \dots, n$. The main idea in Newton–Cotes formulas is to approximate the function $f(x)$ using polynomials that pass through the points (x_i, f_i) and integrate them to approximate the integral from x_1 to x_n . Newton–Cotes formulas are of *closed type* when the endpoints, x_1 and x_n , are included in the set of abscissas and they are called *open type* when the endpoints are not used to approximate the integral.

The basic closed Newton–Cotes formula is the *trapezoidal rule* which uses two points, x_1 and x_2 , and approximates the function $f(x)$ on $[x_1, x_2]$ using a straight line joining (x_1, f_1) and (x_2, f_2) . Then, the function is approximated by the following first-order polynomial,

$$f(x) \approx \left(\frac{f_2 - f_1}{h} \right) x + \frac{x_2 f_1 - x_1 f_2}{h} \quad (5)$$

2 Quadrature and Numerical Integration

This polynomial can be integrated to give the following approximation,

$$\int_{x_1}^{x_2} f(x) dx \approx \int_{x_2}^{x_2} \frac{f_2 - f_1}{h} x + \frac{x_2 f_1 - x_1 f_2}{h} dx$$

$$dx = \frac{h}{2}(f_1 + f_2) \quad (6)$$

Observe that this is called the trapezoidal rule because the area under $f(x)$ is approximated by a trapezoid with bases f_1 and f_2 and height $h = (x_2 - x_1)$, see Figure 1. The error of this approximation can be shown to be given by, see e.g. [2],

$$E_T = -\frac{h^3}{12} f''(\xi) \quad (7)$$

where ξ is some point in the interval $[x_1, x_2]$. Then, the amount of error will not be larger than the maximum value of the second derivative of the function in the interval and it will increase with the curvature of the function. The trapezoidal rule is exact for polynomials up to and including degree 1.

The trapezoidal rule can be used repeatedly to approximate the integral over the whole interval, $[x_1, x_n]$. This is called the extended or composite trapezoidal rule and is given by,

$$\int_{x_1}^{x_n} f(x) dx = \int_{x_1}^{x_2} f(x) dx + \dots + \int_{x_{n-1}}^{x_n} f(x) dx$$

$$\approx h \left(\frac{f_1}{2} + f_2 + \dots + f_{n-1} + \frac{f_n}{2} \right) \quad (8)$$

whose approximation error is equal to $-(n-1)h^3 f''(\xi)/12$. A powerful extension of the trapezoidal

Figure 1 Trapezoidal rule

rule is the Romberg integration, see e.g. [5], which uses a sequence of refinements of the extended trapezoidal rule by increasing carefully the number of subintervals.

The three-point closed Newton–Cotes formula is called the *Simpson's rule* and uses a quadratic polynomial joining the points (x_1, f_1) , (x_2, f_2) and (x_3, f_3) to approximate the function $f(x)$ on the interval $[x_1, x_3]$,

$$f(x) \approx \alpha x^2 + \beta x + \gamma \quad (9)$$

where the coefficients α , β and γ are given by,

$$\alpha = \frac{f_1 - 2f_2 + f_3}{2h^2} \quad (10)$$

$$\beta = \frac{-2x_1(f_1 - 2f_2 + f_3) - h(3f_1 - 4f_2 + f_3)}{2h^2} \quad (11)$$

$$\gamma = \frac{x_1^2(f_1 - 2f_2 + f_3) + hx_1(3f_1 - 4f_2 + f_3) + 2h^2 f_1}{2h^2} \quad (12)$$

Then, we can integrate this second-order polynomial to obtain the Simpson's approximation,

$$\int_{x_1}^{x_3} f(x) dx \approx \frac{h}{3}(f_1 + 4f_2 + f_3) \quad (13)$$

The error in this case can be shown to be given by,

$$E_S = -\frac{h^5}{90} f^{(iv)}(\xi) \quad (14)$$

where $f^{(iv)}(\xi)$ is the fourth derivative of $f(x)$ evaluated at some point ξ such that $x_1 \leq \xi \leq x_3$. Simpson's rule is exact for polynomials up to and including degree 3. This is surprising because it is designed to be exact for quadratic polynomials but, due to the symmetry of the formula, it is also exact for cubic polynomials.

As before, we can use Simpson's rule repeatedly to obtain the following extended or composite Simpson's rule, where the number of points, n , must be odd,

$$\int_{x_1}^{x_n} f(x) dx = \int_{x_1}^{x_3} f(x) dx + \dots + \int_{x_{n-2}}^{x_n} f(x) dx$$

$$\approx \frac{h}{3}(f_1 + 4f_2 + 2f_3 + 4f_4$$

$$+ 2f_5 \dots + 4f_{n-1} + f_n) \quad (15)$$

The approximation error is equal to $-(n-1)h^5 f^{(iv)}(\xi)/180$. Note that Simpson's rule will in general imply better accuracy than the trapezoidal rule if the function $f(x)$ is smooth enough (with finite fourth derivative).

The four-point closed Newton–Cotes formula is called *Simpson's 3/8 rule* and is based on a cubic polynomial approximation,

$$f(x) \approx \alpha x^3 + \beta x^2 + \gamma x + \delta \quad (16)$$

where α , β , γ , and δ are constants such that the polynomial passes through the points $(x_1, f_1), \dots, (x_4, f_4)$. These coefficients can be calculated using the Lagrange interpolation formulas, see e.g. [2]. Then, the Simpson's 3/8 rule can be obtained to be,

$$\int_{x_1}^{x_3} f(x) dx \approx \frac{3h}{8}(f_1 + 3f_2 + 3f_3 + f_4) \quad (17)$$

whose approximation error is given by,

$$E_{\bar{S}} = -\frac{3h^5}{80} f^{(iv)}(\xi) \quad (18)$$

As expected, Simpson's 3/8 rule is exact for polynomials up to and including degree 3. Note that the approximation error for Simpson's 3/8 rule is larger than the ordinary Simpson's error given in equation (14). However, Simpson's 3/8 rule has the advantage that the number of points, n , is not required to be odd when it is used repeatedly to approximate the integral over the whole interval, $[x_1, x_n]$. Then, if n is even, one possibility is using the 3/8 Simpson's rule for the first four points and the ordinary Simpson's rule for the remaining points, whose number (including the fourth point) is definitely odd.

The five-point closed Newton–Cotes formula is called the *Boole's rule* and is given by,

$$\int_{x_1}^{x_5} f(x) dx = \frac{2h}{45}(7f_1 + 32f_2 + 12f_3 + 32f_4 + 7f_5) \quad (19)$$

which can be obtained using the fourth-order Lagrange polynomial that passes through $(x_1, f_1), \dots, (x_5, f_5)$. The error is $-8h^7 f^{(vi)}(\xi)/945$ and it is exact for polynomials of degree 5 or less. Boole's rule is also known as *Bode's rule*, as in e.g. [7], due to an early typo.

Further point closed Newton–Cotes formulas can be obtained by integrating the Lagrange polynomials that pass through the considered points, see e.g. [8].

In general, observe that higher-point formulas will imply higher accuracy only when the function can be well approximated by a polynomial.

Open Newton–Cotes formulas approximate the integral from $a = x_1$ to $b = x_n$ without using the interior points, $x_2, x_2, \dots, x_{n-1}$. Some of these formulas are shown in Table 1. Newton–Cotes formulas of open type can be useful, for example, when the function takes infinite values at the endpoints or when one or both endpoints are infinity. However, these are not very common in practice as it is not reasonable to use them repeatedly to obtain extended open rules. Also, the Gaussian quadrature rules, which will be described in the next section, lead always to more accurate approximations than open Newton–Cotes formulas.

Gaussian Quadrature

Suppose now that we have the freedom to choose the abscissas at which to evaluate the function $f(x)$ rather than being equally spaced points. The Gaussian quadrature rules provide careful choices of these points in order to obtain much more accuracy in approximating the required integral. These are open formulas in the sense that it is not required to evaluate the function at the endpoints. Furthermore, it is possible to define a weighting function, $W(x)$, such that the approximation of the integral will be exact for polynomials times this weight function instead of only for polynomials. Then, the numerical

Table 1 Newton–Cotes formulas of open type

Approximation formula	Error
$\int_{x_1}^{x_3} f(x) dx \approx 2hf_2$	$\frac{h^3}{24} f''(\xi)$
$\int_{x_1}^{x_4} f(x) dx \approx \frac{3h}{2}(f_2 + f_3)$	$\frac{h^3}{4} f''(\xi)$
$\int_{x_1}^{x_5} f(x) dx \approx \frac{4h}{3}(2f_2 - f_3 + 2f_4)$	$\frac{28h^5}{90} f^{(iv)}(\xi)$
$\int_{x_1}^{x_6} f(x) dx \approx \frac{5h}{24} \times (11f_2 + f_3 + f_4 + 11f_5)$	$\frac{95h^5}{144} f^{(iv)}(\xi)$
$\int_{x_1}^{x_7} f(x) dx \approx \frac{6h}{20}(11f_2 - 14f_3 + 26f_4 - 14f_5 + 11f_6)$	$\frac{-41h^7}{140} f^{(vi)}(\xi)$

4 Quadrature and Numerical Integration

approximation will be as follows,

$$\int_a^b W(x) f(x) dx \approx \sum_{i=1}^n \omega_i f(x_i) \quad (20)$$

The advantage of incorporating a weighting function, $W(x)$, is that singularities or difficult terms can be removed from the function to be integrated.

An n -point Gaussian quadrature rule is constructed to be exact for polynomials of degree $(2n - 1)$, by a suitable choice of the points, x_i , and weights, ω_i . In fact, it can be shown (see e.g., [5]) that the abscissas used for the n -point Gaussian quadrature formulas are optimal and given precisely by the roots of the n th orthogonal polynomial, $p_n(x)$, for the same interval, $[a, b]$, and weighting function, $W(x)$. A set of polynomials $\{p_n(x)\}$ is orthogonal if they satisfy the condition,

$$\int_a^b W(x) p_n(x) p_m(x) dx = 0, \quad \text{for } n \neq m \quad (21)$$

The simplest form of Gaussian quadrature uses uniform weighting, $W(x) = 1$, and the reference interval is $[a, b] = [-1, 1]$. The orthogonal polynomials for this weighting function and interval are the Legendre polynomials, see e.g. [5], which are used to approximate the integrand $f(x)$ over the interval $[-1, +1]$ as follows,

$$\int_{-1}^1 f(x) dx \approx \sum_{i=1}^n \omega_i f(x_i) \quad (22)$$

where x_i are the roots of the Legendre polynomials and ω_i are the corresponding weights, which are well known for this case and are given in Table 2. If we are interested in approximating the integral defined on an arbitrary interval, $[a, b]$, we can use a simple change of variable as follows,

$$\begin{aligned} \int_a^b f(x) dx &= k \int_{-1}^1 f(c + kx) dx \\ &\approx k \sum_{i=1}^n \omega_i f(c + kx_i) \end{aligned} \quad (23)$$

where $c = (b + a)/2$ and $k = (b - a)/2$. This is called the *Gauss–Legendre quadrature rule*. The following example illustrates and compares it with the Simpson's approximation.

Example Assume that we are interested in the approximation of the following integral,

$$\int_0^{\pi/2} \cos(x) dx \quad (24)$$

which is known analytically to be one. Firstly, we use the two-point Gauss–Legendre quadrature, given in equation (23), to obtain the following approximation,

$$\begin{aligned} \int_0^{\pi/2} \cos(x) dx &\approx \frac{\pi}{4} \left[1.0 \times \cos\left(\frac{\pi}{4} + \frac{\pi}{4\sqrt{3}}\right) + 1.0 \right. \\ &\quad \left. \times \cos\left(\frac{\pi}{4} - \frac{\pi}{4\sqrt{3}}\right) \right] = 0.99847 \end{aligned} \quad (25)$$

which is very close to the true value of one and gives an approximation error of 0.00153. Now, we approximate the same integral using the three-point Simpson's quadrature, given in equation (13),

$$\begin{aligned} \int_0^{\pi/2} \cos(x) dx &\approx \frac{\pi}{12} \left[\cos(0) + 4 \cos\left(\frac{\pi}{4}\right) \right. \\ &\quad \left. + \cos\left(\frac{\pi}{2}\right) \right] = 1.0023 \end{aligned} \quad (26)$$

This gives an approximation error of 0.0023 which is larger than the error obtained previously with the Gauss–Legendre quadrature that was based only on two points.

The Gaussian quadrature is also superior when it is compared with the composite Simpson's rule. For example, the four-point Gauss–Legendre quadrature gives the following approximation for the same integral,

$$\begin{aligned} \int_0^{\pi/2} \cos(x) dx &\approx \frac{0.65215\pi}{4} \times \cos\left(\frac{\pi}{4} + \frac{0.3399\pi}{4}\right) \\ &\quad + \frac{0.65215\pi}{4} \times \cos\left(\frac{\pi}{4} - \frac{0.3399\pi}{4}\right) \\ &\quad + \frac{0.34785\pi}{4} \times \cos\left(\frac{\pi}{4} + \frac{0.8611\pi}{4}\right) \\ &\quad + \frac{0.34785\pi}{4} \times \cos\left(\frac{\pi}{4} - \frac{0.8611\pi}{4}\right) \\ &= 0.999999977 \end{aligned} \quad (27)$$

Table 2 Gauss–Legendre abscissas and weights

n^o points	2	3	4	5				
x_i	$\pm\sqrt{\frac{1}{3}}$	0.0	± 0.7746	± 0.3399	± 0.8611	0.0	± 0.5385	± 0.9062
ω_i	1.0	0.88889	0.55556	0.65215	0.34785	0.56889	0.47863	0.23693

which is a much better approximation than that obtained with the following composite Simpson’s quadrature based on five points, as given in equation (15),

$$\begin{aligned} \int_0^{\frac{\pi}{2}} \cos(x) \, dx &\approx \frac{\pi}{24} \cos(0) + 4 \cos\left(\frac{\pi}{8}\right) + 2 \cos\left(\frac{\pi}{4}\right) \\ &\quad + 4 \cos\left(\frac{3\pi}{8}\right) + \cos\left(\frac{\pi}{2}\right) \\ &= 1.000134585 \end{aligned} \quad (28)$$

Alternatively to the Gauss–Legendre quadrature, other Gaussian rules can be developed using different classical orthogonal polynomials. Table 3 shows some of these polynomials together with their associated intervals and weighting functions. A large amount of information about these polynomials and their properties can be found in [7] and [9]. See also [5] and [10] for numerical procedures on the calculation of the abscissas and weights.

When we have an unusual choice for $W(x)$, we can develop our own Gaussian quadrature although this task usually becomes more difficult. Firstly, we need to obtain the set of orthogonal polynomials for the considered interval and weighting function. This can be done for example using a recurrence relation as described in [5]. Then, we need to calculate the zeros of these polynomials which will be the points, x_i , at which to evaluate the function. These can be obtained using a root-finding algorithm like Newton’s method or faster procedures as those described in [5].

Table 3 Classical orthogonal polynomials with their intervals and weighting functions

Interval	$W(x)$	Symbol	Polynomial
$[-1, 1]$	1	$P_n(x)$	Legendre
$[0, \infty)$	e^{-x}	$L_n(x)$	Laguerre
$(-\infty, \infty)$	e^{-x^2}	$H_n(x)$	Hermite
$[-1, 1]$	$(1 - x^2)^{-1/2}$	$T_n(x)$	First-kind Chebyshev
$[-1, 1]$	$(1 - x^2)^{1/2}$	$U_n(x)$	Second-kind Chebyshev

Finally, we need to calculate the weights ω_i which can be obtained analytically by integrating the orthogonal polynomials for which the approximation is exact. There are also alternative formulas, which are more efficient for the calculation of these weights, see e.g. [5] and [10].

The Gaussian quadrature can be modified in order to incorporate one or both endpoints in the set of abscissas, leading to the Radau and Lobatto quadrature formulas respectively, see e.g. [10]. These formulas use a uniform weighting function $W(x) = 1$ and the free abscissas are the roots of some polynomials related to the Legendre orthogonal polynomials. Radau and Lobatto quadratures are slightly less optimal than the Gaussian quadrature.

Another important extension of the Gaussian quadrature is the Gauss–Kronrod algorithm, see e.g. [5] and [10]. This is an adaptive Gaussian method where the abscissas are suitably selected such that they can be reused in the next iterations reducing the number of function evaluations. This approach is implemented in various software packages such as Mathematica (Wolfram Research Inc.).

Discussion and Remarks

The generalization of the described quadrature rules to the multidimensional case is not straightforward. The main reason is that the number of function evaluations for an n -dimensional integral increases to the power of n and then, it becomes very expensive even for low-dimensional integrals. An alternative approach for these cases is the use of Monte Carlo integration (*see Monte Carlo Methods; Markov Chain Monte Carlo, Introduction*) which gives reasonable approximations for multidimensional integrals defined over complicated regions.

It is frequent in practice to have a tabulated function at given points, x_i , obtained from experimental data. In these cases, the abscissas are predetermined and cannot be chosen at will. One possibility is to

obtain the Lagrange polynomial which interpolates the observed points and integrate it to approximate the integral, see e.g. [10]. One alternative is the use of splines which are piecewise polynomial functions with some finite derivatives that can be arranged to interpolate the data points, see e.g. [2].

Finally, note that the problem of evaluating an integral such as that given in equation (1) is equivalent to solving the differential equation $y'(x) = f(x)$ with $y(a) = 0$. There are many numerical procedures in the literature for solving differential equations that could be applied for this problem, see e.g. [5]. These would be specially well suited when the function to integrate is concentrated around one or various peaks.

Bayesian Networks in Reliability

Introduction

Definition

Mathematically, a Bayesian network (BN) is a compact representation of a joint statistical distribution function. A BN encodes the **probability density function** governing a set of variables by specifying a set of conditional independence statements together with a set of conditional probability functions (CPFs). More specifically, a BN consists of a qualitative part, a *directed acyclic graph* where the nodes mirror the variables, and a quantitative part, the set of CPFs. An example of a BN is shown in Figure 1, only the qualitative part is given. This BN models the risk of an explosion in a process system. *Explosions* occurs if there is a *Leak* of chemical substance that is not detected by the gas detection system. This system detects all leaks unless it is in its failed state (*GD Failed*). The *Environment* will influence the probability of both leaks and a failure of the gas detection system. Finally, an explosion may lead to a number of *Casualties*.

There is a similar example of a BN in a article named **Bayesian Networks**, where inference and learning in BNs are considered. Here we focus on how BNs may be built, and their use in decision making.

For notational convenience, we consider the variables $\{X_1, \dots, X_n\}$ when we make some general definitions about BNs in the following. Now, we call the nodes with outgoing edges pointing into a specific node the *parents* of that node, and say that X_j is a *descendant* of X_i if and only if there exists a directed path from X_i to X_j in the graph. In Figure 1, *Leak?* and *GD fails?* are the parents of *Explosion?*, written $\text{pa}(\text{Explosion?}) = \{\text{Leak?}, \text{GD fails?}\}$ in short. Furthermore, $\text{pa}(\text{Casualties?}) = \{\text{Explosion?}\}$. Since there are no directed paths from *Casualties?* to any of the other nodes, the descendants of *Casualties?* are given by the empty set and, accordingly, its non-descendants are $\{\text{Environment?}, \text{GD fails?}, \text{Leak?}, \text{Explosion?}\}$. The edges of the graph represent the assertion that a variable is conditionally independent of its nondescendants in the graph given its parents

in the same graph. The graph in Figure 1 does for instance assert that for all distributions compatible with it, we have that *Casualties?* is conditionally independent of $\{\text{Environment?}, \text{GD fails?}, \text{Leak?}\}$ when conditioned on $\{\text{Explosion?}\}$.

The graphical structure has an intuitive interpretation as a model of causal influences. Although this interpretation is not necessarily entirely correct, it is helpful when the BN structure is to be elicited from experts. Furthermore, it can also be defended if some additional assumptions are made.

When it comes to the quantitative part, each variable is described by the CPF of that variable *given the parents* in the graph, that is, the collection of CPFs $\{f(x_i | \text{pa}(x_i))\}_{i=1}^n$ is required. The underlying assumptions of conditional independence encoded in the graph allow us to calculate the joint probability function as

$$f(x_1, \dots, x_n) = \prod_{i=1}^n f(x_i | \text{pa}(x_i)) \quad (1)$$

and this is in fact the main point when working with BNs: Assume that a distribution function $f(x_1, \dots, x_n)$ factorizes according to equation (1). This defines the parent set of each X_i , which in turn defines the graph, and from the graph we can read off the conditional independence statements encoded in the model. As we have seen, this also works the other way around, as the graph defines that the joint distribution *must* factorize according to equation (1). Thus, the graphical representation is the bridging of the gap between the (high-level) conditional independence statements we want to encode in the model and the (low-level) constraints this enforces on the joint distribution function.

After having established the full joint distribution over $\{X_1, \dots, X_n\}$ (using equation (1)), any marginal distribution $f(x_i, x_j, x_k)$, as well as any conditional distribution $f(x_i, x_j | x_k, x_\ell)$, can be calculated using extremely efficient algorithms.

Use of BNs in Reliability

BNs originated in the field of artificial intelligence, where they were used as a robust and efficient framework for reasoning with uncertain knowledge. The history of BNs in reliability can be traced back (at least) to Barlow [1] and Almond [2]; the first real attempt to merge the efforts of the two communities is

2 Bayesian Networks in Reliability

Figure 1 An example BN describing a gas leak scenario. Only the qualitative part of the BN is shown

Figure 2 Three small network fragments describing different structural situations: serial (a), diverging (b), and converging (c)

probably the work of Almond [2], where he proposes the use of the *Graphical-Belief* tool for calculating reliability measures concerning a low-pressure coolant injection system for a nuclear reactor (a problem originally addressed by Martz and Waller [3]).

BNs constitute a modeling framework that is particularly easy to use in interaction with domain experts, also in the reliability field [4]. BNs have found applications in, for example, fault detection and identification, monitoring, software reliability, troubleshooting systems, and **maintenance optimization**.

Further Information on Bayesian Networks

Pearl [5] gives the first full account of BNs, whereas Charniak [6] gives a reader-friendly introduction to the field. The recent book by Jensen and Nielsen [7] gives a comprehensive review of the theory and methods of Bayesian networks and decision graphs. The causal perspective toward BNs is thoroughly analyzed in [8].

Several standard books on statistical modeling and decision theory contain chapters on BNs, and some books on risk and reliability analysis include discussions of these issues, see for example [9]. A review of the usage of BNs in reliability analysis can be found in [10]. The annual *Conference on Uncertainty in Artificial Intelligence* and, in particular, the co-located *Bayesian Modeling Applications Workshops*, are good references for the continuous development in the community.

Many BN tools are available to the practitioners. Examples include Hugin (www.hugin.com), BayesiaLab (www.bayesia.com), and Netica (www.norsys.com). For a comprehensive list of software tools, see the one maintained by Kevin Murphy at www.cs.ubc.ca/~murphyk/Software/BNT/bnsoft.html.

Conditional Independence

The driving force when making BN models is the set of *conditional independence* statements the model encodes. It is common to use the notation $\mathcal{X} \perp\!\!\!\perp \mathcal{Y} \mid \mathcal{Z}$ to denote that the variables in the two sets $\mathcal{X}$ and $\mathcal{Y}$ are conditionally independent given the variables in $\mathcal{Z}$. If $\mathcal{Z}$ is the empty set, we simply write $\mathcal{X} \perp\!\!\!\perp \mathcal{Y}$. Finally, we use $\mathcal{X} \not\perp\!\!\!\perp \mathcal{Y} \mid \mathcal{Z}$ to make explicit that $\mathcal{X}$ and $\mathcal{Y}$ are conditionally *dependent* given $\mathcal{Z}$.

We saw the first example of how we can read conditional independence statements from the graph when we concluded that $\{Casualties?\} \perp\!\!\!\perp \{Environment?, GD\ fails?, Leak?\} \mid \{Explosion?\}$ in Figure 1. The general analysis of conditional independence is a bit broader, and uses the concept of *d-separation*, which centers around the three categories of network fragments shown in Figure 2.

The *serial connection* (Figure 2a) encodes that $X_1 \perp\!\!\!\perp X_3 \mid X_2$, but $X_1 \not\perp\!\!\!\perp X_3$. For example, let X_1 denote the *planned* preventive maintenance (PM) program for a given component, let X_2 be the *implemented* PM, and X_3 the life length of the component. The conditional independence statements encoded

in this model tell us that if we do not know the implemented PM program, then the planned PM can tell us something about the life length of the component ($X_1 \perp\!\!\!\perp X_3$). However, as soon as we learn about the implemented PM program, the *plans* are irrelevant for the life length: $X_1 \perp\!\!\!\perp X_3 \mid X_2$.

Figure 2(b), a *diverging connection*, dictates similar properties: $Y_1 \perp\!\!\!\perp Y_3 \mid Y_2$, but $Y_1 \not\perp\!\!\!\perp Y_3$. This BN can for instance model the quality of the production from an assembly line. Let Y_1 be the quality of the first item that was produced at this line, and Y_3 be the quality of the second item. Finally, let Y_2 be a measure of how well the assembly line operates overall. Now, if Y_2 is unknown to us, information about Y_1 being good (bad) would make us infer that the quality of the line as such (Y_2) was good (bad) as well, and therefore we would expect that Y_3 would be good (bad), too. Thus, $Y_1 \not\perp\!\!\!\perp Y_3$. On the other hand, if the quality of the production line is known, this model says that the quality of each produced item may be seen as independent of each other ($Y_1 \perp\!\!\!\perp Y_3 \mid Y_2$).

Finally, the *converging connection* in Figure 2(c) encodes that $Z_1 \perp\!\!\!\perp Z_3$, but $Z_1 \not\perp\!\!\!\perp Z_3 \mid Z_2$. To understand this part, one can think of Z_1 as the quality of an assembly line, Z_3 as the environmental conditions of the production (temperature, humidity, etc.), and Z_2 as the quality of a product coming from the assembly line. In this model, the quality of the assembly line is *a priori* independent of the environmental conditions ($Z_1 \perp\!\!\!\perp Z_3$), however, as soon as we observe the quality of the product, we can make inference regarding the quality of the line from what is known about the environmental conditions: If the quality of the product is low, although it was produced under good environmental conditions, it is reasonable to assume that this may be because the overall quality of the assembly line is poor ($Z_1 \not\perp\!\!\!\perp Z_3 \mid Z_2$).

Building Bayesian Networks

Building BNs from expert input can be a difficult and time-consuming task. This is typically an assignment given to a group of specialists. A BN expert guides the model building, asks relevant questions, and explains the assumptions that are encoded in the model to the rest of the group. The domain experts, on the other hand, supply their knowledge to the BN expert in a structured fashion. In our experience, it will pay off to start the model building

by familiarization: the BN expert should study the domain, and the reliability analysts require basic knowledge about BNs. As soon as this is established, model building will proceed through a number of phases:

Step 0: Decide what to model. Select the boundary for what to include in the model, and what to leave aside.

Step 1: Defining variables. Select the important variables in the model. The *range* of the continuous variables and the *states* of the discrete variables are also determined at this point.

Step 2: The qualitative part. Next, we define the graphical structure that connects the variables. In this phase it can be beneficial to consider the edges in the graph as *causal*, but the trained domain expert may also be confident about (conditional) dependencies/independencies to include in the model. In the latter case, the *PC algorithm* [11] is a principled way of asking the most efficient questions about conditional independencies. Domain experts can often be very eager to incorporate an unpractically large number of links in the structure in an attempt to “get it right”. The BN expert’s task is in this setting to balance the model’s complexity with the modeling assumptions the domain experts are willing to accept. Often, a post-processing of the structure may reveal void edges (e.g., those creating triangles in the graph [12]).

Step 3: The quantitative part. To define the quantitative part, one must select distributional families for all variables, and fix parameters to specify the distributions. If the BN structure has not been carefully elicited (and pruned) this may be a formidable task. Luckily, the consistency problems common when eliciting large probability distribution functions are tackled by a “divide-and-conquer” strategy here: If each CPF $f(x_i \mid \text{pa}(x_i))$ is defined consistently, then this implies global consistency as well. To elicit the quantitative part from experts, one must acquire all CPFs $\{f(x_i \mid \text{pa}(x_i))\}_{i=1}^n$ in equation (1), and once again the causal interpretation can come in as a handy tool.

To fully specify the set of CPFs, we must (a) select parametric families for each $f(x_i \mid \text{pa}(x_i))$ and (b) determine values for all parameters of each CPF. To do the last part, we must use either statistical data or expert judgment, but since both these sources of information can have low quality, as well as come with a cost, one would like the BN formalism to

minimize the number of parameters required. This is exactly what it attempts to do; it represents the joint distribution in a cost-efficient manner (through its factorized representation in equation (1)). Let us consider the domain represented by $\{X_1, \dots, X_n\}$, and let the nodes be labeled such that $\text{pa}(X_i) \subseteq \{X_1, \dots, X_{i-1}\}$ for $i = 1, \dots, n$ (this can always be obtained through relabeling). Although it is not essential for the following argument, we will for now assume that all variables take on values in $\{0, 1\}$ (these values could for instance signify a component that has either failed or is operating). According to equation (1) we will require CPFs of the type $f(x_i | \text{pa}(x_i))$; these are in this case fully determined by the probability $P(X_i = 1 | \text{pa}(x_i))$. The number of parameters required to specify $f(x_i | \text{pa}(x_i))$ for a given i is thus equal to $2^{|\text{pa}(X_i)|}$, and the total number of parameters is given by $\sum_{i=1}^n 2^{|\text{pa}(X_i)|}$. This number is by construction not higher than $2^n - 1$, that is the number of parameters required to define the full joint distribution (without using the conditional independence statements in the BN structure). Hence, when we use a BN, we are never worse off than if the full joint distribution is defined directly, and we are bound to improve as long as at least one conditional independence assumption can be made. As an example, if all variables of the domain in Figure 1 are binary, then the full joint distribution will require 31 parameters to be specified. Alternatively, the BN representation uses only 11 parameters.

Step 4: Verification. Verification should be performed both through sensitivity analysis as well as by testing how the model behaves when analyzing well-known scenarios. Typically, this step gives need for refinement/redefinition of the model, and this is repeated until the work put into improving the model does not lead to substantial benefits. As pointed out by, for example, [13], the sensitivity with respect to BN structure is relatively high, and the graph is thus

the most vital part. Sensitivity with respect to the parameters is by large dependent on the application.

Lately, some tools that are aimed at guiding model building have emerged. These tools attempt to enable a domain expert to build a BN without interacting with a BN expert. For instance, [14] describes a system that can be used to build troubleshooter systems efficiently.

Decision Graphs

One of the most intriguing properties of the BN framework is that it can easily be extended to represent *decisions*. The basis for the representation is utilities, which are quantified measures for preference. That is, a real number is attached to each possible scenario in question. Let $S = \{s_1, \dots, s_t\}$ be the possible scenarios with the probability distribution $(p_1, \dots, p_t)$, and let $(u_1, \dots, u_t)$ be the corresponding utilities. The expected utility of S is then $EU(S) = \sum_i u_i p_i$.

Example

Assume for the scenario in Figure 1 that we wish to consider the possibility of a structural safety measure (*SSM*). The *SSM* has an impact on the number of casualties in case of an explosion, and the cost of the *SSM* shall be balanced with the expected reduction in costs due to casualties. To represent this, the BN is extended with two types of variables, *decision nodes* (rectangular shaped), representing the various decision options, and *utility nodes* (diamond shaped), representing preferences on a numerical scale. This is done in Figure 3.

The edge from *SSM* to *Casualties?* indicates the impact of an *SSM*, and the quantitative specification is the conditional probability $f(\text{Casualties?} | \text{SSM}, \text{Explosion?})$. The edges to the *Cost* nodes indicate the variables relevant for the cost.

Figure 3 Extending the BN in Figure 1 to optimally choose the level of structural protection (*SSM*)

Figure 4 An influence diagram (ID) extending the one-decision scenario in Figure 3. It can be used to solve the problem with several decisions

That is, $Cost_1$ is a function of SSM , whereas $Cost_2$ is a consequence of the number of casualties (if any). The edge from *Environment?* to SSM indicates that the state of the environment is known when the decision on $SSMs$ is made.

Exploiting probability updating in the BN (Figure 1), it is now easy to calculate the expected utility for each decision option given the environment. The result is an optimal policy, which for any state of the environment selects a decision of maximal expected utility.

Several Decisions

The framework also allows the representation of decision problems involving more than one decision. Assume in the previous decision problem that we also wish to decide a testing regime for the gas detection system. We introduce a decision node GD test to represent the decision on testing frequency (see Figure 4). At the time when this is decided, we know the decision on SSM , and we have also run an on-site verification to quantify the effectiveness of the implemented $SSMs$ (*Verification?*). We use the latter as input to decide the test interval, hence the edge from *Verification?* to GD test.

The result is an optimal policy for SSM as well as for GD Test. The optimal policy for GD test is a function of *Verification?*, *Environment?*, and SSM . The calculation of an optimal policy for SSM is in this situation more complex than in the previous example. When deciding on SSM we need to have an idea of the GD test decision. Therefore, the first thing to calculate is an optimal policy for GD test, and assuming that we will follow this policy, we can determine an optimal policy for SSM . The two policies together form an optimal strategy for the decision problem.

Influence Diagrams

When the decision problem consists of a predefined sequence of observations and decisions (as in the

example above) it can be represented as an influence diagram [15]. An influence diagram is an extension of a BN with decision nodes and utility nodes. An edge from a node A to a decision node D indicates that the state of A is known before the decision D is taken. In order not to overload the graph with edges, the *no-forgetting* property is usually assumed: If the state of A is known when taking decision D , then it is also known when taking all subsequent decisions. To reflect the premise of a predefined sequence of observations and decisions, there is graphical constraint for influence diagrams: there must be a directed path encompassing all decision nodes.

An influence diagram is primarily used to calculate the expected utilities for the first decision variable. To do this, we have to predict the decisions we will take in the future, and in order to decide on the present decision we calculate policies for the future decisions based on the principle of maximizing the expected utility [16–18].

Although influence diagrams are a powerful modeling tool, the framework has its shortcomings. The decision problem must have a finite time horizon, and it must be *symmetric*: the next nodes to observe, and the next decisions to take, must be independent of the current observations and decisions. Work has been done to overcome these shortcomings [19–21], but these languages are much more complex to work with.

Further Pointers to the Literature

BNs are *directed* graphical models. Sometimes, a domain expert may be uncomfortable directing an edge between two nodes. A *chain graph* is a graphical model closely related to BNs, but which accepts both directed and undirected edges. The interested reader is referred to [22].

In this article we have discussed how BNs could be elicited from domain experts. Another possibility is to learn the BNs from historical data. This is an active research topic, see, for example, [23].

Modeling *dynamics* is often a critical part of a reliability application. As an example, consider a fault detection system, which continuously monitors the environment looking for indications that it is about to become unstable. Obviously, modeling development over time is crucial in this situation. There are several special classes of BNs developed for such situations, Smyth [24] uses one of these, *Hidden Markov Models*, for detecting failures in satellite antennas.

We see a preference for *discrete* variables in the BN community, mainly due to the technicalities of the calculation scheme used to calculate the posterior probabilities. We note that the applicability of BNs in risk and reliability analysis would be enormously limited if one would consider only discrete variables, and this is therefore the most important feature that is missing before BNs provide a full framework for such tasks. Numerous efforts have been taken up to solve this problem, ranging from inference by sampling [25], via exact calculations in restricted structures [26, 27], to approximations of the CPFs of the continuous variables [28, 29].

Computational Issues in Network Reliability

Introduction

Networks are pervasive and familiar structures in our technological society, ranging from fiber-optic telecommunication systems, to electrical power distribution systems, to systems of highway and airline connections. Such networks are designed to distribute information, electricity, and people from place to place in an efficient and economical manner. Network systems are composed of *nodes* (representing switching centers, workstations, concentrators, facilities, cities, etc.), which are connected by a collection of *edges* (cables, pipelines, roads, or even wireless connections).

These network components (nodes, edges) are typically prone to failure. At any instant, each component is considered to be either *operating* or *failed*, and as a result the entire network system will be either operational or failed. The reliability of the system measures the probability that the system functions properly. Its value is critically dependent not only on the individual component reliabilities, but also on the manner in which they are interconnected. Important objectives are therefore to determine the reliability of a given network system (analysis) and to design cost-efficient network structures that have improved reliability (design). We focus here on certain computational aspects of network analysis.

The topology of a network is specified by its underlying *graph* $G = (V, E)$, where V denotes the set of nodes and E denotes the set of edges joining pairs of nodes. The graph is *undirected* if links between nodes are symmetric (bidirectional); in this case, the edge $e = (i, j) \in E$ indicates that nodes i and j are adjacent, joined by the undirected edge e . In a *directed* graph, there is a direction associated with each edge $e = (i, j) \in E$ (such as a one-way street); in this case, node j is considered to be adjacent from node i . Of course, an undirected graph can be modeled by replacing each undirected edge $e = (i, j)$ by a pair of oppositely directed edges (i, j) and (j, i) . Of fundamental importance is a *path* $P = [i_0, i_1, \dots, i_k]$ in a graph (undirected or directed): it is a sequence of edges $(i_0, i_1), (i_1, i_2), \dots, (i_{k-1}, i_k)$ leading from node i_0 to node i_k . A *simple* path

contains no repeated nodes. Two edges both joining node i to node j are called *parallel edges*; if there are exactly two edges (i, j) and (j, k) incident on node j , then these two edges are called *series edges*.

In general, both nodes and edges can fail. However, node failures can be simulated by edge failures [1], so we assume for simplicity that only edge failures occur. Specifically, p_e is the probability that edge e is operational at a random instant; $q_e = 1 - p_e$ is the failure probability of edge e . It is common to assume that the failures of distinct edges are statistically independent. Suppose that $S \subseteq E$ denotes the set of operating edges at a given instant, so that the edges in $E - S$ are failed. By independence, the probability of *state* S is given by

$$P(S) = \prod_{e \in S} p_e \prod_{e \in E-S} q_e \quad (1)$$

There are several ways of assessing the *reliability* $R(G, p)$ of a network having the topology specified by the graph $G = (V, E)$ and the edge reliabilities $\{p_e : e \in E\}$. In each of the following models, the system is required to maintain a certain degree of connectivity after random edge failures. If the graph is undirected, the following models are commonly used.

- [M1.] *Two-terminal reliability*: the reliability $R_{st} = R(G, p)$ is the probability that there exists a path of operating edges between two specified nodes s, t in G .
- [M2.] *All-terminal reliability*: the reliability $R_V = R(G, p)$ is the probability that paths of operating edges exist between every pair of nodes in G .
- [M3.] *K-terminal reliability*: the reliability $R_K = R(G, p)$ is the probability that paths of operating edges exist between every pair of nodes in $K \subseteq V$.

When G is directed, the above models generalize as follows.

- [M4.] *s, t connectedness*: the reliability $\vec{R}_{st} = R(G, p)$ is the probability that there exists a path of operating edges joining node s to node t in G .
- [M5.] *s reachability*: the reliability $\vec{R}_V = R(G, p)$ is the probability that paths of operating edges exist from the source node s to every node in G .

2 Computational Issues in Network Reliability

[M6.] s, K *connectedness*: the reliability $\vec{R}_K = R(G, p)$ is the probability that paths of operating edges exist from the source node s to every node in $K \subseteq V$.

In each of the above problems, the system is considered to be operating when the subgraph H of operating edges (defined by state S) possesses a certain structure; states that support operation are generically termed *pathsets*, and sets of edges whose removal leaves a state not supporting the operation are *cutsets*. *Minpaths* are minimal pathsets, and *mincuts* are minimal cutsets (see **Path Sets and Cut Sets in System Reliability Modeling**). For two-terminal reliability, nodes s and t need to be connected in the subgraph H . A minimal requirement then is that nodes s and t are connected by a simple path in H . Thus, the minpaths for this problem are the simple s - t paths in G . Similarly, the minpaths for the all-terminal reliability problem are the spanning trees [2] of G , while the minpaths for the K -terminal reliability problem are trees that span all the nodes in K . Directed analogs of minpaths are also easy to characterize: for example, minpaths for s reachability are directed spanning trees [2] of G , rooted at node s . Determining $R(G, p)$ can then be expressed as computing the probability of certain events associated with the minpaths of the system (see the section titled “Exact Computation of Reliability”).

The *unreliability* $U(G, q)$ of network G is given by $U(G, q) = 1 - R(G, 1 - q)$. It can also be defined more directly in terms of certain “dual” graph structures (mincuts). For example, the two-terminal unreliability U_{st} is equivalently the probability that the failed edges contain a set of edges whose removal disconnects s from t in G . Similarly, the all-terminal unreliability U_V is the probability that removal of the failed edges will disconnect G . Network unreliability $U(G, q)$ can also be expressed in terms of events associated with the mincuts of the system (see the section titled “Exact Computation of Reliability”).

For more complete treatments, and references for the material in subsequent sections, see [1, 3, 4].

Computational Complexity

We consider the special case of the reliability analysis problem that arises when all individual component reliabilities are equal: that is, $p_e = p$ for all edges

$e \in E$. If $|E| = m$, then the reliability can be written as a polynomial in p , $\sum_{i=0}^m F_i p^{m-i} (1-p)^i$, the *reliability polynomial*. The associated computational problem, the *functional reliability analysis problem*, takes a representation of a network (a graph with its associated edge probabilities) as input and produces the coefficients $\{F_i\}$ as output. The *rational reliability analysis problem* instead requires the evaluation of the reliability polynomial at a specific rational probability $p = a/b$.

The general term $F_i p^{m-i} (1-p)^i$ in the reliability polynomial is the probability that exactly $m-i$ edges operate and the system operates. Thus, we can interpret F_i as the number of operating system states (pathsets) having i failed edges. Equivalently the probability of network failure can be written as an *unreliability polynomial*, $\sum_{i=0}^m C_i p^{m-i} (1-p)^i$; here C_i is the number of cutsets with i edges. The problem of determining each of the coefficients F_i or C_i is a counting problem. NP and NP-complete denote classes of recognition problems, but counting problems associated with reliability can be classified as NP-hard when at least as hard as the NP-complete problems [5].

The functional reliability analysis problem can be reduced in polynomial time to the rational reliability analysis problem. Given a network, we define

c = cardinality of a minimum cardinality cutset,

C_c = number of minimum cardinality cutsets,

ℓ = cardinality of a minimum cardinality pathset,

N_ℓ = number of minimum cardinality pathsets.

Then

$$0 \leq F_i \leq \binom{m}{i} \text{ for } i = 0, 1, \dots, m$$

$$F_i = \binom{m}{i} \text{ for } i < c$$

$$F_i = \binom{m}{i} - C_c \text{ for } i = c$$

$$F_i = N_\ell \text{ for } i = m - \ell$$

$$F_i = 0 \text{ for } i > m - \ell \quad (2)$$

Table 1 Computational complexity of recognition and counting problems

	R_K	R_{st}	R_V	$\vec{R}_V$
Minimum cardinality pathset recognition	NP-hard	Polynomial	Polynomial	Polynomial
Minimum cardinality cutset recognition	Polynomial	Polynomial	Polynomial	Polynomial
Minimum cardinality pathset counting	NP-hard	Polynomial	Polynomial	Polynomial
Minimum cardinality cutset counting	NP-hard	NP-hard	NP-hard	Polynomial
General term F_i	NP-hard	NP-hard	NP-hard	NP-hard

Thus, by computing the reliability polynomial we determine important properties of the underlying graph. For example, we can determine from the reliability polynomial the size c of a minimum cardinality cutset. Thus, if the minimum cardinality cutset recognition problem is NP-hard, then computing the reliability polynomial is NP-hard. Indeed, for any network, the functional and rational reliability analysis problems are NP-hard whenever recognition or counting is NP-hard for minimum pathsets or minimum cutsets. Known complexity results for the K -terminal, two-terminal, and all-terminal problems are given in Table 1.

In light of these negative results, much research has been aimed at the analysis of structured networks. The widest class of networks known to be solvable in polynomial time involve series-parallel graphs and certain generalizations. However, the undirected two-terminal reliability problem remains NP-hard over planar networks having node degrees bounded by three and the directed two-terminal reliability analysis problems remain NP-hard over acyclic planar networks having node degrees bounded by three. Directed and undirected all-terminal reliability analysis problems are NP-hard when restricted to planar networks (see [2] for undefined graph-theoretic terms).

Exact Computation of Reliability

Now we outline exact algorithms for computing reliability measures. Most computational methods rely on a simple but important observation: there exist graph transformations that leave the values of various reliability measures unchanged, and these can often be used to simplify the network. Among these, deletion of *irrelevant* nodes and edges (those not appearing in any minpath) and standard series-parallel reductions, are the most frequently used.

When reliability-preserving transformations fail to reduce the network into a restricted class for which an efficient exact method is known, we are forced to resort to potentially exponential-time methods. In the first main class of these exact methods, we examine the possible states of the network.

A *state* of network $G = (V, E)$ is a subset $S \subseteq E$ of operational edges. The conceptually simplest exact algorithm is *complete state enumeration*. If $\mathcal{O}$ is the set of all pathsets, then

$$R(G, p) = \sum_{S \in \mathcal{O}} \prod_{e \in S} p_e \prod_{e \in E-S} (1 - p_e) \quad (3)$$

By generating all states, and determining which are operational, the reliability is “easily” (but not efficiently) computed.

Often, many states can be easily seen to be operational without listing them out one by one. Hence an immediate improvement is obtained by generating the states in a more clever way. A basic ingredient in this is the technique of *factoring*, also called *pivotal decomposition*:

$$R(G, p) = p_e R(G \cdot e, p) + (1 - p_e) R(G - e, p) \quad (4)$$

for any edge e of G . Here $G - e$ means G with edge e deleted, and $G \cdot e$ means G with edge e contracted – that is, the endpoints of e are amalgamated into a single node. Factoring carried out until the networks produced have no edges is just complete state enumeration. However, some simple observations result in improvements. When $G - e$ is failed, any sequence of contractions and deletions results in a failed network, and hence there is no need to factor $G - e$. Moreover, although we may be unable to simplify G with a reliability-preserving transformation, we may well be able to simplify $G \cdot e$ or $G - e$.

When it is possible to generate all minpaths or mincuts of the network, a second important class of algorithms is used. Suppose that the minpaths $P_1, \dots, P_h$ of G have been listed. Let E_i be the event that all edges in minpath P_i are operational. Then the reliability is just the probability that one or more of the events $\{E_i\}$ occurs. Unfortunately, the $\{E_i\}$ are not disjoint events, and hence we cannot simply sum their probabilities of occurrence. For example, representing “or” as $\vee$ and “and” as $\wedge$,

$$\Pr[E_1 \vee E_2] = \Pr[E_1] + \Pr[E_2] - \Pr[E_1 \wedge E_2] \quad (5)$$

In general $R(G, p) = \Pr[E_1 \vee E_2 \vee \dots \vee E_h]$, and hence

$$R(G, p) = \sum_{j=1}^h (-1)^{j+1} \sum_{I \subseteq \{1, \dots, h\}, |I|=j} \Pr[E_I] \quad (6)$$

where E_I is the event that all paths P_i with $i \in I$ are operational, that is, the event $\bigwedge_{i \in I} E_i$. This is a standard inclusion–exclusion expansion [1].

Many Boolean algebra methods simplify such Boolean formulas to represent all of the operational states. For example we can rewrite the probability that at least one minpath is operational as $\sum_{i=1}^h \Pr[\overline{E_1} \wedge \dots \wedge \overline{E_{i-1}} \wedge E_i]$. This expresses the reliability as the sum of h *disjoint* events; in the i th event, all of the first $i - 1$ minpaths fail, but the i th minpath operates. Simplification of the terms $\Pr[\overline{E_1} \wedge \dots \wedge \overline{E_{i-1}} \wedge E_i]$ is the key; existing methods focus on writing each as the conjunction (“and”) of the basic events of edge operation and edge failure (and hence in terms of independent events), in order to produce expressions that are as small as possible and can be calculated as simple sums of products. For algorithms and theory related to Boolean algebra methods in reliability, see [6].

Bounds and Approximations

None of the methods developed succeed in providing exact reliability metrics efficiently. Consequently two main directions have been explored, bounding and approximation. The essence of bounding is to provide practical computation of absolute upper and lower bounds on the reliability measure of interest. Investigations have pursued two quite

different lines. When practical computation is the main concern, and theoretical guarantees of efficiency are not needed, strategies based on inclusion–exclusion for states, pathsets, and cutsets have all been extensively applied. These provide the basis for widely used methods that generate the *most probable states* of the network, since a few states typically account for much of the network operation. See especially [4] for a more detailed exposition.

Theoretical guarantees of efficiency in bounding arise from three main strategies. In the first, the combinatorial or algebraic structure of the collection of operating states is used to determine, from a limited amount of information about these states, information about the rest. When information about all states can be deduced from information about only polynomially many states, efficient bounding techniques are obtained. In the second, transformations that lessen or increase the reliability measure, but at the same time simplify the structure of the network, underlie many effective algorithms. Finally, similar techniques that transform the set of pathsets or cutsets, rather than the network itself, have also proved effective. Detailed discussions of these appear in [1, 3].

Monte Carlo Methods

The intractability of exact computation and the inability of polynomial-time-bounding algorithms to provide tight bounds leads us to *simulation* techniques. The price is that the estimates obtained have a certain degree of uncertainty, but this is often well justified by superior results. The well-studied **Monte Carlo** method is most frequently used to simulate the stochastic behavior of the system.

We are interested in obtaining an estimate $\hat{R}$ for the true **network reliability** $R = R(G, p)$, in which the m edges have reliabilities $p_1, p_2, \dots, p_m$. Recall that the probability of each state $S \subseteq E$ is given by equation (1).

The *crude* method of sampling is straightforward. A sample of K states $S_1, \dots, S_K$ is chosen by generating mK independent samples u_{kj} , $k = 1, \dots, K$, $j = 1, \dots, m$ uniformly at random, and then placing e_j in S_k if and only if $u_{kj} \leq p_j$. Let $\hat{K}$ be the number of states k for which S_k is operating. Then an unbiased estimator for R is $\hat{R} = \hat{K}/K$, with variance $R(1 - R)/K$. Reduction of this variance can

be obtained by a number of standard Monte Carlo sampling techniques, such as *antithetic* and *control variates*, and *conditional*, *importance*, and *stratified sampling*.

Dagger sampling instead “spreads out” the individual edge failures in such a way that repeats of sample states is minimized. *Sequential construction* orders the edges of the graph. The edges begin as all failed, and then edges are successively “repaired”, that is, caused to operate, one by one in the specified ordering, until the system becomes operational. The reliability estimate is then a function of how long it takes for the system to become operational. This can result in better estimates than could be obtained by the crude method. *Sequential destruction* is the analogous process in which edges are removed one at a time.

Sampling using bounds is a powerful hybrid of the classical importance sampling and control variate schemes in Monte Carlo. It can, in principle, be applied to any reliability problem where the system function has associated with it a *lower bounding* function and an *upper bounding* function.

Each of the methods mentioned here admits a substantial theoretical development, and each has been extensively used in problems of practical importance.

A Small Example

Consider a network G with four nodes $V = \{1, 2, 3, 4\}$ and five edges $E = \{e_1 = \{1, 2\}, e_2 = \{1, 3\}, e_3 = \{1, 4\}, e_4 = \{2, 3\}, e_5 = \{3, 4\}\}$. Edge e_i operates with probability p_i and fails with probability $1 - p_i$. By listing the operational edges, a state $S \subseteq E$ is formed; since edges operate independently, its probability of occurrence is $\prod_{e_i \in S} p_i \prod_{e_i \in E \setminus S} (1 - p_i)$. Complete state enumeration lists all $32 = 2^5$ states, and sums the probability of occurrences over the operational states or pathsets. For the specific operation of all-terminal reliability, the single state with 5 edges and all 5 states having 4 edges are pathsets; only 8 of the 10 states with 3 edges are pathsets, and no pathset has fewer than 3 operating edges. By considering the failed edges, equivalently there is one cutset with 5 edges; 5 with 4 edges; 10 with 3 edges; and 2 with 2 edges. Minpaths are spanning trees, which are the pathsets with three edges here. There are six

mincuts: $\{e_1, e_4\}$ and $\{e_3, e_5\}$ of size two; and $\{e_1, e_2, e_3\}$, $\{e_2, e_4, e_5\}$, $\{e_2, e_3, e_4\}$, and $\{e_1, e_2, e_5\}$ of size three.

Factoring chooses an edge to delete or contract. Suppose that we factor G on edge e_1 . First we delete e_1 to form $G - e_1$, the network with $V = \{1, 2, 3, 4\}$ and four edges $E = \{e_2 = \{1, 3\}, e_3 = \{1, 4\}, e_4 = \{2, 3\}, e_5 = \{3, 4\}\}$. Edge e_4 must then operate for the network to remain connected, and hence the reliability of $G - e_1$ can be written as p_4 times the reliability of the network G_2 with $V = \{1, 3, 4\}$ and three edges $E = \{e_2 = \{1, 3\}, e_3 = \{1, 4\}, e_5 = \{3, 4\}\}$. On the other hand, contracting e_1 in G yields a network with $V = \{12, 3, 4\}$ and four edges $E = \{e_2 = \{12, 3\}, e_3 = \{12, 4\}, e_4 = \{12, 3\}, e_5 = \{3, 4\}\}$. Edges e_2 and e_4 are now in parallel and can be replaced by a single edge to produce a simpler network G_1 with the same reliability, with $V = \{12, 3, 4\}$ and three edges $E = \{e_3 = \{12, 4\}, e_5 = \{3, 4\}, e_6 = \{12, 3\}\}$, where $p_6 = p_2 + p_4 - p_2 p_4$. The reliability of G is $p_1 \text{Rel}(G_1) + (1 - p_1) p_4 \text{Rel}(G_2)$; in this case, a single factoring step produces two smaller problems, each involving networks with three edges.

To illustrate methods using minpaths, consider the network G_2 . It has three minpaths: $\{e_2, e_3\}$, $\{e_2, e_5\}$, and $\{e_3, e_5\}$. The probabilities that each occurs are $p_2 p_3$, $p_2 p_5$, and $p_3 p_5$, but these are not disjoint events. The probability that the second minpath operates when the first does not can be computed as $(1 - p_3) p_2 p_5$; the probability that the third operates when neither the first nor the second does is $(1 - p_2) p_3 p_5$. These events are disjoint and hence the reliability of G_2 is $p_2 p_3 + (1 - p_3) p_2 p_5 + (1 - p_2) p_3 p_5$, a disjoint sum-of-products form.

In practice these methods employ powerful techniques to factor so as to achieve the most simplification, or to simplify descriptions of the pathsets or cutsets so as to minimize the number of terms in the expression for the reliability.

Quality Control, Computing in

Introduction

The quality movement has benefited tremendously from the development of computer software making important but difficult and/or time-consuming calculations readily available to practitioners. When these calculations were performed by hand, the default was typically to resort to simpler tools such as “rules of thumb” for sample size. **Measurement Systems analysis** (MSA) called for 10 parts, 3 operators, and 3 replicates with analysis based on the $\bar{X}$ -bar and range method. Statistical process control (SPC) charts were limited to individuals, $\bar{X}$ -bar and range, or attribute charts. The design and analysis of experiments (DOE) were often simple two-level full or fractional factorials with hand calculations of “average of highs minus average of lows”. These simplified approaches are still valuable for training purposes and may work quite well in practice, but can also produce misleading results due to oversimplification or violation of assumptions.

The following is a brief survey of important advances in **quality control** tools that are (or should be) available to practitioners using current statistical quality software tools, as of 2007:

Power and Sample Size

The power of a test ($1 - \beta$) is the probability of rejecting the null hypothesis, given that the alternative hypothesis is true. Power depends on the type of hypothesis test, and is larger with an increase in sample size (which translates to increased cost), effect size (difference to be detected), **significance level** (α), and decrease in population standard deviation (σ) [1, 2].

Power and sample size calculations should be carried out prior to performing a test of hypothesis or design of experiments. Ideally, when planning an experiment, the power results should be displayed in real time as one selects the design type and number of replicates (using standardized effect sizes). This allows the practitioner to balance the cost of an experiment with expected outcome (see **Sample-Size**

Determination in Experimental Designs; Sample-Size Determination).

The details of power calculations are outside of the scope of this article, but note that the calculations for one-sample z , one proportion, and two proportions are straightforward, with statistical power determined using the same distribution function as that used in the significance test. Power calculations for one-sample t , two-sample t , analysis of variance (ANOVA), two-level **factorial**, and χ^2 require a reference distribution function called a *noncentral distribution function* [1]. Modern computer software takes care of the challenges associated with computing these distributions.

Measurement Systems Analysis

MSA studies (also known as *gauge repeatability and reproducibility*, GRR) are often performed with 10 parts, 3 operators/appraisers, and 3 replicates using the Automotive Industry Action Group (AIAG) standard templates ([3], see **Gauge Repeatability and Reproducibility (R&R) Studies; Measurement Systems Analysis, Overview; Measurement Systems Analysis, Capability Measures for**). Unfortunately, these sample sizes typically yield wide **confidence intervals** on GRR statistics such as %GRR (%precision/total) and %precision/tolerance. Without considering the confidence intervals, practitioners run the risk of calling an unacceptable measurement system acceptable (or an acceptable measurement system unacceptable).

Computing confidence intervals for GRR statistics requires the calculation of variance components (see **Variance Components; Gauge Repeatability and Reproducibility (R&R), Variance Components in**), and the confidence intervals associated with these variance components and ratios (see [4]; **Gauge Repeatability and Reproducibility (R&R) Studies, Confidence Intervals for**). Computer software is available to perform these computations.

Statistical Process Control

The SPC chart developed by Walter Shewhart has proved to be an effective and essential tool for quality improvement. As a statistical tool, however, there are times when the **control chart** fails to give proper information about the process. Sometimes

there are false alarms leading to expensive and fruitless searches for assignable causes. On the other hand, the Shewhart chart occasionally fails to detect a significant process shift early enough to prevent rework. These problems are particularly acute in process industries.

In order for control charts to function properly, the underlying assumptions must be valid. Specifically, the observations are assumed to be normally distributed, independent, with fixed mean and constant variance. If one is using an $\bar{X}$ -bar chart, the assumption of normality is usually met because of the central limit theorem – the distribution of sample averages tends to be normal, even if the individual observations are not. If, however, the subgroup size, $n = 1$, and the observations are not normally distributed, a power transformation should be applied to the data. Suggested transformations include X^2 , $\sqrt{X}$, $\ln(X)$, $1/\sqrt{X}$, $1/X$, $1/X^2$.

A power transformation resulting in normality should be utilized. The transformed data is then used to calculate the control limits. Computer software simplifies this task by employing the Box–Cox transformation method (see **Box and Cox Transformation**). If a suitable power transformation cannot be found, an alternative technique such as the Johnson transformation may be used [5].

The requirement for samples to be statistically independent can be a much more serious problem, since there is no similar mechanism to the central limit theorem assuring reasonable results. The presence of serial autocorrelation in data will adversely affect the performance of a Shewhart chart (see **Autocorrelation Function; Autocorrelated Data**). In the process industries, autocorrelation is typically positive due to inertial elements, resulting in false alarms. If, however, the autocorrelation is negative, the Shewhart limits will be too wide, and significant process shifts will not be detected.

The key to dealing with this autocorrelation is to directly model it with **time series** analysis and then use that model to remove the autocorrelation from the data. A Shewhart control chart can then be applied to the residual prediction errors in order to detect significant process disturbances. The exponentially weighted moving average (EWMA); see **Exponentially Weighted Moving Average (EWMA)**; **Exponentially Weighted Moving Average (EWMA) Control Chart** chart can be used as a one-step-ahead

predictor, so it is a valid model to consider when dealing with autocorrelation. The EWMA is an important member of the time series models identified by Box and Jenkins as autoregressive integrated moving average (ARIMA) models (see [6, 7]; **Large Autoregressive Integrated Moving Average (ARIMA) Modeling**). It is equivalent to an ARIMA(0, 1, 1). Practically, the EWMA is a good prediction model in the majority of cases. If, however, the autocorrelation is negative or the mean is drifting too quickly, a different model will be required. Other ARIMA models should be considered using computer software.

Design and Analysis of Experiments

Computer software greatly simplifies the design and analysis of experiments, but the use of computer-generated designs is especially important in situations where standard factorial or **fractional factorial** cannot be utilized due to factor constraints. D-optimal designs are the most widely used type of computer-generated designs (see **Optimal Design**).

Many designed experiments also require the simultaneous optimization of multiple responses. Typically, an algorithm is used to maximize a desirability function to find the optimum settings of the X factors. However, as the number of factors or responses increases, conventional optimization algorithms tend to locate a local optimum rather than the global optimum.

Recent developments using genetic algorithms bring a new level of design efficiency that works well even with highly constrained factor regions [8]. Genetic algorithms are also very useful in multiple response optimization for locating the global optimum [9]. This translates into more effective experiments run at a lower cost.

JOHN NOGUERA

Data Mining in Quality and Reliability

Background

Few applications of data mining in quality control, quality assurance, or reliability have been published. In April 1996, in *Quality Progress*, Bert Gunter [1] urged caution in the use of data mining based on the extraordinary amount of hype and false promises it was receiving at the time. Focusing on formal experimental design, his article validated the methodologies used in data mining but contrasted them with the ability to formulate and test hypotheses using standard statistical techniques.

Since the publication of this article, it has become much easier to collect and store large amounts of data. Volumes of data may be collected from continuous operation of machines, from web logs and web transactions, and from healthcare studies involving claims data or long-term evaluations of patients. In addition to this, computing power has increased exponentially, making it possible to process millions of data points easily and quickly. Articles discussing these and other database aspects of data mining include **Processing of Survey Data, Statistics in Data and Information Quality, and Data Mining, Evaluation Techniques in**. Standard statistical techniques may not be meaningful when applied to these enormous databases because all comparisons with the mean will be significant and standard statistical measures of variability will be extremely small (*see Descriptive Statistics*). Data mining is fundamentally different from statistical analysis but in some ways it resembles some **exploratory data analysis** techniques [2]. However, it strives to identify patterns within the data using both continuous and categorical data. The results of data mining are often measured by “interestingness”. This can be defined as finding patterns in the data that are not obvious. In relating this to examining quality, this may mean finding previously unidentified anomalies in the data that may contribute to a process being out of control or previously undiscovered bias or **outliers** in the data.

In 1998, in *Technometrics*, Gerry Hahn and Roger Hoerl [3] examined the changing role of statistics (and statisticians) in business, citing enormous databases and finding proactive statistical process

control (SPC) methods for understanding and analyzing the questions and issues that arise with these data. While there has been enormous growth in the size of databases, research articles using data mining methods for quality have not followed.

This article uses a large healthcare trial in which data mining techniques provided the only way to analyze the dataset for **data quality**, to identify anomalies and nonrandomness, and to examine lack of homogeneity.

Overview of Supervised and Unsupervised Data Mining Techniques

Data mining techniques can be separated into two primary areas: those using supervised algorithms and those using unsupervised algorithms. Supervised data mining techniques most closely resemble standard statistical modeling because they are predictive with an output variable being predicted by many other variables. Unsupervised data mining techniques are associative. They are used to examine relationships between variables and may or may not have a direction specified with antecedent and consequent variables identified. Apart from traditional correlations between variables, these associations may include variables and data of any type, nominal (including dummy variables), ordinal, interval, and ratio.

Supervised Techniques

These include classification analyses and decision trees (C5.0, classification and regression trees (CaRT), and chi-squared automatic interaction detector (CHAID)), logistic regression, and neural nets. CaRT decision trees and neural nets are discussed at length in **Classification and Regression Tree Methods, Neural Networks: Construction and Evaluation and Neural Networks in Statistical Process Control**.

Decision trees using data mining algorithms differ from their statistical counterparts in that they do not have prespecified splits or branches. Using the C5.0 classification algorithm, the branch splitting is data driven and the split giving the most separation between two (or more) groups is the variable identified first. The tree may be asymmetrical in that variable splits for one branch of the tree may not appear in another branch or may appear at a different level.

This technique will combine groups of a categorical variable if they are so similar that additional branches are unnecessary. This algorithm, the most common in data mining software, uses maximum gain as its criteria for splitting into a new set of branches. It chooses the variable that has the largest expected information gain. In other words, it selects the attribute that will result in the smallest expected size of the subtrees. The definition of information gain is as follows: consider the quantity $\text{Gain}(X, T)$ defined as $\text{Gain}(X, T) = \text{Info}(T) - \text{Info}(X, T)$. This represents the difference between information needed to identify an element of T and information needed to identify an element of T after the value of attribute X has been obtained, that is, this is the gain in information due to attribute X . CaRT identifies the best classification using logistic regression techniques, and CHAID bases its algorithm on the χ^2 distribution. Most tree algorithms require that the target (dependent) variable be categorical. Such algorithms require that continuous variables be binned for use with regression. The most notable exception to this is CaRT, which handles continuous target variables directly.

Neural nets and logistic regression models are similar to each other and resemble least-squares regression in the interpretation of output. Logistic regression models provide coefficients, goodness-of-fit tests, and significance levels while neural nets list the percentage contribution of each variable to the targeted outcome variables. Neural nets are a “black box” algorithm and the output gives no indication of the form of the resulting model.

Unsupervised Techniques

If a predictive model is the desired outcome of an experiment, unsupervised data mining may be the first step in understanding the associations in the data. Primary unsupervised data mining techniques include association webs and Kohonen maps, *a priori* and generalized rule induction (GRI) methods, and cluster and anomaly analyses. Association webs are used solely with categorical data and provide the strength of the links between variables (either as a percentage or an absolute number). The darkest and widest lines connecting two variables (or categories within variables) provide evidence of stronger links and interactions. These webs are often used to construct interactions between variables prior to a supervised model. Kohonen maps provide a multivariate method

for examining associations. The Kohonen algorithm is a type of neural net that creates two (or more) variables from all the variables available and plots important characteristics of the dataset on these two (or more) dimensions. If patterns exist, the data are often clustered in different areas of the plot.

Cluster analysis is a standard multivariate statistical technique that is also a commonly used tool in data mining. It differs from its statistical counterpart by not providing tests between clusters and by allowing the inclusion of any type of variable into the analysis. Cluster analysis can be subdivided into three common data mining algorithms: two-step cluster analysis, where the algorithm will find the best number of clusters; *k*-means cluster analysis, where the number of clusters must be prespecified, and anomaly analyses, where the data points that are furthest from the mean of the cluster are identified as not fitting into any cluster easily. Anomaly analysis is of immediate use and application in quality control for processes with large amounts of data and many factors. It can identify multivariate outliers for error detection and analysis. Of all the data mining techniques outlined, anomaly detection has the easiest and immediate application in the field of quality.

Two other association techniques are *a priori* analysis and GRI. These two techniques are similar in their goal of creating rules in the data with antecedent variables and consequent variables. Often used in analyses of heterogeneous objects such as market baskets, the formation of these rules is based on the support the rule has in the data and the confidence level within the support for the rule. Support is defined as the probability of finding all the variables of interest in the dataset or the proportion of the data containing all the values of these variables. Confidence is defined as the conditional probability of finding one value of one of the variables given that the other variables are also contained. For example, in a sample of defective items, three characteristics of defects, called *A*, *B*, and *C*, exist in 30% of the sample. This is the support for the three characteristics. However, further analysis might show that given that defects *A* and *B* exist, defect *C* exists in 80% of these items. Both algorithms require that the defect of interest, in this case the consequent defect *C*, be categorical. In *a priori* analyses, the antecedents, *A* and *B* must also be categorical. In a GRI the antecedents may be of any type.

Time Series Data Mining

Many assessments of quality have a temporal component and this can be included in a data mining analysis using either supervised or unsupervised methods. In supervised models such as neural nets or logistic regression, time can be included as a variable in the model. In unsupervised models, a transaction ID may be used instead of a variable for time. For example, if a production process on multiple machines is examined over an arbitrary or fixed time interval, the machine ID may be used to gauge the quality of items produced by that machine over time. Similarly, multiple purchases over time can be tracked by customer reward card numbers to examine patterns of behavior and store efficiency.

Example: Using Data Mining for Auditing Data Quality

A multistate study was designed to compare the care given to patients by fee-for-service (FFS) providers with that given by managed care (MC) providers. The study was carried out in multiple sites within a state and over multiple states. Patients entered the study as FFS patients and data was collected on services provided for 1 year prior to being randomized to continue to receive care through a FFS provider or being switched to an MC provider for care. After **randomization**, patients were followed for an additional 24 months. The service provided and the outcomes of care were tracked through insurance claims data. The final database contained over 60 000 patients and 4 million claims. With a database of this size, traditional statistical analyses are not useful and examining patterns of care using data mining was implemented.

Analysis of Homogeneity at Baseline

Homogeneity was initially assumed for patient characteristics across treatment conditions because of strict randomization and, because treatment was standardized by government protocols, patient care within treatment conditions as well as within and between states was initially assumed to be homogenous. However, prior to the analysis of outcomes of the study, these assumptions were investigated. With the enormous number of patients in the database, any strict

statistical comparison of baseline demographics and diagnostic data would be statistically significant so several data mining techniques were used. A subset of data from three states is used for illustration.

Several Analyses to Evaluate the Quality of the Study Randomization.

1. To examine the randomization over all sites, a web and a Kohonen map were constructed.^a The web, shown in Figure 1, plots the strongest connections between baseline variables (gender, race, and diagnosis) and the randomization factor (FFS or MC). The assumption prior to examining the web was that the randomization was balanced with respect to these variables, but examining Figure 1 shows that more women and nonwhites were randomized to the MC providers. Men and whites did not show up with strong links to either MC or FFS provider, this indicates balance with respect to those variables. The Kohonen map in Figure 2 confirms that there are strong patterns in the database separating into racial and gender groups. Table 1 gives a summary of the strong links found in these analyses.
2. Another useful tool for identifying unusual patterns is an anomaly cluster analysis. Figure 3 identifies four clusters within the data and many unusual patients within each cluster. A common pattern of gender and race exists in several of

Figure 1 Web of strong links between managed care, nonwhite, and female

Figure 2 Kohonen map examining race and gender

Table 1 Summary of strong links between variables

Strong Links	Field 1	Field 2
Links		
14 933	Gender = "female"	Type of care = "MC"
13 517	Race = "nonwhite"	Type of care = "MC"
12 036	Gender = "female"	Race = "nonwhite"
8919	Diagnosis = "dual diagnosis"	Type of care = "MC"
7621	Gender = "female"	Diagnosis = "dual diagnosis"
6808	Race = "nonwhite"	Diagnosis = "dual diagnosis"
6595	Diagnosis = "psychosis"	Type of care = "MC"
6128	Diagnosis = "affective"	Type of care = "MC"
5563	Gender = "female"	Diagnosis = "psychosis"
5536	Race = "nonwhite"	Diagnosis = "psychosis"
5413	Gender = "female"	Diagnosis = "affective"
5071	Diagnosis = "other dsm"	Type of care = "MC"
4850	Gender = "female"	Diagnosis = "other dsm"
4689	Race = "nonwhite"	Diagnosis = "affective"
4155	Race = "nonwhite"	Diagnosis = "other dsm"

the clusters confirming the web and Kohonen maps.

- After identifying that the study randomization was biased, a state-by-state and site-by-site analysis was undertaken using standard statistical analysis^b comparing gender balance and racial balance by site and type of care. Figure 4 gives an example of the site analysis showing a plot of

females for three states where it is clear that State 3 had significantly unbalanced randomization of females into MC ($p < 0.001$).

- Solution to this imbalance included modeling the data with baseline characteristics as covariates, as opposed to pooling the study data and doing sensitivity analyses with the imbalanced site excluded. Without the initial association

Figure 3 Anomaly cluster analysis

Figure 4 Females by state by type of care

analysis, this imbalance might not have been identified.

Examination of Patterns of within and between State and Site Differences

Prior to analyzing patterns in types of claims comparing FFS and MC, it was important to examine whether there were unusual patterns of service between states that could not be explained by normal variability of service. All sites followed a government-developed protocol for delivery of service that should have minimized the variability of service delivery. With over 4 million claims and 60,000 patients, using an analysis of variance approach (the standard statistical methodology for examining site differences) would have shown every comparison to be significantly different between states. Here again, a subset of three states was used.

Procedure to Evaluate the Service Heterogeneity over States.

1. A CaRT was utilized to develop a tree model to discriminate between states. This is a classification model that uses logistic regression to separate into branches. The branches are defined in the model to be binary splits of the data and each branch shows the split by the outcome variable (the state in these models). Figure 5 shows the tree with outpatient therapy imbalanced by state. While State 3 has more patients, it has over 90% of the claims for outpatient therapy.
2. After identifying that State 3 had a disproportionate number of claims for outpatient therapy, a state-by-state analysis was undertaken for each service separately using standard statistical analysis comparing type of care by type of service by state. Figure 6 gives an example of the state analysis showing a plot of outpatient therapy service claims for three states where it is clear that State 3 had significantly more claims in FFS and MC, but particularly more so in MC ($p < 0.00001$).
3. Upon further investigation of State 3, it was found that two sites within State 3 were responsible for these excess claims, and were submitting duplicate and fraudulent Medicare claims.

Figure 5 CaRT interactive tree showing State 3 with disproportionate claims for outpatient therapy

Figure 6 Excess claims filed by state by type of claim

Summary

Data mining may be the first line of analysis when a database is very large. Designed to identify unusual patterns, it can be used well for finding departures from homogeneity or identifying outliers requiring further exploration. As illustrated in the example above, the results can lead to surprising conclusions.

End Notes

- All data mining analyses were done in Clementine 10.1 from SPSS Inc., Chicago, Illinois.
- All statistical analyses were done in SPSS version 14.0 for Windows.

Density and Failure Rate Estimation

Introduction

In reliability and quality control, density and failure rate (or hazard) functions provide valuable information about the distribution of failure times. Shapes of density and failure rate functions may contain characteristics of interest, such as number, location, and features of modes; monotone increasing or decreasing features; and information about tail behavior. One can distinguish two basic statistical approaches for estimating density and failure rate functions, given a sample of observed failure times: parametric and nonparametric.

In the parametric approach to **estimation** and model fitting, the starting point is to assume an underlying parametric model which specifies a distribution of the observed data, typically a lifetime distribution such as Weibull, Gompertz, or gamma. The parameters are then usually identified by maximum likelihood (*see* **Maximum Likelihood**) or a Bayesian method (*see* **Bayesian Reliability Analysis**).

The parameters determine the distribution uniquely, and thus also density and failure rate functions. The main advantage of the parametric approach, which we will not discuss further in this article, is ease of inference, efficiency, and the absence of a **bias** issue, provided that the underlying parametric model assumption is correct; the latter assumption requires a leap of faith in many applied situations. In fact the main disadvantage of parametric models is that indeed the underlying distribution must be fully known: under model misspecification, parametric approaches result in inconsistent estimators, and the associated asymptotic bias leads to invalid inference.

The nonparametric or smoothing approach is considerably more flexible. Nothing more than basic smoothness assumptions on the distribution function are needed. Therefore this approach “lets the data speak for themselves”, without imposing hard-to-verify model assumptions. It is thus particularly well suited for exploratory data analysis, and is also used for final analysis in those situations where density functions or failure rates cannot be clearly specified, or when doubts remain about these specifications.

The main disadvantages of nonparametric smoothing methods are that inference, often through confidence bands, is not straightforward, and that a smoothing parameter needs to be specified. While these methods are asymptotically unbiased under weak assumptions, their application often requires one to be aware of and deal with a finite bias issue.

As was already pointed out in Rosenblatt’s seminal 1956 paper, nonparametric density estimates are finitely biased [1]. In parametric approaches, potential bias issues are mostly addressed indirectly through goodness-of-fit checking, and if such bias is detected, the model needs to be changed, often through a data transformation. One can argue that the explicit nature of the bias issue in nonparametric smoothing approaches is actually an advantage, as this bias is small, can be adjusted for, and disappears asymptotically. Although parametric models rarely fit exactly, the resulting bias is often not adequately addressed. For the multivariate case, the so-called curse of dimensionality leads to rapidly declining convergence rates of nonparametric methods as the dimensions increase. This has led to the development of various dimension reduction and semiparametric approaches [2]. In such models, smooth densities are included for low-dimensional parts of the model, while dimension reduction is achieved through a parametric component.

Nonparametric Density Estimation

We begin with basic definitions and relations. Denoting a nonnegative random variable that represents failure time or lifetime by T , the survival function is

$$\bar{F}(t) = P(T \geq t), \quad t \geq 0 \quad (1)$$

where $\bar{F}(t) = 1 - F(t)$ is the cumulative distribution function of the lifetime distribution. If this function is differentiable, we may define the **probability density function** as

$$f(t) = \lim_{\Delta \rightarrow 0} \frac{1}{\Delta} P(t \leq T < t + \Delta), \quad t \geq 0 \quad (2)$$

and the hazard or failure rate function as

$$\lambda(t) = \lim_{\Delta \rightarrow 0} \frac{1}{\Delta} P(t + \Delta > T \geq t | T \geq t) = \frac{f(t)}{\bar{F}(t)}$$

2 Density and Failure Rate Estimation

(3)

The importance of the failure rate λ in reliability is due to its interpretation as a risk function. Specifically, $\lambda(t)$ quantifies imminent risk of failure at time t , and is related with the survival function $\bar{F}$ through

$$\begin{aligned}\bar{F}(t) &= \exp \left[- \int_0^t \lambda(u) du \right], \\ \lambda(t) &= - \frac{d}{dt} \log [\bar{F}(t)]\end{aligned}\quad (4)$$

Both density and failure rate functions characterize the failure time distribution. The transformations from density to failure rate and *vice versa* are as follows [3]:

$$\begin{aligned}\lambda(t) &= \frac{f(t)}{1 - \int_0^t f(u) du}, \\ f(t) &= \lambda(t) \exp \left[- \int_0^t \lambda(u) du \right]\end{aligned}\quad (5)$$

Basic properties of densities f , failure rates λ , and the cumulative hazard rate $\Lambda(t) = \int_0^t \lambda(s) ds$ are

$$\begin{aligned}f &\geq 0, \quad \int f(u) du = 1, \\ \lambda &\geq 0, \quad \Lambda(t) \rightarrow \infty \text{ as } t \rightarrow \infty\end{aligned}\quad (6)$$

Turning to the nonparametric estimation of these functions, historically the first density estimate is the histogram which is still much in use. Other density estimates can be viewed as extensions of the histogram. Besides being of interest in assessing shape, especially symmetry, multimodality, and tails of a distribution, density estimates are also useful for a variety of specific statistical tasks, such as the smoothed **bootstrap**, the construction of **confidence intervals** of estimated **quantiles**, e.g., the median, for obtaining Fisher information, or for classification, as centers of clusters may correspond to modes in a density estimate and often multimodality in a density is of interest.

We proceed with a formal definition of the two most common nonparametric density estimates, histograms and kernel estimators, starting with a sample $X_1, \dots, X_n$ of independent and identically distributed (i.i.d.) univariate data whose distribution has density

f . To construct a *histogram*, one divides the range of the data into m bins $B_1, B_2, \dots, B_m$, which are usually chosen to be of the same size but can also vary in size, and then obtains the histogram

$$\begin{aligned}\hat{f}_{\text{hist}}(x) \\ = \frac{1}{n} \sum_{j=1}^m \frac{(\text{number of data } X_i \text{ falling into bin } B_j)}{(\text{size of bin } B_j)}\end{aligned}\quad (7)$$

The smoothing parameters are the leftmost endpoint of the first bin (which does not matter much) and the bin size (which matters). Advantages of the histogram are that it is straightforward to construct and understand, and that it is ubiquitous in statistical packages. Disadvantages are the relatively slow convergence with increasing sample size and the discontinuity of these density estimates, which is at variance with the assumed smoothness of the underlying density.

Both disadvantages are remedied by kernel density estimates. These can be conceived as generalizations of sliding histograms, or as a convolution of the empirical distribution function with a smooth kernel function,

$$\begin{aligned}\hat{f}_K(x) &= \frac{1}{nh} \sum_{i=1}^n K \left(\frac{x - X_i}{h} \right) \\ &= \int \frac{1}{h} K \left(\frac{x - u}{h} \right) dF_n(u)\end{aligned}\quad (8)$$

where $h = h(n)$ is a sequence of bandwidths or smoothing parameters, K is a kernel function, and dF_n is the empirical measure, which assigns mass $1/n$ to every observation point X_i . The kernel method for density estimation was introduced by Fix and Hodges [4], Rosenblatt [1], and Parzen [5]. The best source for basic asymptotic and finite sample properties of kernel density estimators remains the monograph of Silverman [6], along with the monograph by Scott [7] for the multivariate case. For general background on kernel methods, see [8].

Typical basic results are rates of convergence of (integrated) mean squared error (IMSE or MSE) and asymptotic distributions. Optimal rates of MSE convergence are achieved by kernel estimators and are slower than the parametric rate of n^{-1} , due to the nonparametric nature of these estimators. For example, if the underlying density is twice continuously differentiable, the sequence of bandwidths $h = h(n)$

satisfies $h \rightarrow 0$ and $nh \rightarrow \infty$ as $n \rightarrow \infty$, and the kernel satisfies $\int K(x) dx = 1$, $\int K(x)x dx = 0$, and some other basic regularity conditions, then using an IMSE-minimizing bandwidth sequence, the IMSE of the kernel density estimator satisfies

$$\begin{aligned} & \int E (\hat{f}_K(x) - f(x))^2 dx \\ &= n^{-4/5} \left[\left(\int f^{(2)}(x)^2 dx \right) \left\{ \left(\int K(u)u^2 du \right) \right. \right. \\ & \quad \left. \left. \times \left(\int K(u)^2 du \right)^2 \right\} \right]^{1/5} + o(n^{-4/5}) \end{aligned} \quad (9)$$

The IMSE rate of convergence of $n^{-4/5}$ is better than the corresponding rate $n^{-2/3}$ for histograms.

One of the main issues for nonparametric smoothing methods is the choice of the smoothing parameter. There exists a considerable literature on bandwidth selection for kernel density estimation (*cf.* the overview in Sheather [9] and also in [10]); for the related problem of kernel choice see [11]. Smoothing parameters need to be chosen such that both undersmoothing, associated with large variance and small bias, and oversmoothing, associated with large bias and small variance, are avoided and instead, the optimal trade-off between variance and bias is found.

Visual choice remains a common selection method; often done interactively by increasing a clearly undersmoothing bandwidth, until the first sign of oversmoothing appears. When comparing to a histogram with small bin width, “residuals” defined by differences between histogram values and corresponding fitted density values at bin midpoints start to show signs of lack of fit when oversmoothing sets in. Popular automatic methods are cross-validation and plug-in methods. The main obstacle for data-adaptive selection methods is that the theoretically optimal bandwidth depends on the unknown density, as seen for a special case in equation (3). The best currently known methods are plug-in methods, where these unknown quantities are estimated and substituted. Preliminary estimates of the unknown quantities include estimates of density derivatives. These preliminary estimates are also nonparametric, and their smoothing bandwidths are obtained in turn by estimating further unknown density-dependent

quantities with pre-preliminary estimators; the bandwidths of the preestimators ultimately are obtained by making parametric (usually Gaussian) assumptions on the unknown densities.

A special problem for estimating densities with compact support are boundary effects that arise when estimating at or near the endpoints. These can cause problems when a structure of interest occurs near such endpoints. One remedy is the use of special boundary adjustments such as boundary kernels as described in [12]. The basic density estimation schemes can be generalized to cover the estimation of multivariate densities, of density derivatives, and of densities obtained from incomplete or length-biased data. Other variants that have been studied include density estimation combined with data transformations, density estimation with locally varying bandwidths, density estimation under shape constraints such as unimodality, and the estimation of functionals of densities and of conditional densities. For reliability, applications of density estimation in renewal theory are of particular interest [13–15].

Alternative density estimation schemes include orthogonal series estimators, penalized maximum-likelihood estimators, and various estimation schemes based on the smoothing of histograms. Typically the histograms subjected to a subsequent smoothing step will be strongly undersmoothed and are constructed with very small bins, so that many of the bins remain empty. The midpoints of the m bins x_j and corresponding heights of the histogram bars y_j constitute a scatterplot $\{(x_j, y_j), j = 1, \dots, m\}$ to which a nonparametric regression-type smoother is applied. This smoother can be based on smoothing **splines** or B splines. An easy-to-implement and explicit smoothing scheme that also automatically adjusts for boundary effects is provided by local linear fitting [16], where one uses a nonnegative kernel function K and a bandwidth h as defined above to obtain the minimizers of

$$\sum_{j=1}^m K\left(\frac{t - x_j}{h}\right) [y_j - \{a_0 + a_1(t - x_j)\}]^2 \quad (10)$$

w.r.t. a_0, a_1 . Then the density estimate is $\hat{f}_L(t) = \hat{a}_0(t)$, the estimated intercept at each t . The problem of adjusting density estimates that do not necessarily display the properties of a density (nonnegativity and integrating to 1) have been well studied (e.g., in [17]).

Failure Rate Estimation

The failure rate $\lambda(t) dt$ represents the instantaneous chance that an equipment fails in the interval $(t, t + dt)$, given that it works at age t . The hazard or failure rate function $\lambda(t)$ then provides a trajectory of risk. Nonparametric failure rate estimation often involves the smoothing of an initial failure rate estimate. Available data may be either grouped, in which case failures are reported aggregated over time intervals, or may consist of continuously observed failure times. For continuous data, the analogy of the relationships $F(t) = \int_0^t f(x) dx$ between distribution function F and density f , and $\Lambda(t) = \int_0^t \lambda(x) dx$ between cumulative hazard rate Λ and failure rate function λ motivates kernel estimates for λ and demonstrates the closeness of failure rate and density estimation problems.

One complication that one often faces with lifetime data is that available data are incomplete, due to failure to follow-up or termination of a study. The most commonly encountered type of incompleteness is random censoring [3]. In random censoring, we assume there is a censoring random variable C_i such that observed data are $X_i = \min(T_i, C_i)$, the minimum of the lifetime T_i and censoring time C_i of the i th individual. One also observes the censoring indicator $\delta_i = 1_{\{X_i = T_i\}}$, which is one if the actual lifetime is observed and zero otherwise. Let $(X_{(i)}, \delta_{[i]})$, $i = 1, 2, \dots, n$, be the ordered sample with respect to lifetimes X_i , i.e., $X_{(1)} \leq X_{(2)} \leq \dots \leq X_{(n)}$, with $\delta_{[i]}$ the concomitant censoring indicator of $X_{(i)}$.

Hazard estimators can then be obtained by smoothing the increments of the Nelson–Aalen estimator [18]

$$\Lambda_n(t) = \sum_{i=1}^n \frac{\delta_{[i]} 1_{\{X_{(i)} \leq t\}}}{n - i + 1} \quad (11)$$

of the cumulative hazard function $\Lambda(t)$ (if there are no tied observations). Using the kernel method, we arrive at the kernel failure rate function estimator

$$\hat{\lambda}(t) = \sum_{i=1}^n \frac{1}{h} K\left(\frac{t - X_{(i)}}{h}\right) \frac{\delta_{[i]}}{n - i + 1} \quad (12)$$

if there are no tied observations. Bias and variance issues can be similarly analyzed as for density estimates.

Boundary-corrected kernel estimators and practical bandwidth choices have been considered in [12]

and bootstrap confidence intervals in [19]. For the closely related problem of **intensity function** estimation with applications in reliability, see [20, 21]. Other smoothing methods that have been considered include spline fitting with penalized likelihood [22].

For grouped data, one problem is the aggregation, which can pose problems for nonparametric failure rate estimation. The reason is that the failure rate is defined as a limit. However, nonparametric estimation of failure rates works reasonably well when based on a combination of smoothing central rates of failure and a suitable transformation [23]. Assume the data are aggregated into intervals or bins of length Δ , the number of failures is d_i in the i th such interval, and the number of items in working order and at risk of failure is n_i at the beginning and n_{i+1} at the end of the i th such interval. Then the central failure rate for the i th interval is defined as $q_{c_i} = 2d_i/(n_i + n_{i+1})$.

Denoting the midpoint of the i th interval or bin by t_i , the smoothed central failure rate $\hat{q}_{c_i}$ is obtained by smoothing the data $\{t_i, q_{c_i}\}$, for example with weighted least-squares smoothers as in equation (10) or with spline smoothers (*see Splines and other Metamodels in Reliability Analysis*). Then a recommended transformation estimate to obtain the (continuous) hazard or failure rate is [24]

$$\psi(\hat{q}_c(t)) = \frac{1}{\Delta} \log \frac{2 + \Delta \hat{q}_c(t)}{2 - \Delta \hat{q}_c(t)} \quad (13)$$

It can be shown that this smoothing and transformation approach reduces the unavoidable discretization bias.

To avoid discretization biases it is preferable to record continuous failure times if either the density or the failure rate of the lifetime distribution is of interest. Extensions of the methods discussed here are available for the case where one is interested in determining which features of products influence lifetime. This leads to semiparametric hazard regression models, such as the Cox model or the accelerated failure time model (see [3]). Such models combine a baseline hazard function as a nonparametric component with a parametric part that models the influence of the covariates.

In reliability applications shape-restricted failure rates sometimes play a role. A common assumption is increasing failure rate (IFR). Kernel estimators can be monotonized in various ways, from applying the simple pool adjacent violators algorithm (PAVA) to more

sophisticated schemes [25]. Other shape restrictions such as bathtub shape can also be implemented [21].

Monte Carlo Method

In the world of simulation, a **Monte Carlo** method is a means of solving a deterministic problem using random numbers. The origin of the term comes from a casino in Monaco; the method requires many repetitions of a random process, which is similar to that which occurs in a casino. The term became popular with those using such methods in the 1940s and 1950s, notably Nicholas Metropolis and Stanislaw Ulam [1], among others.

The ideas underpinning the method had been recognized well in advance of this time. For example, the case of Buffon's needle is a classic example of the use of random experiments in order to estimate a deterministic quantity. Since the time of Metropolis and Ulam, the methods have been of direct interest to the statistical community; [2] indeed even in the 1980s it was recognized that such simulation methods were useful, in an age when computers were "powerful" and mathematicians were scarce [3]. Of course, computer power has continued to improve substantially over the past two decades; and such methods are increasingly common [4, 5].

In order to describe the method in more detail, we look at a simple example. Following this, some technical considerations will be highlighted, together with a discussion of how the method can be applied to a more complex situation. We then note how the method relates to that of ensembles. Finally we examine some particular methods.

A Simple Example

In order to demonstrate the idea, we solve a very simple problem using such a method.

Consider the question "What is the area of a circle inscribed within the unit square?" Graphically, the region of interest is highlighted in Figure 1. The total area from which the simulation will be carried out is the white square, with the circle shaded in black.

Figure 1 Pictorial representation of circle in unit square

In order to answer this, we consider an "experiment" in which there is an element of chance. The idea is that we "throw" darts uniformly at the unit square. For each of the darts, we then determine whether or not it has fallen within the shaded circle. If it has, then we count it as a success. Otherwise we think of it as a failure. The relative area of the circle to the square is then approximated by the proportion of successes to the total number of throws.

Thus, the formal algorithm, noting that the circle is centered at (0.5,0.5) and has radius 0.5 proceeds as follows;

- Set $s = 0$.
- Repeat N times
 - Generate $x \sim U[0, 1]$.
 - Generate $y \sim U[0, 1]$.
 - If $(x - 0.5)^2 + (y - 0.5)^2 < (0.5)^2$ then $s = s + 1$.

The area is then estimated as the fraction, s divided by the total number of simulations, N .

Characteristics of the Algorithm

We note that the method has the following characteristics;

2 Monte Carlo Methods, Univariate and Multivariate

- The method requires a source of random numbers (the $U[0,1]$).
- There are many repetitions of a simple process (the throwing of the darts).
- The answer that is obtained is an approximation to that which is required.

Indeed, the first of these conditions is not strictly true; it is sufficient that the source of “random” numbers be pseudorandom – the key requirement is that there is no relationship between what is being estimated and the source we are using.

We (the persons carrying out the experiment) are in charge of the number of such repetitions that we obtain. In practice, since computers are typically used to carry out this simulation process, it is “cheap” to carry out each repetition. Thus the main barrier to the size of the collection of realizations is the time available and the processor power and memory storage available to us.

Even though the answer we obtain is only an approximation to that which is required, we can quantify the size of the error. This is termed *Monte Carlo error*, and by varying the number of simulations we can make this arbitrarily small. Since this last point is important, a little more detail is provided below.

Monte Carlo Error

Where independent simulations have been obtained it is possible to quantify the size of the Monte Carlo error by the following considerations;

Consider the example above. Formally we describe the probability of the “dart” being in the unit square by a parameter, p . The throwing of each “dart” is then a Bernoulli trial; that is the result of the throw is 1 (i.e., success – landing inside the circle) with probability p and 0 (i.e., failure – landing outside the circle) with probability $1 - p$. We denote this random variable as X .

If we consider a large collection (n) of independent realizations of such random variables, we end up with a collection $\{x_1, x_2, \dots, x_n\}$ of zeroes or ones. The sum of these n realizations may be denoted S_n . It is clear that S_n is then a random variable which has a binomial distribution with parameters (n, p) . In this case, the expectation and variance of the random variable may readily be obtained as np and $np(1 - p)$ respectively.

Thus, if we consider the derived random variable $p_{\text{est}}(n)$, given by;

$$p_{\text{est}}(n) = \frac{S_n}{n} \quad (1)$$

then this has expected value p and variance $\frac{p(1-p)}{n}$. Thus, as n gets large, we are increasingly confident that $p_{\text{est}}(n)$ is close to p .

Returning to the question, we wish to estimate the relative area of the circle. By considering the setup, we note that this relative area is exactly the probability of a uniformly thrown “dart” hitting the circle. Thus, it is equal to p , and our task is to estimate p to a given degree of accuracy.

Using the central limit theorem, we note that as n increases there is approximately 95% probability of $p_{\text{est}}(n)$ being contained in a ball that stretches 2 standard deviations from p , and 99.9% probability of being in a ball that extends about 3 standard deviations from p . Thus, since we can construct $p_{\text{est}}(n)$ by “experiment” we have a method of estimating p .

By observing this fact, and noticing that we can increase n to be arbitrarily large, we note that we can obtain estimates of p that are accurate to a given accuracy.

The residual uncertainty that exists because $p_{\text{est}}(n)$ only *approximates* p may be quantified in terms of the standard deviation of the estimator considered as a random variable. This, as outlined above is $\sqrt{\frac{p(1-p)}{n}}$.

It is this residual uncertainty that is termed the *Monte Carlo error*. In any situation where a Monte Carlo method is used, it is essential that some reference be made to this quantity – either explicitly or even just to note that the relative size of the Monte Carlo error is “small”.

In general, the Monte Carlo error may be estimated using the standard deviation of the generated sequence; in the example above, this would be the standard deviation of the sequence of realizations of the Bernoulli random variables.

An Extension of the Example

The example that has been used is a particularly simple one. Indeed, it has the status of a “toy” and is used simply to illustrate the method.

However, we may readily consider situations that are of real practical interest to us.

Consider a system, S , which takes a number of inputs; we may think of the system as being described by $S(I_1, I_2, \dots, I_m; 0)$ at time 0. We may be interested in an indicator function, R , which takes the value 1 if the system is functioning and the value 0 if it has failed.

Thus, $R(S(I_1, I_2, \dots, I_m; 0)) = 1$ tells us that the system with the given inputs was functioning initially; and if $R(S(I_1, I_2, \dots, I_m; t_1)) = 1$ and the quantity at a later time is given by $R(S(I_1, I_2, \dots, I_m; t_2)) = 0$ we know that the system was functioning at t_1 but had failed by t_2 .

Now, in general, it is possible that the inputs are uncertain – that is that $I_1, I_2, \dots, I_m$ may be thought of as realizations of a multivariate random variable. It is likely that it is possible to quantify our uncertainty about the inputs in the form of a probability distribution – for example if I_1 is temperature, it may be possible to say it can be thought of as normally distributed centered at room temperature.

Regardless of the fact that the inputs are random variables, we are still concerned with some derived quantity – for example the probability that the system is operational at 100h, say. This may be obtained by integrating across the probability distribution for the multivariate inputs, and thus calculating the expectation of $R(S(I_1, I_2, \dots, I_m; 100))$. That is;

$$\begin{aligned} P(R(S(\mathbf{I}; 100))) &= 1 \\ &= E(R(S(\mathbf{I}; 100))) \\ &= \int R(S(\mathbf{I}; 100))f(\mathbf{I}) d\mathbf{I} \quad (2) \end{aligned}$$

In principle, such a calculation is possible. In practice, it is analytically intractable. Where the input space is of high dimension, it is difficult to do this using quadrature or other standard techniques [6].

Thus, a procedure exactly analogous to that used with the random dart above is employed. In this case it runs as follows;

- Repeat N times
 - Generate $\mathbf{I} \sim f(\mathbf{u})$.
 - Evolve the system to 100h.
 - If $R(S(I_1, I_2, \dots, I_m; 100)) = 1$ then $s = s + 1$

The reliability of the system at 100h may then be estimated as $\frac{s}{N}$.

Relationship with Method of Ensembles

A closely related idea is the *method of ensembles*. The notion here is to consider a large number (N) of realizations of the system, where for each of the realizations, a new value of the input parameters is simulated. The resulting collection is then termed an *ensemble* and may be thought of as providing the analyst with realizations of the system in N parallel universes.

This method is commonly used in statistical mechanics, and increasingly so in applications where financial risk is the key consideration.

The analyst then examines these multiple realizations to summarize a key quantity of interest. For example, if we are interested in whether the system has failed by 100h, we examine the ensemble, and the “best guess” at this probability is the fraction of the ensemble for which the system has failed. The method is exactly the same as the Monte Carlo strategy described above, but the way in which we express it is slightly different.

The advantage of expressing our findings in terms of an ensemble is that it is often easier for those not used to the language of probability, marginalization and expectation to think in this fashion. However, the technical considerations are exactly the same; we must concern ourselves with how many members are in the ensemble, and the associated Monte Carlo error.

Particular Examples of Direct Monte Carlo Methods

A number of specific techniques are worthy of exploration. These are briefly outlined in what follows.

Univariate Rejection Method

One method of obtaining deviates from a distribution of known form is the rejection algorithm (sometimes termed the *accept–reject method*). This is a very flexible method, which permits a wide class of probability distributions to be used in Monte Carlo simulation strategies.

4 Monte Carlo Methods, Univariate and Multivariate

The rejection method is a two stage process. Let the probability distribution from which a deviate is required be denoted $f(\cdot)$.

The first step is that a proposed deviate is generated from a proposal probability distribution. This proposal distribution, let us call it $g(\cdot)$ is chosen such that $Mg(x) > f(x)$ for some scalar M and for all x in the domain of interest. Typically the form of $g(\cdot)$ is simple, in that deviates are cheaply available.

The second step involves preferentially accepting proposed deviates from areas of $f(\cdot)$ that have high probability. Explicitly, this is done by accepting a proposed deviate x_{prop} with probability given by;

$$p_{\text{accept}} = \frac{f(x_{\text{prop}})}{Mg(x_{\text{prop}})} \quad (3)$$

If the proposed deviate is not accepted, then a new proposal is generated and the process is repeated.

Thus the algorithm is as follows;

- Generate $x_{\text{prop}} \sim g(x)$.
- Calculate $p_{\text{accept}} = f(x_{\text{prop}})/Mg(x_{\text{prop}})$.
- Generate $u \sim U[0, 1)$.
- If $u < p_{\text{accept}}$ then accept x_{prop} ;
- Else repeat the process.

The choice of $g(\cdot)$ is of critical importance in determining the efficiency of the algorithm. If $Mg(\cdot)$ does not tightly bound $f(\cdot)$, then a large number of deviates will be generated for each one that is accepted. Depending on the cost of sampling from $g(\cdot)$ the algorithm may then be impractical. It can easily be shown that the expected number of times the sampler will have to draw from $g(\cdot)$ for each successfully accepted deviate is given by the scalar, M .

A pictorial representation of the setup is shown in Figure 2.

Multivariate Rejection Method

If the density to be simulated from, $f(\mathbf{x}) = f(x_1, x_2, \dots, x_m)$ which is a multivariate density, then the multivariate version of the algorithm can be used. In order to do this, a multivariate proposal density, $g(\mathbf{x})$ is required, with the same bounding conditions.

Figure 2 Typical situation where rejection is used

In this instance, the scalar, M , typically has to be much bigger, and thus the algorithm is correspondingly less efficient. Thus, in practice, fully multivariate versions of the rejection algorithm are not commonly used.

Importance Sampling

If the cost of generating deviates from the probability distribution of interest is substantial, then it makes sense that we use these as efficiently as possible. One such method, which ensures that we examine the event frequently of interest to us (and consequently reduces the variance of our estimator), is called *importance sampling*.

The idea behind importance sampling is to “adjust” the proposal from which deviates are selected, in order that the Monte Carlo algorithm evaluates the function in the region of interest more frequently. The fact that the proposal density has been adjusted has to subsequently be corrected for; this is done by reweighting the sampled values. An example makes this idea clear.

Consider the use of importance sampling in numerically approximating an integral. The basic principle is as follows:

In wanting to estimate

$$I = \int_{-\infty}^{\infty} g(x)f(x) dx \quad (4)$$

where $f(x)$ is a density function, one could sample n values of x from $f(x)$ and then approximate with

$$\hat{I} = \frac{1}{n} \sum_{i=1}^n g(x_i) \quad (5)$$

Alternatively, m values of x could be sampled from another density $h(x)$ and then I could be estimated using

$$\hat{I} = \frac{1}{m} \sum_{i=1}^m \frac{g(x_i)f(x_i)}{h(x_i)} \quad (6)$$

We have to be careful about how $h(x)$ is chosen so that the estimator is most efficient. It turns out that the most efficient form for $h(x)$, samples from areas where $g(x)$ is large, provided that $f(x)$ is not small [2].

These results extend easily to the multivariate setting. However, effective choice of $h(x)$ is more difficult in the multidimensional setting. Thus, if we have good intuition about what areas of $g(x)$ are of interest, we can exploit them using this technique. The risk, however, is that if we choose poorly we will obtain a much less efficient **estimation** strategy.

Importance sampling can be particularly useful in reliability modeling where we are concerned with rare or extreme events; for example, we may be interested in extreme loadings to a structure, which have high probability of causing damage. Thus, in order to estimate the overall reliability of the structure, we may wish to ensure we simulate many of these “high-impact events”. We then adjust the overall weighting of these according to their true probability, in order to reduce the variability of the estimated survival function in the region where it changes most.

Composition

When a density can be described as a combination of other densities, the method of composition can be used. The simplest example of this is the context in which the density is a mixture distribution.

For example, consider a situation in which we are interested in estimating the probability that a system copes with a random loading event. There may be two possible loading modes, M_1 and M_2 ; and the damage caused may be described by a random variable for each of the possible modes. Thus, for example, if M_1 occurs, the damage may be $D \sim \text{Gamma}(\alpha_1, \beta_1)$ and

if M_2 then $D \sim \text{Gamma}(\alpha_2, \beta_2)$. If we know that the probability of M_1 is p_1 then we can decompose the **pdf** for D into two parts. Specifically;

$$f(D) = p_1 f_1 + p_2 f_2 \quad (7)$$

where f_1 is $\text{Gamma}(\alpha_1, \beta_1)$ and f_2 is $\text{Gamma}(\alpha_2, \beta_2)$.

In order to simulate from such a decomposed distribution, one proceeds using the “broken stick” method as follows;

- Generate $u \sim U[0, 1)$.
- If $u < p_1$ then simulate $D \sim f_1(\cdot)$.
- Else $D \sim f_2(\cdot)$.

Thus, we simulate D from the first component with probability p_1 and from the second with probability p_2 . This can be applied to a mixture with any number of components.

It is noted that some distributions can be very well approximated by mixtures; for example, early implementations yielding deviates from a Gaussian used this method, as outlined in [3].

Box–Muller

An example of a transformation method which efficiently generates from the bivariate **normal distribution** is the Box–Muller transform. The method is a simple transformation method, which takes deviates from the uniform unit square and maps them to the bivariate standard normal. It proceeds as follows;

- Generate $u_1 \sim U[0, 1)$.
- Generate $u_2 \sim U[0, 1)$.
- Let $\theta = 2\pi u_1$.
- Let $R = \sqrt{(-2 \ln(u_2))}$.
- Return (x, y) by transformation of polar (R, θ) .

Then the pair (x, y) are independent standard normal deviates.

The advantage of this method is that it efficiently generates from the required distribution. None of the deviates are “wasted” through rejection. It is easy to implement. Such transformation methods exist for other situations.

Correlated Random Variables

Special concern is needed when the probability distributions of interest to us are correlated. This is

critical when considering the tails of distributions. Such issues arise in the context of reliability applications, and applications in **finance**, such as the probability of ruin.

As an example, consider the simple sum of standard normally distributed random variables, $Y = X_1 + X_2$. If X_1 and X_2 are independent of each other, then a Monte Carlo strategy involving Y could proceed with X_1 and X_2 each being simulated without consideration of the other. However, if there is a positive **correlation** between the random variables – that is large values of X_1 are seen more often in combination with large values of X_2 – then extreme values of Y are more likely than we would observe if we simulated them independently. Similarly, if there is a negative correlation between X_1 and X_2 , we will see extreme values of the combination less frequently than we might naively expect.

In order to ensure that we correctly account for correlation between the random variables, we could simulate X_1 from the marginal distribution and X_2 from the conditional distribution.

Other Extensions and Considerations

What has been described in this section is the Monte Carlo method in general. It should be clear that much of the work involved in implementing a Monte Carlo strategy involves careful consideration of how to simulate from the density of interest to us. This has not been discussed here as it is the subject of other articles.

In particular, the fact that we use pseudorandom numbers, that is a sequence of deviates generated by a computer which “looks” random, is a fact that has been glossed over. The detail of how such a sequence may be generated, some of the pitfalls, and some of the features of the resulting sequence one may wish to check are all the subject of other articles.

If one wishes to sample from a distribution that is not uniform, then one needs a method of doing this. For example, in considering **system reliability** above, one of the parameters was sampled from a normal distribution. For completeness, it is necessary for us to demonstrate that it is in general possible to do this. It is sufficient to note that, given the cumulative distribution function, this is always possible using the inverse transform sampling method. However, more

efficient techniques often exist, as highlighted for particular situations; for example methods for particular parametric distributions are discussed elsewhere [7–10].

Other articles [11, 12], discuss derived techniques such as **Markov chain Monte Carlo**, where the samples that are generated are no longer independent of one another. The extension has substantial advantages in high dimensional problems. However, the consideration of Monte Carlo error is not as straightforward as outlined above. Additionally, care is needed to ensure that the sampler is well behaved.

CATHAL D. WALSH

Discrete-Event Simulation for Reliability Prediction

Introduction

System reliability is achieved by a combination of **component reliability**, system architecture, and maintenance. In some cases, where the structure of a system is simple and component models are well-defined then analytical solution of a systems reliability is often possible, although this often requires a large number of assumptions about specific probability models, and hence rather limits the applicability of the results. As soon as we move away from simple models into real-world situations then the mathematics gets far too difficult to solve analytically and so we need to move to an empirical approach. Discrete-event simulation (DES) is one such empirical approach. DES allows us to build real-world models and attempts to use them to predict what is likely to happen to the reliability of a system in the future. It should be kept in mind that DES produces an output based on probabilities of events occurring and so cannot be absolutely accurate but with enough experimental runs the uncertainty can be reduced sufficiently for the results to be useful. For this reason DES is widely used in reliability work and forms part of the internal workings in many pieces of reliability software.

Simulation

Simulation is primarily about the evaluation of a system design to establish its performance under various operating conditions before we commit capital or other resources. To be able to predict performance requires that we develop some kind of model of the proposed system that is independent of the real system but will anticipate its physical behavior with an acceptable degree of accuracy. All models are, by definition, simplifications and will not reproduce the behavior of the real system exactly. Simulation is about modeling, but this alone is not sufficient; it is also about conducting experiments using the model. We conduct experiments using a model to predict performance but the results are never exact. The way in which the experiments are set up, the

initial conditions, duration of “run”, and the way in which statistics are recorded can have a significant affect on the quality of results. Lastly, we have to be careful about how the results are presented and how they are interpreted. The results of a simulation are, typically, only one piece of evidence used to support the decision-making process. Sometimes the results are neither what are expected nor desired and in such cases, unfortunately, may be ignored, perhaps with “disastrous” consequences. The basic simulation process is to use a model to calculate the system state at some time t and then to move time by a small increment and recalculate the system state. Many more details about simulation in general can be found in [1].

Applying Simulation to Reliability Prediction

The root of computer simulation modeling of system reliability is **Monte Carlo simulation** [2]. Monte Carlo simulation (*see Monte Carlo Methods, Univariate and Multivariate; System Reliability: Monte Carlo Estimation*) randomly creates individual component failures, using information about each component’s failure influences, and monitors the overall system state according to predetermined rules about which components need to be operating for the system to be functional. The individual component failure distributions are easily modeled for most theoretical failure distributions and where a component failure distribution cannot be modeled theoretically, or there is insufficient information, failures and other events can be modeled by histograms or by empirical distributions [3].

An important feature of Monte Carlo simulation is that it “knows” what state the system is in at any point in time during a particular run. Accordingly, it is possible to introduce “business” and “managerial” decisions as to how to proceed in the event of a particular condition. For example, “If insufficient manpower to carry out repair, and go-no-go conditions not violated allow continued operation under restricted conditions.” This is a powerful tool for improving the veracity of the analysis, because it significantly improves the “real-life” factors that affect equipment operation.

Each Monte Carlo run will produce (internally) an answer of when the system was serviceable, and when

2 Discrete-Event Simulation for Reliability Prediction

it was in a failed state, and indeed any other pertinent conditions. Many subsequent runs will give different answers, because failure events are being created randomly. However, the many runs will show when analyzed that, say, $x\%$ of runs showed the system to be serviceable at time t . Therefore, the point estimate of reliability is $x\%$ at time t . Other parameters, such as the number of repairs being undertaken concurrently, or the spare part consumption, etc., may also be monitored and, across the many runs, estimates of the average values at any all points can be derived.

However, the answer itself is subject to variability. If the many Monte Carlo runs were repeated, a slightly different result would be obtained. To place confidence limits on the answer, the number of runs within each “simulation” must be considered. The greater the number of individual runs, the less would be the variability between several complete simulations. The formula for calculation of the variability is strictly a binomial confidence limit, but because of the extremely large number of individual runs usually undertaken, the normal approximation is appropriate [4].

Classical Monte Carlo Method

The classical method of Monte Carlo simulation is to examine the serviceability of each component at very fine time-slice intervals. If a component was serviceable at time t , the probability of it failing in time δt is small but known, and therefore, following random number generation, its serviceability at time $t + \delta t$ is deduced. Quite clearly when using very fine time slices, the serviceability of each component is calculated a very large number of times, each according to the failure distribution of the individual object. For large systems, this very quickly leads to a very slow simulation, expensive in computer time and so this approach is not recommended.

Discrete-Event Monte Carlo

A more modern approach to Monte Carlo simulation is to determine the complete time to failure of a component, rather than the failure event within small time increments, and to then to save (remember) the time when the event will occur. All simulation events which occur before that time will, by definition, show the component serviceable. The same philosophy

applies to all other events within the simulation. The operation of the system is then modeled, not by uniform time slices, but by jumping from one discrete-event to another. Provided all events have been initially calculated, or have a mechanism for being updated by the simulation itself (the usual case), then there is no change in system state between events. Accordingly, no fidelity is lost by jumping between events. Indeed, because time can now be a continuous variable rather than a finite slice, the DES offers greater fidelity.

A discrete-event Monte Carlo simulation usually must include the logic to update the list of future events as it proceeds. This will be illustrated by example. Consider a two-unit warm standby system (without repair), with $f_a(t)$ for the active component and $f_s(t)$ when in standby. The standby component adopts $f_a(t)$ when it becomes active. Initial random selection: sample $f_a(t)$ and $f_s(t)$, derive t_a and t_b being the future times when the active and standby components will fail within the particular simulation run.

1. If $t_a > t_s$, event 1 is at t_s (dormant failure of standby component), and event 2 is at t_a (failure of active component, system failure).
2. If $t_a < t_s$, event 1 is at t_a (failure of active component, standby component becomes active). This leads to a new event calculation: sample $f_a(t)$ for the new active component and derive new t_{a2} , leading to event 2 at $t_a + t_{a2}$ (second component failure, system failure).
3. If $t_a = t_s$, event 1 is at t_a (failure of both components, system failure).

Thus, in the case of 2 above, a second event calculation is made, which continues the simulation to the next event. Indeed, for this system, there are never more than three individual event calculations before system failure. Quite clearly this is far more efficient than taking fine time slices and sampling each.

More complex simulations are equally easily built-up. The logic of determining subsequent events is straightforward following each previous event. For example, in a repairable system, subsequent events following component failure would be to “initiate repair”. At the time of the failure event, the availability of “technicians” and “spare parts” could be examined within the simulation (i.e., their individual state, determined by their own events),

Figure 1 Discrete-event Monte Carlo simulation flow diagram

and rules governing the start and duration of repair sampled (probably also randomly sampled from a distribution, but equally easily obtained from discrete predetermined values). The simulation need only sample as far as the next logical event. New logical events may also override previously calculated event times, but such changes are easily included in the simulation model such that the list of future events is always the latest and correct list.

Thus, if the two-component warm standby system above was repairable, then a failure event would, by logic, lead to a “request” for repair. In practice, a logical flow diagram is often useful in understanding and declaring the sequence of events and decisions affecting a system’s operation. Figure 1 is a simple example of such a flow diagram. At the time of failure, the availability of technicians and spares is given by the simulation state. In the flow diagram in Figure 1, it is procedural that a spares request is initiated before a manpower request. The manpower request is only made when a spare is available. Manpower is allocated directly from the pool, if available. Otherwise the request is redirected to the manpower allocation procedure. The manpower allocation procedure is (for example) able to determine priority between competing repair tasks and maintains a list of flags, which identify waiting repair tasks. Manpower is always returned through the allocation procedure,

which would in turn return the manpower to the pool if there are no other tasks awaiting manpower. There are many variations on the flow diagram above. This particular diagram is given as way of illustration of the concept of discrete-event Monte Carlo simulation. Each procedure generates another event in response to a request. Thus, the simulation is self generating until an “end” condition is met.

Data

Supporting data is always required to create events. This applies equally to probabilistic and deterministic parameters. The more detailed the data available, the more detailed can be the computer simulation. The corollary is that with less data, it is false fidelity to apply greater detail to the model structure. The data must match the structure and *vice versa*.

In the example above, spares requirements are modeled probabilistically from the failure event. However, the level of detail with which the spare is identified should be commensurate with the level of failure probability and design information available. Where only system level information is available to any degree of accuracy, a system level “spare” should be generated by the simulation model (e.g., “engine”). Only where more detailed failure information is available, and the objectives of the simulation require

it, should more detailed breakdown be used (e.g., “inlet valve”).

Modeling Methods

Discrete-event probabilistic modeling is very closely allied to the development of a distributed database system. In a distributed database system, user inputs will generate events. The events may be arrival of data, analysis of data, output of data summaries, etc. Logical methodologies and development notation now exists to manage the specification and building of software systems in general, such as database systems. Use of such methodologies, particularly object oriented methodologies such as Booch notation [5], is highly recommended in the development of simulation models as without them, it is very easy to lose control of the event generation and flow.

Modeling Tools

A simulation model can be built using low level computer languages, such as C++. However, by far the most effective tools are dedicated, high-level tools such as Simula [6], Simscript [7], and Witness [8]. Clearly the performance of the PC will limit the size of simulation which can be run with any degree of efficiency.

DES for reliability purposes does not need to model component reliability, system architecture and maintenance using a single methodology. Rather, DES may adopt the most appropriate methodology for each. Therefore component status and maintenance are separately modeled and are inputs to a system state-space model. There are several analytical methods to derive state space. This article will briefly consider Petri nets [9], Markov diagrams [10], **fault trees** [11], reliability block diagram (RBD) [12], event trees [13], and path sets [14] as ways of representing system structure within DES.

Petri Nets. Petri nets have states (often called *places*) and transitions, and model the dynamic system state by addition and deletion of “tokens”. Petri nets provide opportunity to model every potential system state, and therefore “success”, “partial success”, “failed”, and indeed any other definable system condition of interest can be specifically identified. Therefore, it is a rich analysis methodology. A Petri

net is usually represented by a “transition matrix” and by a “token vector” prior to further computer-aided analysis, including for DES. The matrix describes the addition and deletion of “tokens” when triggered by certain input conditions, such as component failure. The total presence of “tokens”, as denoted by the “token vector”, denotes the system state. A system may remain in a given state for a period of time (say, using a simple stochastic component failure model) before addition/deletion of tokens, or may wait for external input (discrete-event) to trigger such change. The matrix cell values for stochastic models represent the probability of transfer but when a Petri net is linked to external trigger, the cells will be binary. For DES purposes, the most appropriate method is external input and, therefore, the simpler binary transfer matrix is more appropriate. When an external event triggers the Petri “token” vector, a change is calculated by repeated additive matrix/vector multiplication until a steady state is obtained in the “token” vector.

Markov Analysis. Markov analysis (*see Markov Processes; Maintenance and Markov Decision Models; Markov Renewal Processes in Reliability Modeling*) is an equally rich analysis method that also identifies all system states individually. As with Petri nets, the system states are usually represented by a matrix. A standard Markov transition matrix is also the form $k^m \times k^m$, where m is the number of components and k the number of possible component states. Each component would have an associated transition vector of length k^m . Therefore, computer representation and calculation of system state derived from Markov analysis would suffer from the same “state explosion” as from Petri nets, however, the matrix and vector size may be minimized if all system failed states are combined, as with Petri nets.

However, White developed an alternate transition matrix representation [15]. Instead of using a binary vector (matrix row) to identify the state transfer, he enumerates the states and forms a matrix of “component fault mode” and “system state”, thus immediately reducing the state matrix to $k(m-1) \times k^m$. White’s method has the advantage that no matrix multiplication is required to identify the new state. State change is identified through indexing, which is time efficient.

Fault Tree, Event Tree, and RBD. Fault trees (see **Failure Modes and Effects Analysis, Implementation of; Fault Tree Analysis for Large Systems**), event trees, and RBD may visually represent dynamic conditions, such as sequence and functional dependency, but such conditions cannot be analyzed without first being converted to, say, a Markov representation. Therefore, use of fault and event tree or RBD is often restricted to static conditions. Results from fault tree, event tree, or RBD are commonly represented as cut or path sets. These are binary vectors of (for paths) component states that, collectively, indicate system function. A fault tree captures system configurations that would lead to a specific “top” event, usually system failure. An event tree, because it potentially identifies each and every system outcome, will contain path sets or cut sets for each outcome category.

When applied to DES, the system state upon failure or repair of a component is simply an issue of updating the binary state vector, and identifying which category the new vector resides, cut or path set. This is a “find” function, usually of moderate computing efficiency $O(\ln(n))$.

Path Sets. Path and cut sets (see **Path Sets and Cut Sets in System Reliability Modeling**) collectively describe the full combination of possible component states. Therefore, dynamic systems do not increase the overall number of possibilities but, rather, conditionally change a path into a cut. If a system state is statically failed, it is not reasonable for it to be dynamically functional. Therefore, dynamic systems would not conditionally change a cut into a path. Thus, it is implicitly possible to model dynamic systems while still using path and cut sets, provided an additional data-structure is feasible to capture and identify conditions where a statically functional system is dynamically failed.

Failure Modes and Effects Analysis, Implementation of

Introduction

Failure modes and effects analysis (FMEA) is a structured, logical, and systematic analysis of a system. To perform a FMEA an analyst examines each item in a system, considers how that item can fail, and then determines how each failure will affect the operation of the system.

FMEA provides a basis for improving a system's design by recognizing component failure modes identified in historical "lessons learned" and from component and system prototype tests. It is used to assess the safety of system components (*see Reliability, Safety, and Risk Management*), and to identify design modifications and corrective actions needed to mitigate the effects of a failure on the system. It is used in planning system maintenance activities, subsystem design, and as a framework for system failure detection and isolation capabilities. A FMEA can be performed functionally (functional FMEA), on subsystem interfaces (interface FMEA), or on the piece parts of which the system is composed (detailed FMEA). It can be applied to the processes through which a system is manufactured and maintained (process FMEA) as well as on the electrical, mechanical, and software components of the system (product FMEA).

FMEA developed as a formal methodology during the 1950s at Grumman Aircraft Corporation, where it was used to analyze the safety of flight control systems for naval aircraft [1]. During the 1970s and 1980s, various military and professional society standards were written to define the analysis methodology. Mil-Std-1629 (ships), "Procedures for Performing a Failure Mode, Effects and Criticality Analysis" [2] was published in 1974, and, through several revisions, became the basic approach for doing the analysis. The Society of Automotive Engineers Ground Vehicle Recommended Practice, J1739 [3] defines the procedure used by the major automobile companies and their suppliers. IEC 60812, "Analysis techniques for system reliability – Procedure for failure mode

and effects analysis (FMEA)" [4] is the most recent international standard specifying the technique.

The terms *FMEA* – *failure modes and effects analysis* – and *FMECA* – *failure modes, effects, and criticality analysis* – are often used almost interchangeably. Some authors take the view that FMEA is limited to an analysis of the effects of item failure modes and that FMECA also includes assessing the probability of a failure mode's occurrence. Others take the view that FMECA extends the analysis to include a ranking of the failure modes based on a combination of their probability of occurrence and the severity of their effects. Here we use FMEA as the general term and include prioritizations based on the failure mode's severity and probability of occurrence under its scope.

Example: Analysis of a Domestic Hot Water Heater

To illustrate the basic FMEA technique we will begin with an analysis of the gas stop valve for a domestic hot water heater whose schematic is shown in Figure 1.

Functionally, the hot water heater takes cold water and gas as inputs and produces hot water as an output; flue gases and heat leakage are also produced as waste outputs. The water temperature is regulated by the controller opening and closing the main gas valve (labeled *stop valve*) to keep the water temperature within the preset limits of 140–180°F. The pilot light is always on and the gas valve operates the main burner in full-on/full-off modes. The controller is operated by the temperature measuring and comparing device. The check valve in the water inlet pipe prevents reverse flow due to overpressure in the hot water system, and the relief valve opens if the system pressure exceeds 100 psi (pounds-force per square inch).

Table 1 shows the results of the FMEA on the stop valve. Observe that the analyst has identified all the ways in which the stop valve can fail and determines the effect of each failure locally, on the stop valve itself, and on the entire system. In most cases the analyst also identifies the possible causes of failure and attempts to either eliminate them from the design or, if that is not possible, mitigate their effects. For example, the stop valve could fail to open or close properly due to corrosion. This, in turn, could be caused by electrolysis between different

2 FMEA, Implementation of

Figure 1 Schematic for a gas hot water heater

metals, or by a reaction of the valve material with the gas. Careful consideration of the valve materials would eliminate this failure mode. (At least it would eliminate this cause of the failure mode; there could be other causes.)

An analysis of the pilot light would reveal the hazard of gas leakage if it fails (it is not lit) and the gas is on. This failure mode cannot readily be eliminated but it can be mitigated by adding an interlock to prevent the gas valve from opening if

the pilot light is not on. Many gas hot water heaters have this type of interlock. If the interlock fails, the burner will not be able to heat the water even if the pilot light is on.

FMEA Methodology

The FMEA methodology is based on a hierarchical, inductive approach to analysis. The basic procedure consists of:

1. Identify all item failure modes;
2. Determine the effect of the failure for each failure mode both locally and on the overall system being analyzed, and if necessary, for each subsystem of which the item is a part;
3. Classify the failure by its effects on the system operation and mission;
4. Determine the failure's probability of occurrence (if possible);
5. Identify how the failure mode can be detected (This is especially important for fault tolerant configurations.);
6. Identify any design changes to eliminate the failure mode, or if that is not possible, mitigate or compensate for its effects.

The results of the analysis are captured on analysis worksheets, which provide a description of the failure modes and their consequences traceable to diagrams or other design documentation. Generally the worksheets include:

- identification of the component being analyzed;

Table 1 FMEA analysis of the stop valve for a hot water heater

Component	Failure mode	Effect	
		Local	System
Stop valve	1. Fails closed	Burner off	No hot water
	2. Fails open	Burner will not shut off	Overheats, release valve releases pressure, may get scalded
	3. Does not open fully	Burner not fully on	Water heats slowly or does not reach desired temperature
	4. Does not respond to controller – stays open	(same as 2)	
	5. Does not respond to controller – stays closed	(same as 1)	
	6. Leaks through valve	Burner will not shut off, burns at low level	Water overheats (possibly)
	7. Leaks around valve	Gas leaks into room	Possible fire or gas asphyxiation

- its purpose or function;
- the component failure mode being analyzed;
- the cause of the failure and how the failure is detected;
- the local, subsystem, and system-level effects of the failure mode;
- the severity classification and probability of occurrence of the failure mode.

A FMEA normally analyzes each item failure as if it were the only failure within the system. However, when the failure is undetectable or latent or the item is redundant, the analysis may be extended to determine the effects of another failure, which in combination with the first failure could result in an undesirable condition.

When analyzing failure effects, the analyst must also be concerned about possible failure cascades and common cause failures where a single event can lead to multiple failures. Such failures often result from the physical placement of the components rather than their operational functions. For example, a failure of a disk turbine in which the disk disintegrates and throws off pieces of broken metal could disable several independent hydraulic systems in an aircraft if they are all routed near the turbine.

The FMEA Process

The FMEA process tracks the system development from concept to detailed implementation. It starts with a functional fault analysis, progresses to an interface analysis, and concludes with a detailed analysis. Each analysis represents a more detailed iteration from the previous analyses. Data needed for the FMEA include the system operating modes and functions, required performance levels, environmental considerations, and safety or regulatory requirements. Libraries with descriptions of failure modes and consequences are also useful. Such libraries provide direction as to the level of detail for the analysis and help ensure consistency in terminology, types of failure modes considered, and so on, among all the analysts (including future analysts) contributing to the project. Ground rules specifying assumptions, limitations, boundary conditions, and what constitutes a failure should also be established before beginning the analysis [5]. The ground rules for the analysis of the hot water heater included the assumption of a continuous supply of gas and water, the water heater is for home use, and it is operated between 140–180 °F.

Functional Fault Analysis

A functional fault analysis is performed on the conceptual design to verify that provisions to compensate for component failures are both necessary and sufficient. The relief valve in the hot water heater is an example of such a compensating provision; it is intended to relieve excessive pressure that potentially could rupture the tank if the water overheats. A functional FMEA of the hot water heater would show that it is needed and that it provides the required protection. The relief valve also illustrates the concern about undetected failures – how does one know that the valve is operating properly? Thus, in addition to showing that the valve is needed, the functional FMEA might also result in a requirement for periodic inspections of the relief valve or a requirement for a monitor to detect a failure of the valve.

Typical functional failure modes are of the form: “function fails to perform”, or “function is performed at the wrong time”. In the hot water heater example, the function of the stop valve is to control the flow of gas in full-on/full-off mode. Thus its functional failure modes are a failure to control the flow of the gas; for example, the gas is on when it should be off, or the gas is not full-on or full-off.

Ideally, a functional fault analysis focuses on the functions that an item, or group of items, performs rather than the characteristics of the specific components used in their implementation. In practice, the types of failure modes considered for a function may depend on how the function will be implemented. When a functional analysis is applied to manufacturing processes, typical failure mode categories include manufacturing and assembly operations, receiving inspection, and testing. Process failure modes are described by process characteristics such as part misorientation, part hole off-center, and so on. When the analysis is applied to software typical functional failure modes are, failure to execute, execution at an incorrect time (early or late), or incorrect result [6].

A major benefit of a functional FMEA is that the functional failure modes can be identified in the conceptual design phase before the detailed design has been developed. Typical results of the analysis identify functional failure modes that need to be eliminated or mitigated by changing the functional system design or the requirements [5].

Interface Fault Analysis

An interface fault analysis focuses on determining the characteristics of failures in the interconnections between subsystem modules. The analysis begins by defining the failure modes for the specific type of interface between subsystem elements. A typical electrical failure mode would be “input shorted to ground”; a typical mechanical failure mode would be “hydraulic pressure low”. Software interface failure modes focus on failures affecting the interfaces between disparate software elements or software and hardware elements such as incorrect timing, or errors in the values presented at the interface. Process errors that could result in misalignment or improper connections are important failure modes for a process interface FMEA.

For the hot water heater, typical failure modes that would need to be considered at the temperature/controller interface would include “no signal” and “incorrect temperature transmitted”.

The advantage of a separate interface fault analysis is that it can be performed as soon as the subsystem inputs, outputs, and their interconnections are defined. This is usually well before detailed module designs are available. Typical results of this analysis are interface failure modes that need to be eliminated or mitigated by interface design changes.

Detailed Fault Analysis

A detailed fault analysis is used to verify that the design complies with the system requirements for: (a) failures that can cause the loss of system functions; (b) single point failures; and (c) fault detection and isolation capabilities. A detailed fault analysis on the system hardware (sometimes called a *piece part fault analysis* since it is done on the “piece parts” that comprise the system) is what has traditionally been done in a FMEA. Table 1 is an example of such an analysis. To perform the analysis, a set of component failure modes and their corresponding occurrence ratios are especially useful. For example, the failure modes normally considered for a capacitor, are “open”, “short”, and “leaking”. Failure mode ratios allow the item failure probability to be apportioned among its failure modes to give the failure mode probability of occurrence. Such ratios are best obtained from field data that is representative of the particular item application but generic references

such as [7] can be used for guidance if such data is not available. Failure mode ratios for a particular component type often vary widely depending on the operating environment, manufacturer, application, and other factors.

A detailed software fault analysis is intended to assess the effect of failures on the software functionality or on the variables used in the software. Unlike hardware, the software errors analyzed by a FMEA are not due to “potential failures”; rather, they already exist and will be activated under the “right” set of conditions [5, 6]. Detailed procedures for performing a FMEA on software are given in [7, 8]. Process related failure modes are specific to the manufacturing or maintenance process. For example a wax coating may be applied too thinly to provide the corrosion protection it is intended to provide.

One problem associated with a detailed fault analysis is that it cannot be initiated until the design has matured to the point that detailed schematics and parts lists are available. This means that any major errors found by the analysis are likely to be very expensive to fix. Conversely, errors, even major errors in the design concept, are relatively easy to fix in the early design phase when the functional and interface fault analyses are done.

Identify Failure Consequences

The consequences of a failure mode analyzed in a FMEA are its effects, a classification of the severity of the failure mode based on its system-level effects, and the probability of the failure mode occurrence. The analysis is conducted for all phases of the system operation including normal operating modes, contingency modes, and test modes. After the effects of an item failure mode have been determined corrective actions or compensating provisions must be identified within each applicable operating mode.

Assessment of the failure mode effects must identify the system conditions or operational modes that manifest the anomalous behavior. For example, failures in the landing gear of an airplane that would cause “loss of landing gear extension” will have very different effects if the failure occurs on the ground than if it occurs while attempting to land. Likewise, the discovery mechanism for detecting the failure may be different.

Failure modes are usually classified by an assessment of the significance of the end-effect on the

system operation and mission. The FMEA ground rules developed in the planning stage should provide a ranking and classification system, and appropriate criteria for assessing the severity of failures for the product being analyzed. In many cases a four-level classification system with severity classifications ranging from catastrophic to insignificant is sufficient [2, 4]. When items are redundant and there is no warning that a redundant item has failed, the severity should be assessed as if all of the redundant items have failed.

The Failure Cause Model

A failure cause model is used to combine the causes of the failure mode and evaluate the failure mode probability of occurrence [5, 9]. The failure cause model often takes the form of a fault tree (*see Fault Trees; Fault Tree Analysis for Large Systems*) whose top event is the failure mode of interest. The fault tree can include operational causes of failure, manufacturing process errors, and design errors. Thus, the failure cause model for a failure mode unifies the various types of FMEA for product, process, software, and so on.

To the extent possible, statistical data should be used to determine the failure mode probability of occurrence. If sufficient data is not available it can be estimated from field data, laboratory or simulation studies, experience with similar systems, tables of generic component failure rates, and so on.

Corrective Action Recommendations

Corrective actions are needed for undetectable faults and for faults having significant consequences – for example, unsafe conditions, mission or safety-critical single point failures, adverse effects on operating capability, or high maintenance costs. Corrective actions may not be needed if the risks for the specific consequence(s) of a failure are acceptable based on a low enough probability of occurrence. Corrective actions generally take the form of changes in requirements, design, processes, procedures, or materials to eliminate the design deficiency.

Once a corrective action is implemented, the affected fault analyses must be revised to reflect the new baseline configuration. When design changes to correct a deficiency are not possible or feasible, compensating provisions, often in the form of design

provisions or designated operator actions, must be identified to circumvent or mitigate the effect of the failure when it occurs.

Prioritization

A FMEA on even a moderately sized system usually results in the identification of hundreds of potential failure modes whose effects may range from insignificant to catastrophic. Hence, it is necessary to prioritize them for corrective actions. Most prioritization techniques are based on an assessment of the severity of the failure effect and the probability of the failure mode occurrence. Generally, failure modes within a severity class having probabilities of occurrence above some threshold must be corrected, but the threshold may vary, depending on the severity category. For example, corrective actions may be required for any catastrophic failure mode with a probability of occurrence of more than 10^{-9} , but a failure mode resulting in an operating limitation may be acceptable if its frequency of occurrence is less than 10^{-4} .

The automobile FMEA [3] specifies the use of a risk priority number (RPN) to rank failure modes. This methodology ranks the severity (S), probability of occurrence (O), and likelihood of detection (D) on a scale from 1 to 10 and multiplies them to obtain the RPN. High RPNs are assumed to be more serious than lower RPNs. Use of the RPN to rank failure modes requires caution and good judgment [4].

Automation

When done manually, FMEAs tend to be tedious and time-consuming tasks. Product designers usually prefer to focus on the tasks a system must do and how to design the system to do those tasks well rather than on what can go wrong. Analyzing what will happen when something fails requires viewing the system in a different way and propagating a failure mode from the component to system level is often difficult.

A number of computer-based tools have been developed to aid the analysis process. The simplest do little more than provide a consistent format for the analysis. Others have features that help improve the quality of the analysis such as providing lists of appropriate component failure modes and their apportionments or making completeness and consistency checks. Some specialized programs may

even simulate the system to help the designer evaluate how various component failure modes will affect the system operation and output [10].

Summary

FMEA has evolved from an *ad hoc* technique, dependent on the designer's "experience", to a formal and accepted analysis technique applicable at all phases of the system development process. Failure modes can be described functionally and their effects analyzed early in the design phase. Interface and detailed FMEAs can be applied as the design detail develops. Fault trees can be used to combine the contributions to the failure mode due to design errors, material properties, manufacturing errors, service mistakes, and even user errors to assess the probability with which the failure mode occurs. Failure modes can be eliminated by removing their causes or at least have their probabilities of failure reduced to acceptable levels.

Fault Tree Analysis for Large Systems

Introduction

Fault tree analysis (*see* **Fault Trees**) is commonly used for the quantification of system failure probability or frequency. The analysis, which for all but the simplest of system structures requires a software, is traditionally performed using the two-stage method of kinetic tree theory developed by Vesely [1]. Stage one of the computer implementation manipulates the fault tree structure using the rules of Boolean algebra to determine what are known as *minimal cut sets* (*see* **System Reliability: Computational Algebra Methods**). A *cut set* is a list of component-failed states which result in system failure. The more useful concept is that of a *minimal cut set*, which is a list of necessary and sufficient component failure events that result in system failure. In a logic equation expressing the system failure causes, the events within a minimal cut set are combined with an AND ($\cdot$) as they are all required to occur. Since any of the N_c minimal cut sets will result in a system failure, the top event, T , (system failure mode) can be expressed as:

$$T = C_1 + C_2 + \cdots + C_{N_c} \quad (1)$$

where C_i are the minimal cut sets and “+” represents OR.

The process of generating the minimal cut sets is very simple and can be performed top down or bottom up on the fault tree [2]. Cut sets are formed by sequentially substituting out gate events in the causes of the system failure, by events appearing lower down in the tree structure. This continues until only basic events remain. The cut sets are then minimized. During this activity, the software has to do many comparisons between the different events within each cut set and then between the cut sets themselves applying the laws of idempotence (equations 2 and 3) and absorption (equation 4). The two idempotence laws ensure that repeated events do not appear within the component failure combinations (equation 2) nor do repeated failure combinations occur (equation 3). Equation (4) deletes any nonminimal failure combinations and

reduces the logic expression to the minimal cut sets. Although the process is simple, since the implementation requires many comparisons, it is time consuming.

Idempotent

$$A \cdot A = A \quad (2)$$

$$A + A = A \quad (3)$$

Absorption

$$A + A \cdot B = A \quad (4)$$

A second difficulty which has to be overcome is the way the information is stored within the computer memory during processing. One approach is to form a two-dimensional array (table) where the rows provide a list of the cut sets and the entries in the row (columns) contain the component failures which appear in the cut sets. This approach requires the number of columns to be set at the maximum number of components which occur in any cut set (prior to any minimization). Since many, usually most, of the minimal cut sets will not need this amount of storage space, it becomes inefficient and may result in insufficient memory to solve the problem. The housekeeping routines required to overcome this again increases the processing time.

Stage two of the analysis is then to use the minimal cut sets, together with the component failure characteristics to predict the failure probability or the failure frequency of the system. Having obtained the minimal cut sets, we can express the top event logic equation as the disjunction (OR) of the minimal cut sets (equation 1). The system failure probability, Q_{sys} is then the probability of this disjunction given by the inclusion–exclusion expansion:

$$Q_{sys} = P(T) = P(C_1 + C_2 + \cdots + C_{N_c}) \quad (5)$$

$$\begin{aligned} Q_{sys} = & \sum_{i=1}^{N_c} P(C_i) - \sum_{i=2}^{N_c} \sum_{j=1}^{i-1} P(C_i \cap C_j) \\ & + \sum_{i=3}^{N_c} \sum_{j=2}^{i-1} \sum_{k=1}^{j-1} P(C_i \cap C_j \cap C_k) - \cdots \\ & \cdots + (-1)^{N_c+1} P(C_1 \cap C_2 \cdots \cap C_{N_c}) \quad (6) \end{aligned}$$

2 Fault Tree Analysis for Large Systems

This process too is computationally intensive. Consider a moderate sized fault tree which delivers 100 000 minimal cut sets. The number of elements in first summation term of equation (6) is 10^5 , in the second term $\approx 5 \times 10^9$ and in the third term $\approx 1.7 \times 10^{14}$ and so on for the 10^5 terms in the equation. Even with modern, fast, digital computers, this is an enormous number of calculations and will take a considerable time to complete. In practice, approximations are required for the quantification.

Binary Decision Diagrams

A method that overcomes the deficiencies identified in the section titled “Introduction” is the binary decision diagram (BDD) method. Figure 1 shows the form of the BDD [3], which like the fault tree, represents the causes of failure of the system in terms of the failure of its basic events or components. In this case, the BDD shows how failures of basic events A, B, and C combine to cause system malfunction.

The entry point on the BDD is the root vertex. The intermediate nodes all correspond to components in the system and two paths leave each node: a “1” branch representing component failure and a “0” branch for component functioning. To construct the diagram, an “ordering” must be assigned to the basic events, which specifies the order in which each component is considered when constructing the diagram. A path on the diagram starts at the root vertex and progresses along a specific output branch from each node which determines the status of that particular component. As soon as the component conditions specified on any path establish the system status, then the path is terminated with the appropriate terminal-0 or terminal-1 node for system functioning

Figure 1 Binary decision diagram structure

or system failure respectively. The concise nature of these diagrams is appealing from the mathematical perspective as they possess characteristics which result in efficient and accurate analysis. From the engineering perspective, they are not documented and do not develop the failure logic in any structured way. As such, it is usually best to develop the system failure logic as a fault tree and then convert to a BDD for analysis.

Binary Decision Diagram Construction

The most efficient fault tree conversion process manipulates equations using a special ite (if–then–else) form. Consider the basic event represented by a node X.

IF the event X occurs

THEN we pass down the “1-branch” and consider the Boolean function, f1, represented by the BDD connected to this branch.

ELSE (the event has not occurred), we pass down the “0-branch” and consider the Boolean function, f2, represented by the BDD connected to this branch.

This can be written in a very concise way:

$$\text{ite}(X, f1, f2) \quad (7)$$

With the ite notation allowing us to express each node on the BDD, mathematical rules can be established which are applied in a bottom-up fashion to the fault tree and deliver the BDD form. Initially each basic event in the fault tree is expressed in the ite notation. So for any basic event X we have:

$$X = \text{ite}(X, 1, 0) \quad (8)$$

When we encounter a gate of logic type $\oplus$, (where $\oplus$ = AND or OR), which has two inputs G and H already expressed in ite form:

$$G = \text{ite}(X, g1, g2) \text{ and } H = \text{ite}(Y, h1, h2) \quad (9)$$

Then the following rules [4] can be applied to get an ite expression for the gate event. It depends on where the basic events X and Y appear in the ordering. Either $X < Y$ (X appears before Y) or $X = Y$ (X

and Y are the same variable). Then:

$$G \oplus H = \text{ite}(X, g1 \oplus H, g2 \oplus H) \quad (10)$$

$$\text{Or}G \oplus H = \text{ite}(X, g1 \oplus h1, g2 \oplus h2) \quad (11)$$

Once an ite expression is formed for any gate it is simplified as much as possible using the Boolean identities:

$$G + 1 = 1 \quad (12a)$$

$$G + 0 = G \quad (12b)$$

$$G \cdot 1 = G \quad (12c)$$

$$G \cdot 0 = 0 \quad (12d)$$

As an example of the construction process, consider the fault tree illustrated in Figure 2. We will use the rules expressed in equations (10) and (11) and an ordering of the basic events $A < B < C$ to convert this to a BDD. First all basic events are put into ite form:

$$\text{ite}(A, 1, 0) \quad \text{ite}(B, 1, 0) \quad \text{ite}(C, 1, 0)$$

Considering now GATE1:

$$\begin{aligned} \text{GATE1} &= A + C \\ &= \text{ite}(A, 1, 0) + \text{ite}(C, 1, 0) \end{aligned}$$

Figure 2 Example fault tree structure

$$= \text{ite}(A, 1 + \text{ite}(C, 1, 0), 0 + \text{ite}(C, 1, 0))$$

using equation 10

$$= \text{ite}(A, 1, \text{ite}(C, 1, 0))$$

using equation 12a, b (13)

In exactly the same way GATE2 can be expressed as:

$$\begin{aligned} \text{GATE2} &= B + C \\ &= \text{ite}(B, 1, \text{ite}(C, 1, 0)) \end{aligned} \quad (14)$$

Having now established expressions for GATE1 and GATE2, the process can now consider the top event:

$$\begin{aligned} \text{TOP} &= \text{GATE1} \cdot \text{GATE2} \\ &= \text{ite}(A, 1, \text{ite}(C, 1, 0)) \cdot \text{ite}(B, 1, \text{ite}(C, 1, 0)) \\ &\text{using equation (10), gives:} \\ &= \text{ite}(A, 1 \cdot \text{ite}(B, 1, \text{ite}(C, 1, 0))), \\ &\quad \text{ite}(C, 1, 0) \cdot \text{ite}(B, 1, \text{ite}(C, 1, 0))) \end{aligned} \quad (15)$$

applying equation (12c) to the 1-branch and equation (10) to the term on the 0-branch of the above expression gives:

$$\begin{aligned} &= \text{ite}(A, \text{ite}(B, 1, \text{ite}(C, 1, 0))), \text{ite}(B, 1 \cdot \text{ite}(C, 1, 0), \\ &\quad \text{ite}(C, 1, 0) \cdot \text{ite}(C, 1, 0))) \end{aligned}$$

Simplifying

$$\begin{aligned} &= \text{ite}(A, \text{ite}(B, 1, \text{ite}(C, 1, 0))), \text{ite}(B, \text{ite}(C, 1, 0), \\ &\quad \text{ite}(C, 1, 0))) \\ &= \text{ite}(A, \text{ite}(B, 1, \text{ite}(C, 1, 0))), \text{ite}(C, 1, 0)) \end{aligned} \quad (16)$$

Equation (16) represents the ite expression for the final BDD. It can be seen that the root vertex is A. On its “1-branch” it has the expression $\text{ite}(B, 1, \text{ite}(C, 1, 0))$, i.e. it is connected to the vertex B which has 1 and $\text{ite}(C, 1, 0)$ on its 1 and 0 branches respectively. The “0-branch” of A is connected to vertex C. This produces the BDD illustrated in Figure 1.

The ite structure lends itself very well to computer implementation as each node on the BDD can be represented as an ordered triple: the variable name, a pointer to the node on the 1-branch, and a pointer to the node on the 0-branch. The whole BDD is a list of its nodes.

System Failure Probability

It is with the system quantification that the BDD scores heavily over the conventional fault tree analysis method. Due to the way that the BDD is formed, it has the characteristic that all paths through the BDD are disjoint. Consider any intermediate node X . A path will pass this node on either the 1-branch meaning that the event has occurred or the 0-branch meaning that it has not. These conditions are mutually exclusive and so all failure causes progressing below the 1-branch therefore contain the component-failed state and will be mutually exclusive to any path through the 0-branch on which the component is considered to function. The branching at all other variables results in all paths being disjoint.

Since the BDD expresses the system structure in a disjoint form, the system failure probability is then simply the sum of the probability of all paths from the root node to a terminal-1 node (accounting for the failure/success of all components included in the path):

$$Q_{\text{sys}} = \sum_{\text{all paths}} P(\text{path } i \text{ to terminal } - 1) \quad (17)$$

For the BDD shown in Figure 3, the disjoint paths to a terminal-1 node are:

1. $A \cdot C \cdot B$
 2. $A \cdot \bar{C} \cdot B \cdot D$
 3. $\bar{A} \cdot B \cdot D$
- (18)

Summing the probabilities of these paths gives:

$$\begin{aligned} Q_{\text{sys}} &= q_a q_b q_c + q_a (1 - q_c) q_b q_d \\ &\quad + (1 - q_a) q_b q_d \\ &= q_a q_b q_c + q_b q_d - q_a q_b q_c q_d \end{aligned} \quad (19)$$

The points to note about this process are:

1. the top event probability obtained is exact [5] (approximations are not needed on any size of problem) and
2. the minimal cut sets were not required as an intermediate step in the calculations [6].

This gives the BDD approach advantages in terms of both accuracy and efficiency over the conventional fault tree analysis method.

Figure 3 Example BDD

The procedure to evaluate the system failure frequency from the BDD is given in references [3] and [5].

Qualitative System Analysis

As indicated in the previous sections the minimal cut sets are not needed to quantify the system reliability performance. They do however provide useful information in their own right indicating how the system fails and can be determined from the BDD structure.

Each path leading to a terminal-1 node contains the component conditions required for system failure. If the working component states are ignored and only the failed component states are listed, then this corresponds to a cut set. For the BDD shown in Figure 1, there is a path to a terminal 1 passing through nodes A and B on their 1-branches. So AB is a cut set. There are two paths passing through the BDD to the second terminal-1 node. The first passes through the 1-branch of A, the 0-branch of B, and the 1-branch of C, giving cut set AC. The second passes through the 0-branch of A and the 1-branch of C, giving cut set C. Component failure combinations leading to system failure are:

1. AB
2. AC
3. C

Since we can remove component A from combination 2 and the system remains in the failed state, we can see that this is not a minimal cut set. Removing this from the list gives the minimal cut sets {AB}, {C}.

The above approach demonstrates the way minimal cut sets can be obtained in a system assessment; however, for a full minimal cut set analysis, the efficient process would be to construct a zero-suppressed BDD, which encodes only minimal cut sets. Details can be found in reference [7].

Variable Ordering Schemes

The sequence specified to determine the order in which the component events are considered for inclusion in the BDD structure plays a vital role in determining the size, and therefore the efficiency of the BDD produced to represent the logic function. Consider the fault tree given in Figure 4.

With the two ordering schemes of $A < B < C < D$ and $D < C < B < A$, the resulting BDDs are illustrated in Figure 5(a,b) respectively.

The BDD in Figure 5(a) has four intermediate nodes and produces three cut sets (all minimal). The BDD in Figure 5(b) is not such an efficient representation producing five cut sets (two nonminimal). For a problem of this size, the efficiency of the representation of the system failure logic is not important. However, as the size of the system grows, this can be

Figure 4 Fault tree to investigate ordering schemes

critical if a BDD is to be constructed. There is no universally accepted way in which the variable ordering can be specified; a number of approaches are possible. The problem then becomes: given the characteristics of the original fault tree, select which strategy should be used to specify the variable ordering. **Neural networks** have been used for this selection process (references [8–10]).

Potential strategies to order the fault tree basic events are:

- “Neighborhood” methods where the fault tree is traversed in a specified way and basic events listed as they are encountered. One of the most

Figure 5 BDDs for different basic event ordering schemes

common ordering methods falls in this category and is known as *top down, left right* where the tree is traversed from top to bottom and on each level encountered from left to right listing the variables as they are encountered for the first time.

- “Structural importance” methods allow nodes to be selected from anywhere in the tree structure. Nodes are allocated a “weighting” which indicates their contribution to the top event. Highest “weightings” are ordered first.

Summary

This article has described the basic properties of the BDD technique which provides a fast, efficient, and accurate method by which fault trees can be analyzed. The implementation of this method has increasing benefits with the size of the problem and offers significant advantages for fault trees constructed to represent the failure causes of large complex systems. In using the BDD method, the system variables, basic events in the fault tree, need to be placed in an ordering. Care should be taken with the process to obtain a concise BDD structure.

Integrating Computer and Physical Experiment Data

Calibration and Prediction for Scalar Outputs

This article provides motivation for a statistical approach to *calibrate* a physics simulation model to experimental data and to *predict* a future experiment given information from calculations and data already in hand. These notions will be made more specific as this discussion proceeds. The statistical framework for the calibration and prediction methodology outlined below is Bayesian [1–3]. To begin, assume that experimental data y , as a function of *system* inputs $\mathbf{x}$, follows a basic measurement error model,

$$y(\mathbf{x}) = \zeta(\mathbf{x}) + \epsilon(\mathbf{x}) \quad (1)$$

Here, $y(\mathbf{x})$ represents the data actually observed, $\zeta(\mathbf{x})$ represents the *true, unknown* response of the physical system, and $\epsilon(\mathbf{x})$ represents observation error. The system inputs $\mathbf{x}$ are known to the scientist with certainty. They represent such quantities as physical constants (e.g., ambient temperature, nominal density) or variables specific to the geometry of the physical system under study, such as spatial coordinates or time. The concepts involved in what follows will be illustrated for the simple physical setting shown in Figure 1. The *observed* datum $y(x)$ is a measurement of the time required for an object to impact the ground after being dropped at rest from height x . In this setting there is one system input (height), but in general multiple system inputs are allowed. The system response $\zeta(x)$ represents the true underlying physical relationship between height x and impact time. This function is generally not observable, due to measurement error and other components of uncertainty inherent in collecting data, represented broadly here by the error term $\epsilon(x)$. The function $\zeta(x)$ is an object of statistical inference.

For complicated physical systems, actual experimental data may only exist for a very small number of $\mathbf{x}$ values. Replicated data may not be available. In this situation, inference about complex functions $\zeta(\mathbf{x})$ is difficult or impossible if based on the observed data alone. For this reason, scientists build intricate simulation models that incorporate advanced physics

Figure 1 The time taken for an object to drop from each of six floors of a tower (solid lines) is recorded. Predictions of unobserved times are desired for drops from higher floors (dashed lines)

with the goal of effectively modeling $\zeta(\mathbf{x})$. These simulation models produce output as a function of the system inputs $\mathbf{x}$, but they often include additional parameters $\mathbf{t}$ that are commonly used in practice to tune the simulation model to experimental data. These additional parameters are often referred to as *knobs*. They may represent actual physical concepts in the mathematical description underlying the simulation model, or they may represent abstractions employed to account for physical concepts that cannot be or are not explicitly modeled, or they may

2 Integrating Computer and Physical Experiment Data

represent parameters in an empirical model serving as the representation of a physical system. Whatever these parameters represent, in contrast to the system inputs $\mathbf{x}$, they possess uncertainty in their values. *Tuning* refers to any methodology designed to find optimal point estimates of the knobs $\mathbf{t}$, with optimal being defined in terms of minimizing a criterion function such as the sum absolute or squared differences between experimental data and calculations.

For a simulation model that can be made to perfectly represent the physical system through appropriate choice of knob settings $\mathbf{t} = \boldsymbol{\theta}$,

$$\zeta(\mathbf{x}) = \eta(\mathbf{x}, \boldsymbol{\theta}) \quad (2)$$

where $\eta(\mathbf{x}, \boldsymbol{\theta})$ denotes the simulator output at system inputs $\mathbf{x}$ and the true value of the knobs $\boldsymbol{\theta}$. In application, the true value $\boldsymbol{\theta}$ is unknown and must be estimated, traditionally using tuning criteria such as those suggested previously. In the example introduced above, the simulation model implements a differential equation that provides the relationship between the position of the object and time:

$$\frac{d^2s}{d\tau^2} = -1 - \theta \frac{ds}{d\tau} \quad (3)$$

where s and τ represent position and time respectively. The initial conditions are given by

$$s(0) = x \text{ and } \left. \frac{ds}{d\tau} \right|_{\tau=0} = 0 \quad (4)$$

The constant term represents acceleration due to gravity. The height x is assigned to the initial position of the object, and the model output $\eta(x, \theta)$ is the root of the equation $s(\tau) = 0$. The knob θ is called the *drag coefficient*, and it represents the effect of air resistance on the falling object. The value of this parameter is clearly uncertain, as it depends on environmental conditions in effect when the object is dropped.

In many applications, the simulation model does not contain all of the relevant physics to explain the physical system being represented. This can be due to lack of knowledge about applicable physics for certain components of the system or inability to implement advanced physics due to computational complexity. A corollary to this situation is a simulation model that contains all of the (known) relevant physics but for which simplifications are required (such as collapsing over dimensions or choice of mesh) for computational tractability.

Many applications involve inadequate physics *and* computational simplification. In this reality, a model for the physical system can be specified as follows,

$$\zeta(\mathbf{x}) = \eta(\mathbf{x}, \boldsymbol{\theta}) + \delta(\mathbf{x}) \quad (5)$$

Here, $\delta(\mathbf{x})$ is defined as the difference $\zeta(\mathbf{x}) - \eta(\mathbf{x}, \boldsymbol{\theta})$ between the true physical system response $\zeta(\mathbf{x})$ and the simulation model evaluated at the best value for the knobs $\boldsymbol{\theta}$, $\eta(\mathbf{x}, \boldsymbol{\theta})$. This term is often referred to as *discrepancy* or *model inadequacy*. Nonzero values for $\delta(\mathbf{x})$ indicate that for system inputs $\mathbf{x}$, the simulation model evaluated at optimal settings for the knobs $\boldsymbol{\theta}$ is an incomplete representation of the physical system. For example, suppose the simulation model solves the differential equation $s''(\tau) = -1$, subject to the initial conditions $s(0) = x$ and $s'(0) = 0$. The impact time $\eta(x, 0)$ is the root of the equation $s(\tau) = 0$. This model is appropriate for releasing objects in a vacuum but inadequate under any circumstances where air resistance affects the velocity of the falling object. If the latter applies, $\delta(x)$ will be an increasing function of x as the effect of drag on impact time will increase with drop height.

Figure 2 illustrates the concept of model inadequacy for the situation where the simulator produces output under the assumption of a vacuum ($\theta = 0$) while data has been generated under the assumption of a positive drag coefficient ($\theta = 0.5$) with a small amount of observation error. In the notation of the previous development, the physical system response is $\zeta(x) = \eta(x, 0.5)$ and the discrepancy function is $\delta(x) = \eta(x, 0.5) - \eta(x, 0)$, that is, the difference between the system response and the simulation model $\eta(x, 0)$. In this example, the simulation model is so simple that there are no calibration parameters. All statistical modeling of these data is concentrated on the discrepancy function. It is important to note that statistical modeling does a reasonable job of predicting the system response within the range of available data, but does quite poorly when extrapolating to drop heights beyond the upper range of the data, as indicated by the rapidly increasing spread in the **quantiles** of the predicted system response. This highlights the difficulty of using extrapolations with an inadequate simulator. This behavior is a consequence of the fact that statistical modeling of discrepancy in this example does not incorporate any knowledge of physics to assist predictive capability in data-poor regimes. Statistical discrepancy modeling can be used to identify the possible presence of

Figure 2 (a) The black trace is the assumed simulation model (vacuum release) and the black dots are data (drag coefficient, 0.5) with two standard deviation error bars. A statistical model was fit to these data ($y(x)$), resulting in 500 predictions of the physical system response $\zeta(x)$. The 11 gray traces are the 0.05, 0.1 (0.1) 0.9, 0.95 quantiles of these predicted curves. (b) The black trace is the discrepancy function $\delta(x)$ and the black dots are residual data ($y(x) - \eta(x, 0)$) with two standard deviation error bars. The 11 gray traces represent the above specified quantiles of 500 discrepancy curve predictions

inadequate physics in simulation models under the following circumstances:

- nonzero discrepancy predictions in the range of the data,
- poor extrapolation of system response predictions.

Of course, absence of these indicators does not imply that the simulation model contains completely adequate physics.

In many applications, there will be no single value of the knobs θ that best matches the data. Many values of θ will give similar results. Multiple experimental datasets will generally be associated with different best estimates of θ . Changing experimental conditions could influence the best θ , such as the degree of laminar or turbulent flow on the best drag coefficient. Different values of θ may be appropriate across changing sets of conditions in dynamic simulations; for example, best material strength parameters varying as a function of strain rate and temperature. For these reasons, the statistical approach to inference about θ assumes that initial uncertainty about the value of θ is represented as a probability distribution. This prior assessment of θ is updated using experimental data and simulation runs to yield a refined assessment of uncertainty in θ . This process

is referred to as *calibration* of the simulation model to experimental data. It is distinct from tuning in that the end product is a probability distribution for θ , while tuning produces a single best estimate for θ . The calibration approach to gaining information about θ recognizes that typically there will be residual uncertainty in knowledge about θ even after updating this knowledge with data and calculations. This remaining uncertainty should be accounted for in any follow-on analysis (such as prediction) involving the knob parameters.

A common inferential problem at this stage is to *predict* the value of experimental data at system inputs x , which are generally composed of input conditions at which no experiment has previously been conducted. That is, the goal is to provide a best estimate with uncertainty bounds for the value of data that would be generated by a future experiment. Several prediction problems are of interest: prediction of physical system response $\zeta(x)$ using the *calibrated simulator*, where the refined uncertainty in the knob parameters from the calibration analysis is essentially propagated through the simulator to predict $\zeta(x)$; prediction of discrepancy $\delta(x)$, where differences between data and simulation model are examined; prediction of $\zeta(x)$ using the discrepancy-adjusted calibrated simulator; and

prediction of experimental data $y(\mathbf{x})$ based on the entire model, which incorporates uncertainties from observation error in addition to the above sources (calibrated simulation and discrepancy). Predictions of discrepancy with uncertainty bars not containing zero can be used as one diagnostic tool for making an assessment of inadequate physics in the simulation model, as discussed previously.

Figure 3 shows results obtained by enhancing the physics of the drop-time simulation model for vacuum environments of Figure 2 to incorporate air resistance. The data set shown in Figure 2 is used to calibrate this improved simulator. Initial uncertainty in the drag coefficient θ was assumed to be uniform on the unit interval $[0, 1]$. The experimental data constrains this uncertainty substantially so that all probability in the calibrated θ is tightly concentrated around 0.5, the value used in generating the data for this example. It is also evident that the reduction in uncertainty of θ due to calibration leads to much more informative (less variable) predictions of the system response. The discrepancy is probabilistically zero in this analysis, so that the calibrated simulator is an effective predictor of the system response. It is evident that extrapolation of the calibrated simulator beyond the upper range of drop heights in the observed data leads to well-behaved predictions of the system response. This is to be expected when the simulation model incorporates all or most of the relevant physics.

Calibration and Prediction for Functional Outputs

The calibration and prediction methodology described above can be extended to functional computer model (and experimental data) outputs. Let $\boldsymbol{\eta}(\mathbf{x}, t)$ denote a vector of computer model output calculated at input specification $(\mathbf{x}, t)$. The output vector can be functional (e.g., velocity as a function of time) or a multivariate collection of selected quantities (e.g., important features extracted from curves). It is assumed that the computer model is expensive to evaluate, so that a limited number of model runs is feasible and a statistical model must be adopted to approximate the computer model output at unsampled inputs based on the information available from the limited runs (*see Computer Experiments*). In particular, the code is run at m different combinations of the inputs $(\mathbf{x}, t)$ as specified by an experimental design (*see Assessment of Experimental Designs*).

Statistical modeling of the computer model output focuses on dimension reduction. An orthogonal basis representation for the code output is specified:

$$\boldsymbol{\eta}(\mathbf{x}, t) = \mathbf{k}_1 w_1(\mathbf{x}, t) + \cdots + \mathbf{k}_{p_\eta} w_{p_\eta}(\mathbf{x}, t) = \mathbf{K} \mathbf{w}(\mathbf{x}, t) \quad (6)$$

The basis vectors $\mathbf{k}_1, \dots, \mathbf{k}_{p_\eta}$ are fixed, while the coefficients $w_i(\mathbf{x}, t)$ are assigned independent, mean-zero Gaussian process (GP) models [4, 5]. A common

Figure 3 (a) Comparison of the initial uncertainty distribution of the drag coefficient θ (gray; 0.05, 0.1 (0.1) 0.9, 0.95 quantiles indicated) with the calibrated distribution (black; 0.05, 0.5, and 0.95 quantiles indicated). (b) Simulation model output for θ set to the indicated quantiles of its initial distribution (gray) and its calibrated distribution (black)

and efficient approach to obtaining an orthogonal set of basis vectors involves calculating the principal components of standardized computer model output via the singular value decomposition. Often fewer than five components are required to explain over 99% of the variation in computer model output, resulting in considerable dimension reduction and hence more efficient statistical analysis.

The statistical model for discrepancy $\delta(\mathbf{x})$ assumes a basis representation as well,

$$\delta(\mathbf{x}) = \mathbf{d}_1 v_1(\mathbf{x}) + \cdots + \mathbf{d}_{p_\delta} v_{p_\delta}(\mathbf{x}) = \mathbf{D} \mathbf{v}(\mathbf{x}) \quad (7)$$

For functional data, the basis vectors $\mathbf{d}_1, \dots, \mathbf{d}_{p_\delta}$ are often chosen to be local in extent (such as a kernel basis) to accommodate nonstationarity that often arises in the discrepancy process. The coefficients $v_i(\mathbf{x})$ are assumed to be independent, zero-mean GP models. Depending on the application, the coefficients may be partitioned into groups having common GP models. The discrepancy and computer model coefficients are assumed *a priori* to be independent.

Each field experiment may produce different amounts of functional data. The code and discrepancy

bases must be interpolated onto the grid of locations available for each of the field experiments. The statistical model for field experiment i is thus given by

$$\mathbf{y}(\mathbf{x}_i) = \mathbf{K}_i \mathbf{w}(\mathbf{x}_i, \boldsymbol{\theta}) + \mathbf{D}_i \mathbf{v}(\mathbf{x}_i) + \boldsymbol{\varepsilon}(\mathbf{x}_i) \quad (8)$$

where $\boldsymbol{\varepsilon}(\cdot)$ represents the observational error model.

These developments are illustrated with computer simulations of a tantalum flyer plate experiment. These experiments are conducted to explore the behavior of materials subjected to high strain rates. Flyer plate experiments involve forcing a plane shock wave through stationary test samples of material and measuring the free surface velocity at the back side of the target as a function of time. This experiment can be modeled as a function of 10 parameters governing the equation of state (EOS), material strength, and spall strength of the target material [3]. Material strength is incorporated through the Preston–Tonks–Wallace (PTW) model of plastic deformation [6]. Seven PTW model parameters are calibrated.

The simulator was run at 128 unique combinations of the 10 calibration parameters as specified by an orthogonal array (OA)-based Latin hypercube design (*see Orthogonal Arrays; Latin Hypercube*

Figure 4 Marginal and bivariate posterior density estimates of 10 calibration parameters. Black contours represent 90% and 50% bivariate posterior probability regions

Figure 5 Assessment of calibrated code predictions and discrepancy. Calculated velocity profiles (gray curves) and velocity measurements (black dots). The black curves give 5%/95% pointwise probability intervals for the calibrated code, system response, and discrepancy predictions (a, b, and c)

Designs) generated from a two-level, strength 3 OA design [7]. For each run in the experimental design, a velocity profile (velocity as a function of time) is calculated. A basis consisting of the first three empirical orthogonal functions computed from the 128 velocity profiles was adopted to represent the simulation outputs. A basis consisting of 31 localized Gaussian kernels was adopted to accommodate considerable nonstationarity in the discrepancy process.

A Bayesian hierarchical model fit of the PTW model to independent stress–strain data provided the prior distribution for all seven material strength parameters, coupled with uniform priors on the initial ranges of the remaining parameters. Figure 4 shows projections of the posterior distributions for all 10 calibration parameters resulting from incorporating the flyer plate experimental data as an additional constraint. Note, in particular, the considerable amount of knowledge gained about the first parameter (EOS perturbation ϵ): it began with a uniform distribution

on $[-5\%, 5\%]$ and calibrates to 95% of its probability on $[-3.34\%, -1.4\%]$.

Figure 5 provides an assessment of computer model performance as measured by the ability of a properly calibrated code to predict experimental data. Substantial discrepancy is present in code predictions of the initial loading phase and throughout the release phase of the flyer plate experiment. The 10 calibration parameters are probabilistically tuned to be consistent with experiment during part of the loading phase and throughout the peak velocity phase.

This article has focused on calibration of uncertain computer model parameters to available experimental data, assessment of calibrated model predictions, and the associated evaluation of model discrepancy. However, the statistical model adopted for these objectives can be used for other analyses as well. In particular, practitioners are often interested in some form of global sensitivity analysis, which involves quantitative assessments of input parameter variations on model output variation [8].

Markov Chain Monte Carlo, Introduction

Introduction to Monte Carlo Simulation

High-dimensional integrals and simulation problems are seen in areas such as statistics, reliability, statistical physics, and so on. For example, in Bayesian statistics, given a prior distribution $P(\theta)$ and a likelihood function $l(\theta|\text{data})$, then the posterior mean of θ is calculated *via* Bayes theorem as

$$E[\theta|\text{data}] = \frac{\int \theta P(\theta) l(\theta|\text{data}) d\theta}{\int P(\theta) l(\theta|\text{data}) d\theta} \quad (1)$$

In many cases, the integrals in the numerator and denominator cannot be evaluated analytically and various alternatives may be considered. One possibility is to use numerical integration techniques (*see Quadrature and Numerical Integration*), and an alternative is to use analytic approximations of the integrands such as the Laplace approximation, (*see e.g. [1] for a general review and Laplace Approximations in Bayesian Lifetime Analysis in the context of lifetime data analysis*). However, the first method suffers strongly from the curse of dimensionality and approximation methods are only appropriate under restricted conditions. A more general approach is to use simulation.

Suppose then that for a variable X with distribution π that we wish to estimate the expected value of some functional $f(X)$. Then the **Monte Carlo** method, see [2], is to generate a sample of values $x_1, \dots, x_N$ from the density π and estimate the expectation using the sample mean

$$E_\pi[f(X)] \approx \frac{\sum_{i=1}^N f(x_i) \pi(x_i)}{\sum_{i=1}^N \pi(x_i)} \quad (2)$$

It is usually difficult or impossible to directly sample from the density π so that certain alternatives such as importance sampling or rejection sampling may be used. A full review of the Monte Carlo approach is

given in **Monte Carlo Methods**. See also **System Reliability: Monte Carlo Estimation**.

In a large number of cases, however, exact Monte Carlo samples may not be easily constructed. Therefore, an alternative strategy is to try to generate an approximate Monte Carlo sample. One approach is to construct a discrete-time stochastic process (**Markov chain**) such that the distribution of the states of the process converges over time to the distribution of interest π when a sample can be taken and used in the same way as a standard Monte Carlo sample. This is the basis of the Markov chain Monte Carlo (MCMC) algorithms.

Markov Chains

Before introducing the different MCMC algorithms, it is first useful to review the properties of Markov chains. A full review is given in, for example [3].

A Markov chain, $\{X_t\}$, is defined to be a sequence of variables $X_1, X_2, \dots$ such that the distribution of X_t , given the previous values $X_0, \dots, X_{t-1}$ only depends on X_{t-1} , so that

$$P(X_t \in A | X_1, \dots, X_{t-1}) = P(X_t \in A | X_{t-1}) \quad (3)$$

for any set A , where, $P(\cdot|\cdot)$ represents a conditional probability. A Markov chain is further said to be time homogeneous if

$$P(X_{t+k} \in A | X_t) = P(X_k \in A | X_0) \quad (4)$$

for any k . A time homogeneous Markov chain is thereby determined by the distribution or value of the initial state X_0 and by the transition kernel

$$P(x, y) = P(X_{t+1} = y | X_t = x) \quad (5)$$

For most problems of interest to us in the context of MCMC, the Markov chain will take values in some subset of $\mathbb{R}^m$ for some possibly large m . However, in order to illustrate the most important concepts, it is convenient to assume that the state space is countable so that the possible states of the chain can be represented as the nonnegative integers $\{0, 1, 2, \dots\}$. We can then denote the t -step transition probabilities as

$$p_{ij}(t) = P(X_t = j | X_0 = i) \quad (6)$$

2 Markov Chain Monte Carlo, Introduction

Then our interest concerns the conditions under which the t -step transition probabilities converge to a stationary distribution π so that

$$p_{ij}(t) \longrightarrow \pi(j) \quad \text{for all } i, j, \quad \text{as } t \longrightarrow \infty \quad (7)$$

so that the distribution of the states of the chain becomes approximately independent of the initial state or distribution as t increases.

A first necessary condition is that the Markov chain is irreducible. A Markov chain is said to be irreducible if every state can be reached from any initial state, that is if $p_{ij}(t) > 0$ for some t and all i, j . Secondly, all states of the Markov chain must be positive recurrent. A state, i , is said to be recurrent, if the Markov chain is certain to return to i , so if we define $\tau_i = \min\{t > 0 : X_t = i | X_0 = i\}$ to be the time taken to return to state i , then $P(\tau_i < \infty) = 1$. A recurrent state i is said to be positive recurrent if its expected recurrence time is finite, that is if $E[\tau_i] < \infty$. For an irreducible Markov chain, it can be demonstrated that if any state is positive recurrent, then all states are positive recurrent. Finally, all states of the chain must be aperiodic. The period of state i is defined to be $d(i)$ where,

$$d(i) = \text{greatest common divider } \{t : p_{ii}(t) > 0\} \quad (8)$$

For an irreducible Markov chain, it can be shown that all states have the same period. The chain is said to be aperiodic if this period is one.

It can then be shown that for an irreducible, positive recurrent, aperiodic Markov chain, a unique stationary distribution π exists so that for all i, j ,

$$\pi(j) = \lim_{t \rightarrow \infty} p_{ij}(t) \quad (9)$$

Moreover, suppose that X is a random variable with distribution π and that $f(X)$ is a function such that $E_\pi[|f(X)|] < \infty$. Then it follows that if $\{X_t\}$ is a Markov chain with stationary distribution π , then

$$\frac{1}{T} \sum_{t=1}^T f(X_t) \longrightarrow E_\pi[f(X)] \quad (10)$$

as $t \rightarrow \infty$.

A sufficient condition for the existence of a unique stationary distribution is that of reversibility. A Markov chain with transition probabilities $p_{ij} =$

$P(X_{t+1} = j | X_t = i)$ is said to be (time) reversible, if there exists a probability density π that satisfies the detailed balance equation so that for any i, j , then

$$p_{ij}\pi(i) = p_{ji}\pi(j) \quad (11)$$

For a time-reversible Markov chain, then it can be immediately demonstrated that π is then a stationary distribution of the Markov chain because, in this case,

$$\sum_i p_{ij}\pi(i) = \sum_i p_{ji}\pi(j) = \pi(j) \quad (12)$$

The previous ideas can be generalized to the case of a continuous state space, although the conditions are slightly more technical, for details, see [4, 20]. In this case, given a transition kernel $P(x, y)$ such that

$$\int_y P(x, y) dy = 1 \quad (13)$$

then the stationary distribution π satisfies

$$\pi(y) = \int_x \pi(x) P(x, y) dx \quad (14)$$

The objective of the MCMC approach is therefore to construct a Markov chain with a given stationary distribution π . A general algorithm for doing this is discussed in the following section.

The Metropolis–Hastings Algorithm

The Metropolis–Hastings algorithm of [5, 6] is a general method of constructing a Markov chain with a given equilibrium distribution $X \sim \pi$. A full description is given in [7]. The algorithm generates a Markov chain in which each state only depends on the previous state as follows.

1. Given the current value, $X_t = x$, generate a candidate value, y , from a proposal density $q(y|x)$.
2. Calculate the acceptance probability

$$\alpha(x, y) = \min \left\{ 1, \frac{\pi(y)q(x|y)}{\pi(x)q(y|x)} \right\} \quad (15)$$

3. With probability $\alpha(x, y)$ define $X_{t+1} = y$ and otherwise reject the proposed value and set $X_{t+1} = x$.
4. Repeat until convergence is judged and a sample of the desired size is obtained.

Firstly, it is clear that the acceptance probability $\alpha(x, y)$ used in the Metropolis–Hastings algorithm only depends on the ratio $\pi(y)/\pi(x)$, which is not dependent upon the integration constant of the density π . Secondly, it is straightforward to demonstrate that π is a stationary distribution of the Markov chain as follows. The transition kernel for the density of a move from x to y is given by

$$P(x, y) = \alpha(x, y)q(y|x) + \left(1 - \int \alpha(x, y)q(y|x) dy\right) \delta_x \quad (16)$$

where δ_x is the Dirac mass at x . Now it is easy to show that

$$\pi(x)q(y|x)\alpha(x, y) = \pi(y)q(x|y)\alpha(y, x) \quad (17)$$

and that

$$\left(1 - \int \alpha(x, y)q(y|x) dy\right) \delta_x = \left(1 - \int \alpha(y, x)q(x|y) dx\right) \delta_y \quad (18)$$

and therefore, we have the detailed balance equation

$$\pi(x)P(x, y) = \pi(y)P(y, x) \quad (19)$$

as in equation (11) which implies that π is the stationary distribution of the chain. Note also that if the proposal density $q(y|x) = \pi(y)$, then the Metropolis–Hastings algorithm simply reduces to standard Monte Carlo sampling.

One might expect that the Metropolis–Hastings algorithm would, in general, be more efficient if the acceptance probability $\alpha(x, y)$ was high. However, this is not the case in general. In [8] it is recommended that for high-dimensional models, the acceptance rate for random walk type Metropolis–Hastings algorithms (see below) should be around 25%, whereas in models of dimension one or two, the acceptance rate should be around 50%. However, general results are not available and the efficiency of a Metropolis–Hastings algorithm will generally be heavily dependent on the proposal density $q(y|x)$. Various possibilities are considered in the following section.

Different Types of MCMC Samplers

Theoretically, the Metropolis–Hastings algorithm can be implemented with almost any proposal density $q(\cdot|\cdot)$. However, the performance of the algorithm can be influenced by the form of this density. Usually, the proposal density is chosen so that it is easy to sample from.

One possibility is to use an independence sampler, see e.g. [9] that is $q(y|x) = q(y)$ independent of x . This will often work very well if the density q is similar to π , although with somewhat heavier tails, in a similar way, to the rejection sampler in standard Monte Carlo sampling.

Another alternative is the Metropolis [5] sampler which has the property that $q(x|y) = q(y|x)$ and has the advantage of simplifying the acceptance probability in equation (15) to $\alpha(x, y) = \pi(y)/\pi(x)$. A special case is the random walk Metropolis algorithm, which assumes that $q(y|x) = q(|y - x|)$.

In many cases, X will be a high-dimensional random variable and it may be much more convenient to implement the Metropolis–Hastings algorithm in blocks $X = (X_1, \dots, X_k)$. The simplest algorithm of this type is the so-called Gibbs sampler (see [10, 11]). In order to illustrate this approach, suppose initially that $X = (X_1, X_2)$ has joint density $\pi(x_1, x_2)$ and that the marginal densities are $\pi_{X_1}(x_1)$ and $\pi_{X_2}(x_2)$, then the Gibbs sampler proceeds as follows:

1. Set an initial value $X_1 = x_{10}$.
2. For $t = 1, 2, \dots$ generate:
 - (a) $X_{2t} \sim \pi_{X_2|X_1}(\cdot|X_1 = x_{1t-1})$
 - (b) $X_{1t} \sim \pi_{X_1|X_2}(\cdot|X_2 = x_{2t})$
 where $\pi_{X_1|X_2}(\cdot|x_2)$ and $\pi_{X_2|X_1}(\cdot|x_1)$ are the associated conditional distributions so that $\pi_{X_1|X_2}(x_1|x_2) = \frac{\pi(x_1, x_2)}{\pi_{X_2}(x_2)}$ and $\pi_{X_2|X_1}(x_2|x_1) = \frac{\pi(x_1, x_2)}{\pi_{X_1}(x_1)}$.

This algorithm can be easily extended to the case of a higher-dimensional X by successively sampling from the full conditional distributions $\pi_{X_i|X_{-i}}(x_i|x_{-i})$ where $X_{-i} = (X_1, \dots, X_{i-1}, X_{i+1}, \dots, X_k)$ of each component at each step.

It is clear that the Gibbs algorithm generates a Markov chain and it can be shown that it corresponds to a composition of Metropolis–Hastings steps with acceptance probabilities equal to 1 and stationary distribution π . Full descriptions of the Gibbs sampler are given in [12, 20].

A number of methods have been developed for the implementation of Gibbs sampling algorithms. Firstly, the adaptive rejection sampler for log concave densities was introduced in [13] and extended to arbitrary densities in [14]. Generic software, e.g. WinBUGS, for implementation of Gibbs sampling based on these methods is available (see [15]), and software for assessing convergence of Gibbs samplers, e.g. CODA, has also been developed (see [16]).

When full Gibbs sampling is impossible, as some of the conditional distributions cannot be sampled directly, it is possible to use Metropolis–Hastings updates in these steps which produces a hybrid, Metropolis–within–Gibbs sampler, see e.g. [9].

Note finally that as well as the various options discussed here, many alternative MCMC samplers have been developed. Of particular importance, we may cite the slice sampler [17] which is a simple approach for sampling relatively low-dimensional distributions and the reversible jump sampler [18], which has been developed to sample over state spaces of various dimensions and the perfect sampler [19] which, for a restricted range of problems, is designed to avoid the problems of assessing MCMC convergence by generating an exact sample from the target distribution π . See e.g. [20] for more details.

Apart from the perfect sampler, although theoretically, the Metropolis–Hastings algorithm guarantees convergence to the stationary distribution. In practice, this may be very slow and the performance of the algorithm will depend on both the initial values chosen to start the chain and the form of the proposal distribution $q(\cdot|\cdot)$. Different convergence monitoring techniques are discussed in the following section.

Monitoring the Markov Chain

The objective of this section is to present the basic techniques for monitoring the output of a Markov chain for convergence. Full reviews of this area are given in, e.g. [21, 23]. Firstly, it is important to assess when the sampled values X_t have approximately converged to the stationary distribution π . This will depend largely on how well the MCMC algorithm is able to explore the state space and also on the levels of correlation between the X_t 's. Secondly, it is important to assess the convergence of MCMC averages $\frac{1}{T} \sum_{t=1}^T f(X_t)$, as in equation (10), and finally we need to be able to assess how close a given sample is to being independent and identically distributed.

When assessing the performance of an MCMC algorithm, one possibility is to consider running the algorithm various times independently with a variety of widely dispersed starting values. Then, for example, one might assess convergence to equilibrium by examining the time at which the sample averages of functionals $f(X)$ of interest have converged for all the chains. Formal diagnostics for doing this are introduced in, e.g. [22].

An alternative is to use a single run of a Markov chain. In this case, it is always useful to produce simple graphs of the generated values X_t *versus* time, which can be used to assess how quickly or slowly the Markov chain moves or any deviations from stationarity. Furthermore, convergence may be assessed using graphs of sample averages as in equation (10). More formal approaches are discussed in, e.g. [23].

Figure 1 shows the states generated using the Metropolis sampler described in the section titled “Example” when this is run for 5000 iterations starting from the same initial value with standard deviations of 50 and 0.01, respectively.

In the first case, the chain mixes quite badly; only 3% of the proposed values are accepted and the chain spends relatively long periods in the same state before jumping to another value. In the second case, almost all of the proposed values (around 99%) are accepted, but it is clear that the chain has not explored the full sample space. We can improve the mixing of the chain by changing the standard deviation of the proposal distribution. It is often useful, in general, to use the first part of a Metropolis–Hastings run to tune the sampler (for example, by varying the variance of the proposal distribution) to achieve reasonable mixing and movement through the state space so that equilibrium can be reached.

Even when convergence has been assessed, it is important to take into account that for any Markov chain–based sampler, the output is correlated. Although this does not affect the estimation of the mean, a standard Monte Carlo estimate of the variance of X ,

$$\frac{1}{T} \sum_{i=1}^T (x_i - \bar{x})^2 \quad (20)$$

will underestimate the true variance because of the positive correlation between the sampled data. One method of taking this into account is to calculate the

Figure 1 Metropolis samplers showing poor mixing properties

effective sample size T/κ , where $\kappa = 1 + 2 \sum_{i=1}^{\infty} \rho_i$, where ρ_i is the autocorrelation (see **Autocorrelation Function**) of lag i (see [24]). For example, in the case discussed earlier of running the Metropolis sampler with $\sigma = 50$, for 5000 iterations, the effective sample size is approximately 125.

A full review of the different strategies for improving the convergence and mixing of MCMC algorithms is given in **Convergence and Mixing in Markov Chain Monte Carlo**.

Example

We wish to sample a distribution of the form

$$\pi(x) \propto \phi\left(\frac{x + 0.94}{5/\sqrt{14}}\right) \bar{\Phi}\left(\frac{5 - x}{5}\right)^6 \quad (21)$$

where $\phi(x) = \exp(-\frac{1}{2}x^2)$ is the standard normal density function and $\bar{\Phi}(x) = \int_x^{\infty} \phi(u) du$ is the normal survivor function. This distribution is the posterior distribution derived from observing a sample of 20 normally distributed lifetimes with mean x and standard deviation 5, $Z_i|x \sim N(x, 25)$, where 14 values less than 5, say $z_1, \dots, z_{14}$ are observed completely and have mean -0.94 and the remaining 6 values are truncated so that it is only known that they take values greater than 5 and a uniform prior distribution for X is assumed.

We shall consider three different MCMC samplers: an independence sampler $q(y|x) = N(0.85, 5)$, a Metropolis sampler $q(y|x) = N(x, 5)$ with initial values $x_0 = 0.85$ in both cases, and thirdly a Gibbs.

The Gibbs sampler is implemented by defining and introducing truncated normal latent variables $Z_i|x \sim TN(x, 5)$ such that $Z_i > 5$, for $i = 15, \dots, 20$ to represent the true values of the truncated normal data. Note that it is straightforward to sample from a truncated normal distribution *via* rejection sampling (see e.g. [25]; **Monte Carlo Methods**). Given the full sample $z_1, \dots, z_{14}, Z_{15} = z_{15}, Z_{20} = z_{20}$, the conditional density of X is normal

$$X|z_1, \dots, z_{14}, z_{15}, \dots, z_{20} \sim N\left(\frac{0.94 \times 14 + \sum_{i=15}^{20} z_i}{20}, \frac{5}{\sqrt{20}}\right) \quad (22)$$

This leads to the Gibbs sampling algorithm:

1. Fix $x_0 = 0.85$.
2. For $t = 1, 2, \dots$
 - (a) Generate $z_{ti} \sim TN(x_{t-1}, 5)$ for $i = 15, \dots, 20$.
 - (b) Calculate $\mu_t = (0.94 \times 14 + \sum_{i=15}^{20} z_{ti})/20$.
 - (c) Generate $x_t \sim N(\mu_t, 5/\sqrt{20})$.

Figure 2 gives the convergence of the means $\frac{1}{T} \sum_{i=1}^T x_i$ for each of the three algorithms. In this case, the mean for the Gibbs algorithm has converged after about 5000 iterations, whereas the Metropolis and independence samplers perform somewhat worse. In Figure 3 a histogram of the data generated from

Figure 2 Convergence of the sample estimates of $E[X]$

Figure 3 Histogram of the Gibbs-sampled data and fitted density estimate

the Gibbs algorithm along with an estimate of the density function of X is shown. The modal value is very close to 2 which was the true value of x used to generate these data.

Laplace Approximations in Bayesian Lifetime Analysis

Introduction

The French mathematician and astronomer Pierre-Simon Marquis de Laplace (1749–1827) receives the most credit from statisticians for his seminal work on the central limit theorem, which in turn fueled the development of statistical asymptotic theory. Laplace of course was one the original “Bayesians”, as evidenced by his mathematical system of inductive reasoning and the resulting *rule of succession*. Perhaps not surprisingly, the roots of Laplace approximation can also be traced to a Bayesian problem, as reported in [1], where, in 1774, Laplace solved a quandary Thomas Bayes could not. He was able to construct the posterior distribution of a binomial probability arising from a uniform prior, which led to an approximation of the incomplete beta-function. Further modifications on this approximation method resulted in Laplace’s Fourier-type inversion formula for point probabilities associated with the generating function of a sum of independent discrete random variables [1]. It is noteworthy that this approximation method was also influential in Laplace’s development of the central limit theorem and was later generalized greatly to the behavior of sums of independent variables.

In the rest of this article, we will first briefly introduce the paradigm of Bayesian inference. Please see **Bayesian Reliability Analysis, Empirical Bayes Estimation of Reliability**, and the references therein for more detailed introduction and more comprehensive treatment of this vast area. We will then provide some details of the mechanics and the properties of Laplace approximation followed by a few examples of its use in **Bayesian reliability** literature, as a modest attempt to demonstrate the method’s utility in this area.

A Brief Introduction to the Bayesian Paradigm

Observed data are used to test scientific hypotheses, which are often stated in the form of probability distributions with unknown parameters. In

the perhaps more familiar frequentist (also known as *classical*) statistics approaches, these parameters are treated as fixed yet unknown constants to be estimated from the observed data. In contrast, the Bayesian framework treats these parameters as random variables and allows *a priori* beliefs about them to be expressed *via* what are called *prior distributions*. As relevant data becomes available, these priors are updated and the modified knowledge is expressed *via* what are called *posterior distributions*. These posterior distributions provide the basis for Bayesian inference. We will now briefly summarize the procedure involved in data-based updating procedure that leads to these posterior distributions mainly to set up the notation that will be used in the rest of this article.

As stated above, the Bayesian approach is based on the assumption that the unobserved parameter vector Θ is random and has a known distribution $\pi(\Theta)$, called the *prior distribution*. A Bayesian statistical model can be dissected into the following components [2]:

1. an observed random variable or random vector $\mathbf{X} \in \mathbf{X}$, where $\mathbf{X}$ is the data and $\mathbf{X}$ is the sample space;
2. an unobserved random variable or vector $\underline{\Theta} \in \Omega$, where Ω is the parameter space;
3. the conditional density $f(\mathbf{X}|\underline{\theta})$ of $\mathbf{X}$ given $\underline{\theta}$, also called the *likelihood*; and
4. the marginal density $\pi(\underline{\theta})$ of $\underline{\theta}$, also called the *prior*.

As stated above, most Bayesian inferential procedures depend on the so-called *posterior distribution* of $\underline{\Theta}$, which is defined as the conditional distribution of $\underline{\Theta}$ given $\mathbf{X}$. This posterior distribution can be obtained using the components provided above *via*

$$f(\underline{\theta}|\mathbf{X}) = \frac{f(\mathbf{X}|\underline{\theta})\pi(\underline{\theta})}{\int f(\mathbf{X}|\underline{\theta})\pi(\underline{\theta}) d\underline{\theta}} \quad (1)$$

This posterior distribution represents the updated knowledge about $\underline{\Theta}$ based on the observed data, $\mathbf{X}$.

Note that the functional form of the posterior is highly dependent on the form of the prior distribution, which represents our beliefs about the parameters before data collection. When little or no information is available about the parameters, it could be difficult to find a suitable prior. In such cases, what is called a *noninformative prior* can be used. Such priors

2 Laplace Approximations in Bayesian Lifetime Analysis

assign equal probability to each possible value of the parameter and they are often improper, i.e. they have infinite mass.

In principle, the posterior distributions can always be obtained; however, if the problem at hand is complex enough—and many realistic applications are—or when the problem formulation does not involve a conjugate prior-likelihood pair, then the necessary integrals may not be available in a closed form and thus, they may have to be approximated or numerically estimated. The Laplace's approximation is a desirable analytical method which may be employed for this purpose. It is often more accurate than the normal approximation, yet it is not as computationally intensive as purely numerical methods such as Markov chain Monte Carlo (*see* [3]; **Hierarchical Markov Chain Monte Carlo (MCMC) for Bayesian System Reliability; Markov Chain Monte Carlo, Introduction**).

Laplace's Approximation Method

Laplace's method attempts to approximate the density to be integrated by a **normal distribution** centered at the posterior mode. The variance of this normal distribution is given by the inverse of the second derivative of the log-posterior density evaluated at its mode. As long as the posterior distribution is unimodal, or it is at least dominated by a single mode, this approximation will produce reasonable results [4], provided the dimensionality of the parameter vector is not too high compared to the available sample size.

Laplace's approach to approximating integrals has wide applicability as it can be employed with all functions that can be expressed in the following form:

$$I = \int f(\underline{\theta}) \exp\{-nh(\underline{\theta})\} d\underline{\theta} \quad (2)$$

In equation (2), f is assumed to be a smooth positive function of $\underline{\theta}$, which is a p -dimensional parameter vector; and h is a smooth function of $\underline{\theta}$ where $-h$ has a maximum at $\hat{\underline{\theta}}$. The intuition behind the Laplace approximation is as follows [1]: Suppose that $\exp\{-nh(\underline{\theta})\}$ has a very strong peak at $\hat{\underline{\theta}}$ and decreases very rapidly as one moves away from $\hat{\underline{\theta}}$ on $\theta \in \Omega$ as $n \rightarrow \infty$. Then as $n \rightarrow \infty$, the major contribution to I can be attributed to the behavior of the integrand in a small neighborhood around $\hat{\underline{\theta}}$. The approximation of equation (2) is achieved by

expanding f and h using Taylor series about $\hat{\underline{\theta}}$. In the univariate case, the presentation given in [5], can be summarized as follows [6]:

Using a Taylor series expansion on f and h ,

$$\begin{aligned} I &\approx \int \left[f(\hat{\theta}) + \frac{f'(\hat{\theta})}{1!}(\theta - \hat{\theta}) \right. \\ &\quad \left. + \frac{f''(\hat{\theta})}{2!}(\theta - \hat{\theta})^2 \right] \times \exp \left\{ -nh(\hat{\theta}) \right. \\ &\quad \left. - \frac{nh'(\hat{\theta})}{1!}(\theta - \hat{\theta}) + \frac{nh''(\hat{\theta})}{2!}(\theta - \hat{\theta})^2 \right\} d\theta \\ &= e^{-nh(\hat{\theta})} \int \left[f(\hat{\theta}) + \frac{f'(\hat{\theta})}{1!}(\theta - \hat{\theta}) + \frac{f''(\hat{\theta})}{2!} \right. \\ &\quad \left. \times (\theta - \hat{\theta})^2 \right] \times \exp \left\{ -\frac{(\theta - \hat{\theta})^2}{2(nh''(\hat{\theta}))^{-1}} \right\} d\theta \quad (3) \end{aligned}$$

since $h'(\hat{\theta}) = 0$ from the definition of $\hat{\theta}$. Given that the exponential term inside the integral is proportional to an $N\left(\hat{\theta}, \frac{1}{nh''(\hat{\theta})}\right)$ density for θ , this implies that the $f'(\hat{\theta})(\theta - \hat{\theta})$ term will vanish since $E(\theta - \hat{\theta}) = 0$. Therefore the integral can be approximated as

$$\hat{I} \approx e^{-nh(\hat{\theta})} f(\hat{\theta}) \left(\frac{2\pi}{n} \right)^{1/2} \sigma \left(1 + \frac{f''(\hat{\theta})}{2f(\hat{\theta})} \sigma^2 \right) \quad (4)$$

where $\sigma = (h''(\hat{\theta}))^{-1/2} = O(\frac{1}{n})$.

For the cases where $\underline{\theta}$ is p dimensional, the approximate integral can be written as

$$\hat{I} \approx (2\pi)^{p/2} \{\det(nD^2h(\hat{\underline{\theta}}))\}^{-1/2} f(\hat{\underline{\theta}}) \exp\{-nh(\hat{\underline{\theta}})\} \quad (5)$$

where $\hat{\underline{\theta}}$ maximizes $-h(\underline{\theta})$ and where $D^2h(\hat{\underline{\theta}})$ is the Hessian matrix of h evaluated at $\hat{\underline{\theta}}$.

The seminal work in [4] provides a modification to this general approach, which is tailored for obtaining the marginal posterior densities necessary for Bayesian analysis. The authors note that their approach is similar to the saddle-point method [7] and proceeds as follows:

Consider the partition $\underline{\theta} = (\theta_1, \dots, \theta_p) = (\theta_1, \underline{\theta}_2)$, where θ_1 is the first component of $\underline{\theta}$ and $\underline{\theta}_2$ is a $(p-1) \times 1$ vector composed of the remaining components. Let $\hat{\underline{\theta}} = (\theta_1, \hat{\underline{\theta}}_2)$ represent the posterior

mode, i.e. $\hat{\theta}$ maximizes πe^ℓ , where π is the prior density and ℓ is the log-likelihood function. Now define Σ , a $p \times p$ matrix, as the negative inverse of the Hessian of $\frac{\ell + \ln \pi}{n}$ at $\hat{\theta}$. Note that for a given θ_1 , $\hat{\theta}_2^* = \hat{\theta}_2^*(\theta_1)$ is a $(p-1) \times 1$ vector and it maximizes $h(\cdot) = \pi(\theta_1, \cdot) e^{\ell(\theta_1, \cdot)}$. In other words, the function $h(\cdot)$ is equivalent to πe^ℓ with θ_1 held fixed. Similarly, we can define $\Sigma^* = \Sigma^*(\theta_1)$, where Σ^* is a $(p-1) \times (p-1)$ matrix and represents the negative inverse of the Hessian of $\frac{\ln h(\cdot)}{n}$. The following expression can be used to obtain the marginal posterior of θ_1

$$\pi_1(\theta_1 | \mathbf{X}^{(n)}) = \frac{\int \pi(\theta_1, \theta_2) e^{\ell(\theta_1, \theta_2)} d\theta_2}{\int \pi(\theta) e^{\ell(\theta)} d\theta} \quad (6)$$

and applying Laplace's method to its numerator and denominator leads to the following approximation:

$$\hat{\pi}_1(\theta_1 | \mathbf{X}^{(n)}) = \left(\frac{\det \Sigma^*(\theta_1)}{2\pi n \det \Sigma} \right) \frac{\pi(\theta_1, \hat{\theta}_2^*) e^{\ell(\theta_1, \hat{\theta}_2^*)} d\theta_2}{\pi(\hat{\theta}) e^{\ell(\hat{\theta})} d\theta} \quad (7)$$

It has been shown [4] that the error associated with this approximation is

$$\pi_1(\theta_1 | \mathbf{X}^{(n)}) = \hat{\pi}_1(\theta_1 | \mathbf{X}^{(n)}) \left(1 + O_{\theta_1} \left(\frac{1}{n} \right) \right) \quad (8)$$

where $O_{\theta_1}(\frac{1}{n})$ is of order $O(\frac{1}{n})$ and depends on θ_1 . Given the true parameter vector $\underline{\theta}_0$, under certain regularity conditions [8] it can be shown that for θ_1 in some fixed neighborhood of $\theta_{0,1}$, the first component of $\underline{\theta}_0$, the error term $O_{\theta_1}(\frac{1}{n})$ is uniformly of order $O(\frac{1}{n})$. In contrast, the absolute error of the usual normal approximation is only of order $O(\frac{1}{\sqrt{n}})$. Recall that the relative error of all Edgeworth-type approximations, which include the normal approximation, usually tends to zero at a rate of $1/\sqrt{n}$ on neighborhoods that shrink toward $\theta_{0,1}$ [4]. The error in equation (8) is larger mainly due to the fact that the dimensions of the two integrals in the numerator and the denominator are different. The error in the functional form of $\pi_1(\theta_1 | \mathbf{X}^{(n)})$ is in fact on the order of $O(\frac{1}{\sqrt{n}})$ in $1/\sqrt{n}$ neighborhoods of $\hat{\theta}_1$. It is the constant of integration which is associated with the larger error.

As an illustration, consider a case where a new product is tested until it fails. Suppose 120 items

are put on test and the variable of interest is posterior odds, i.e. the ratio of the number that failed over the number that did not. In this scenario, let Y , the number of items that fail, have a binomial distribution, i.e. $Y \sim \text{Binomial}(120, \theta)$. Suppose prior experience indicates that a Beta(1, 5) is an appropriate prior for θ . Then the marginal distribution of the posterior odds, $\lambda = \frac{\theta}{1-\theta}$ can be easily obtained using the Laplace approximation. In this case, the exact distribution is also analytically tractable and can be obtained by simply generating realizations from the posterior distribution of θ and calculating the value of λ for each realization. The following plot displays the exact distribution as well as the marginal posterior obtained *via* the Laplace approximation. As expected the agreement between the two curves is quite good (Figure 1).

Some Example Applications from Bayesian Reliability Literature

In this section, we provide a few application examples from the reliability literature where Laplace approximation was utilized. The examples below are not meant to be comprehensive in any way and they were chosen without any particular criteria other than their familiarity to the author.

Laplace approximations have been used in Bayesian residual analysis of regression models for lifetime data with and without censoring [9]. In this work, posterior probabilities of observations being **outliers** have been obtained utilizing an approach

Figure 1 The exact distribution and the corresponding laplace approximation of the marginal distribution of posterior odds ratio

similar to the one that led to Cox–Snell residuals [10]. The posterior distributions of the realized errors, which represent the uncertainty about the functions of the parameters, are obtained *via* Laplace approximations, which are then used to estimate realized errors *via* intervals.

Laplace approximations have also been employed in estimating the survival function of the Pareto distribution of the second kind in the context of failure-censored data [11]. In this work, the authors compared their approach to an alternative technique proposed by Lindley [12] and to the maximum-likelihood method. They concluded that for small samples, the approach in [12] was slightly superior, whereas for large samples, all three methods gave comparable results.

Laplace approximations have been popular especially in the context of Bayesian accelerated testing applications (*see Accelerated Life Models; Accelerated Life Tests; Bayesian Design; Accelerated Life Tests: Designs Comparison within a Bayesian Framework*). The link functions used in this setting to represent the dependence of the survival distribution parameters on the acceleration variables often lead to intractable integrals for the posteriors, providing a fertile ground for the use of approximation or numerical methods. For example, Laplace’s method along with Jeffreys’ and reverse-reference priors was used in constructing the marginal posterior distributions of the acceleration and the model parameters associated with the accelerated inverse Gaussian distribution in a cumulative damage setting [13]. Similarly the approach was employed in modeling accelerated life test data under a stress–response relationship with a threshold stress, where the lifetimes are assumed to be exponential [14].

Discussion

Having introduced the Laplace approximation method, it may be useful to summarize some of its advantages and disadvantages [6]. Laplace’s method has been desirable partially due to the fact that it is not very complex and is relatively fast computationally, since it does not require an iterative algorithm. Further, since the approach requires numerical differentiation, it is often easier and numerically more stable than techniques that require numerical integration. Additionally Laplace’s method

does not rely on random numbers, i.e. it is deterministic, and hence the consistency of the results can be checked by other users provided the same prior, the same model, and the same data set are used.

Laplace’s approximation also has several limitations. As mentioned previously, in order to achieve a valid approximation, the approach requires a posterior distribution which is at least dominated by a single mode. Further, the accuracy of the approximation depends on the parameterization used (e.g. θ vs $\log \theta$), which could be problematic since choosing the correct one may be difficult. On this issue, the use of a variance-stabilizing transformation is recommended in order to enhance the performance of the Laplace approximation method [15–17]. Another possible limitation of the Laplace method is that the size of the data set used must be fairly “large” – where “large” is likely to be problem specific. One of the major drawbacks of the method however, is the fact that the associated asymptotics are in n , which implies that in order to improve the accuracy of the approximation, one needs to collect more data. Finally, if $\underline{\theta}$ is moderate-to-high dimensional, it will not only be very difficult to perform the required computations associated with the Hessian matrices, but the accuracy of the approximation provided by Laplace’s method will often be insufficient as well. It has been suggested that the Laplace approximation is reliable when the dimension of the parameter vector, $p = O(n^{1/3})$, and some modifications have been proposed [18] when the intention is to use the method to approximate high-dimensional integrals.

Since the Tierney and Kadane [4] paper, which largely enabled the use of Laplace approximation in both Bayesian and non-Bayesian applications, other attractive and largely computational alternatives, most notably Markov chain Monte Carlo, have emerged and have been made accessible to a large audience *via* user friendly software such as WinBugs (<http://www.mrc-bsu.cam.ac.uk/bugs/>). Despite the availability of such alternatives, Laplace’s approximation remains a viable option especially for problems that are not excessively complex or very high dimensional.

Neural Networks in Statistical Process Control

Introduction

The resurgence of research interests in neural computing came about in the early 1980s. Enormous interest exists in studying and applying neural computing in almost all fields of science and technology (engineering, business, and medical science, to name a few). The application of **neural networks** in industrial, production engineering or related domains started gaining popularity in the latter 1980s. The momentum of the growing research interest peaked around the mid-1990s and is still sustaining a high interest level as of 2006. The tremendous interest and wide applicability of neural computing theories and technology motivate researchers to explore how this class of modeling tools can be effectively applied to statistical process control (SPC).

The fundamental issue at the core of classical statistical quality control has remained relatively unchanged since the introduction of **control charts** by Walter Shewhart in the 1920s (*see Statistical Quality Control*). The basic principle for a control scheme is to signal an out-of-control state when the behavior of critical quality variables in a process is considered statistically abnormal, but also to leave the process intact when no evidence of statistical abnormality is present. However, as a result of modern computer and data acquisition technology, the manifestation of an out-of-control state in a process may take various forms, e.g., characteristically patterned or highly autocorrelated. Under the circumstances, the data collected often render the traditional statistical control charts ineffective or inapplicable. From the process improvement point of view, practitioners desire to have the knowledge about a faulty process beyond just “a violation of a certain set of control limits, e.g., 3σ ” (*see Control Charts and Process Capability; Quality Management, Overview; Six Sigma*). The aforementioned concerns have been recognized and the need to identify nonrandom or unnatural patterns was well documented long ago, e.g., in the widely referenced *Statistical Quality Control Handbook* [1]. They also have drawn keen attention from the statistical quality control research community in the last couple

of decades (*see Sampling Inspection of Products and Statistical Process Control; Control Charts, Overview; Control Charts for the Mean; Exponentially Weighted Moving Average (EWMA) Control Chart; Cumulative Sum (CUSUM) Chart; Multivariate Control Charts Overview; Hotelling's T^2 Chart; Multivariate Exponentially Weighted Moving Average (MEWMA) Control Chart; Multivariate Control Charts, Interpretation of; Control Charts for Short Production Runs; Control Charts for Batch Processes; Control Charts, Selection of; Statistical Process Control in Clinical Medicine*).

Two primary categories of problems are the detection of shifts and the recognition of unnatural patterns from the process monitored. The former is concerned with process mean shift, which may occur when the process variable is independently and identically distributed (i.i.d.), or under some underlying structure such as **autocorrelation** (*see Autocorrelated Data*). The latter focuses on patterns exhibited within the typical control limits, which cannot be recognized using conventional decision criteria. The neural network-based schemes are flexible and adaptable enough to deal with both categories of problems. The expanded capabilities to distinguish between mean shift and structural change or patterns are of great value for the purpose of process control. The article focuses on various models appropriate in the SPC context and the general modeling approach employing various neural network algorithms.

Process Models

Modeling Unnatural Patterns and Shifts

The realization of a process variable over time, X_t , can be considered comprising of the process mean and two noise components, i.e., one from the random cause and the other is a special disturbance from assignable causes, as expressed in equation (1).

$$X_t = \mu + x_t + d_t \quad (1)$$

where

- X_t : quality measurement at time t ,
- μ : process mean when the process is in control,
- σ : process standard deviation when the process is in control,

2 Neural Networks in Statistical Process Control

- x_t : random normal variate at time t , $x_t \sim N(0, k\sigma)$, $0 < k \leq 1$,
 d_t : special disturbance at time t .

Note that d_t may take in various forms to model unnatural patterns such as trends, cycles, systematic variables, mixtures, stratification, and sudden shift in level, and so on [2]. A shift in process mean can be expressed as a type of unnatural pattern.

Modeling Shifts under Autocorrelation

Let Z_t represent the generic form of an autoregressive and moving average (ARMA) model (see **Large Autoregressive Integrated Moving Average (ARIMA) Modeling**). Suppose the process under consideration is one that has an additive, deterministic step shift of magnitude, δ , at some point of time, ψ . Then the process can be represented by equation (2).

$$X_t = Z_t + \delta h_t \quad (2)$$

where

$$h_t = \begin{cases} 0 & \text{if } t < \psi \\ 1 & \text{if } t \geq \psi \end{cases} \quad (3)$$

Modeling Shifts in Multivariate Processes

Suppose there are p process variables which are jointly distributed following a p -variate **normal distribution** with known mean vector μ , and known **covariance** matrix Σ . Equation (4) represents a multivariate process.

$$X_t = \mu + x_t + \Delta_t \quad (4)$$

where

- X_t : a vector of p quality measurements at time t ,
 μ : a vector of process means when the process is in control,
 x_t : a vector of random normal variate at time t , x_t follows a p -variate normal distribution with mean vector of zeros and known covariance matrix Σ ,
 Δ_t : step shift vector at time t .

Modeling Shifts in Multivariate Autocorrelated Processes

A multivariate autocorrelated process of p variables can be expressed as a vector autoregressive

model. Equation (5) represents a Vector Autoregressive model of order p , or VAR(p).

$$Y_t - \mu_t = \Phi_1(Y_{t-1} - \mu_{t-1}) + \Phi_2(Y_{t-2} - \mu_{t-2}) + \cdots + \Phi_p(Y_{t-p} - \mu_{t-p}) + \varepsilon_t \quad (5)$$

where μ_t is the vector of mean values at time t , ε_t is an independent multivariate normal random vector with the mean vector of zeros and covariance matrix Σ , and Φ_i ($i = 1, 2, \dots, p$) is a matrix of autocorrelation parameters.

Let $Z_t = Y_t - \mu_t$. Equation (6) describes a process that has an additive, deterministic step shift vector, Δ , beginning at some point of time, ψ .

$$X_t = Z_t + \Delta h_t \quad (6)$$

where

$$h_t = \begin{cases} 0 & \text{if } t < \psi \\ I & \text{if } t \geq \psi \end{cases} \quad (7)$$

The above models represent some of the widely characterized processes. Other forms of process models are possible.

Neural Network Modeling

Algorithms

Some of the neural network algorithms that have been adopted include two-layer, multilayer perceptrons with the widely used and proven learning algorithm backpropagation [2, 3], radial basis function (RBF) [4], Boltzmann machines [5, 6], adaptive resonance theory (ART) [7, 8] and its variants ARTMAP and fuzzy ARTMAP [9], and learning vector quantization (LVQ) network [10]. The data types handled can be coded binary or raw analog data series. The network output is in the form of pattern class, predicted magnitude of the shift, or value of the observation in the series. The network training regimes include supervised, e.g., backpropagation, and unsupervised, e.g., ART. Supervised training requires the desired or target output to be presented during the learning, while unsupervised training does not. In terms of the functionality of the system developed, it can be a general-purpose or special-purpose system.

Beyond doubt, the backpropagation algorithm is the most widely adopted in building neural networks

for a wide range of applications including both pattern recognition and shift detection. The standard backpropagation uses a generalized Delta rule [3] that updates network connection weights according to the gradient descent method using equation (8).

$$\Delta w_{ij} = \eta \delta_i o_j \quad (8)$$

where o_j is the actual output of the j th unit, η is the learning constant and δ_i is defined as follows:

$$\delta_i = (t_i - o_i) f'(net_i) \quad (9)$$

where $f'(net_i)$ is the derivative of the activation function f for the i th unit evaluated at the net total input net_i and t_i is the desired output of the i th unit. Two of the most widely used activation functions are the sigmoid (equation 10) and the hyperbolic tangent (equation 11).

$$f(z) = (1 + e^{-z})^{-1} \quad (10)$$

$$f(z) = \frac{e^z - e^{-z}}{e^z + e^{-z}} \quad (11)$$

For more discussions about neural networks, *see* [11, 12] and **Neural Networks: Construction and Evaluation**. For a review of applying neural networks to SPC, *see* [13].

The Modeling Process

The modeling process typically consists of two stages, namely, network development and performance evaluation. In the network development stage, one has to determine the following key parameters: the window size of input data, the number of hidden layers and hidden nodes, the number of output nodes, the size of the training file, the size of the testing file, the learning rule, the **transfer function**, the training termination or convergence criterion, and so on. These decisions have direct impact on the capabilities of the trained network. Depending on detecting shifts or recognizing patterns, the requirement of the window size varies. The window size should be as small as possible, say five or lesser, and yet sufficient to capture the nature of the data series. When the underlying structure of the process data is more complex, such as autocorrelation, or the patterns of interest are more complicated, such as concurrent presence of multiple patterns or features, the window size has to be sufficiently large, say 50 or more. *See* [14–16]

for some guiding principles, e.g., avoid ambiguity, adequate representation, and balanced representation, in designing the training data sets. The goal at the end of this stage is to develop a network that has not only learned all the training examples well but can also be applied to new, unseen data series with reasonable generalization capabilities. Root mean squared (RMS) errors are frequently used as the measure to determine the stability of learning or if a satisfactory level of training has been reached.

Performance Evaluation

To evaluate the capabilities of the trained network, one needs to measure the probabilities of type I and type II errors. In the case of shift detection, the primary concern is how quickly the trained network can detect the shift when it actually occurs without generating too many false alarms. Similar to the conventional SPC measures, average run length (ARL) is a useful performance measure (*see* **Average Run Lengths and Operating Characteristic Curves**). Given a prespecified in-control ARL, the trained network is “tuned” to a corresponding level of discriminating **power**. For instance, this level will be determined by choosing an appropriate output activation threshold value in a backpropagation neural network.

In the case of pattern recognition, one is concerned with not only the correct classification rates but also the timeliness of the recognition. Run length measures similar to the conventional ARL should be considered. However, depending on the number of pattern classes to be recognized, the possible outcomes for each classification are not dichotomous. Therefore, the run length must be based only on the correct classifications. Target-pattern-based measures and ARL indices, which combine both the correct classification rate and the ARL, should be used [2].

An Illustrated Example

Consider a situation whereby two vendors order the same type of goods from the same supplier. The order quantities placed by each vendor form a **time series** with autocorrelation. Owing to the common demand population and the common source of supply, the two vendors’ order quantities are also cross-correlated, thus, the order quantities follow a VAR(1)

Figure 1 VAR(1): The standardized order quantities

model. At some point in time, one of the vendors embarked on a promotional drive to stimulate the demand. Over a 3-month period, order quantities were collected and shown as in Figure 1. The data are preprocessed as moving windows of data (see Figure 2) and presented to a backpropagation neural network previously trained for similar data. The network has a configuration of 100 input nodes and 5 output nodes, with no hidden layers. The 100 input nodes receive 50 pairs of (X, Y) observations. The five output nodes represent shift in X , shift in Y , autocorrelation in X , autocorrelation in Y , and cross-correlation between X and Y , respectively.

Figure 3 presents the neural network output chart for the first two output nodes, i.e., shift in X and shift in Y . The chart clearly indicates the progression of the two time series. The upward shift in order quantities from vendor Y can be clearly observed. In fact, the mean increases by an amount equivalent to 0.5 times the standard deviation of the existing ordering process from observation no. 60 onward. With proper tuning of in-control ARL, the cutoff threshold is set at 0.190768. The neural network-based control scheme detected the shift and identified the source at observation no. 65 (or in window no. 16).

Figure 2 Moving windows for neural network input

Strengths

Being flexible, adaptable, and capable of learning are the three major strengths. A neural network can be trained for a wide range of data. Unlike traditional statistical approaches, to apply a trained network does not require assumptions about the data distribution, the time series model, or the prediction errors of the new data. The approach is relieved of the requirement of the validity of typical statistical assumptions. Neural networks are more flexible and can be applied to a wider range of data.

The capabilities of a network are closely dependent on the data upon which it was trained. By carefully designing and selecting the training data set, a network can be trained to adapt to any particular data set or a set of features. For example, one may adapt a network to focus more on small to moderate shifts by providing more training data of such features. Neural networks are more adaptable and ideal for developing special-purpose systems.

By presenting the training data to a neural network, the network learns to capture the features or form clusters from the data. In addition to learning from the given desired outputs, so-called supervised learning, neural networks can also learn to form unknown clusters or pattern classes. The progression of learning can be in stages at different times and cumulative. In other words, what is learned in the past can become part of the memory and the basis upon which new learning may take place.

Weaknesses

A lack of analytical robustness and the need for intensive data are the two major weaknesses. The production of the data sets used in training and/or testing

Figure 3 The neural network output chart

involves some degree of randomness. The process of iterative training itself also involves randomness. Despite the efforts in producing pseudorandom data and in training for stability, the resultant trained network is not an outcome of some analytical modeling. As a result, the outcome is often data-dependent or training-dependent making it difficult to offer a robust analysis or explanation of the results. In terms of the amount of data required, the neural network approach suffers from the scalability problem, e.g., when dealing with processes of high dimension.

Summary

The pattern classification capability of neural networks enables one to develop pattern recognizers while the adaptive learning capability allows networks to be “equipped” for different types of patterns or different purposes for process control. As the nature of modern industry or business transactions evolves and the mode of data acquisition advances, the need for dealing with complex and enormous amounts of data becomes more pressing. As demonstrated in this article, it is promising to explore further the utility of neural networks in dealing with data collected from autocorrelated processes in a multivariate setting. The advantages of the neural network approach over the traditional statistical approaches in such applications will depend highly on the ability to interpret the neural network outputs and the diagnosis of the assignable causes associated with each of the variables. These two domains must be integrated to develop a highly automated and intelligent neural network-based SPC system. Much work remains to be done.

Bayesian Robustness: Theory and Computation

Introduction

Robustness is an important issue in Bayesian analysis, being concerned with the sensitivity of the analysis itself to the assumptions of the model adopted, in particular, to the prior distribution which is usually difficult to assess in practice.

The state of the art up to the year 2000 is reviewed in [1]; in particular, in [2] an overview of the robust Bayesian approach is presented; this latter is usually subdivided into the global robustness approach, in which the class of all priors compatible with the elicited prior information is considered, and the local robustness approach, where the interest is in the rate of change in inferences with respect to changes in the prior.

Most contributions to the subject are of a theoretical nature and not much work has been done about effective algorithms for robustness. As a result, this article is quite technical mathematically, reflecting the nature of the work done on the subject up to now. Developing effective and practical algorithms for Bayesian robustness that work in general situations has proved difficult to do.

In the case of global robustness with respect to the prior (in short robustness in the sequel), an important link with the possibility of providing effective algorithms is available when the class of priors is defined by generalized moment conditions. Indeed in this case the problem of analyzing Bayesian robustness reduces to a problem of linear semi-infinite programming (LSIP).

Generalized moment classes have been considered in connection with robustness first in [3] and then in several other papers (see [4] and its references). Such classes, whose features are recalled in the section titled “Generalized Moment Classes and Bayesian Robustness”, incorporate a number of interesting situations – the most common being the one in which bounds on **quantiles** of the prior distribution are available – and have been widely studied in other contexts, so that a rather comprehensive theory exists for optimization of linear functions defined over them, originated by [5–7], which we review in the section titled “Application

of the Generalized Moment Theory to Bayesian Robustness”. In robustness analysis, the function to be optimized is not linear but, as it is shown in the section titled “Generalized Moment Classes and Bayesian Robustness”, it is possible to obtain linearity by a suitable transformation, so that the above theory can be applied to robustness analysis as well.

Once the problem is reduced to an LSIP one, its numerical solution can be accomplished by algorithms developed in this latter context. A review of such algorithms is presented in the section titled “LSIP Algorithms and Bayesian Robustness”. In the section titled “An Example” the application to robustness problems of the so-called accelerated central cutting plane (ACCP) algorithm, which has the attractive feature of converging under mild conditions on the problem constraint functions, is illustrated by an example. A C++ implementation of the ACCP algorithm and its interface with robustness analysis has been developed by the author and is available on request.

Generalized Moment Classes and Bayesian Robustness

Let X be a random variable on a dominated statistical space $(\mathcal{X}, \mathcal{F}_X, \{P_\theta, \theta \in (\Theta, \mathcal{F})\})$, with density $f(x | \theta)$ with respect to the dominant measure λ , where the parameter space $(\Theta, \mathcal{F})$ is such that Θ is a subset of a finite-dimensional euclidean space; denote by $l_x(\theta)$ (or simply by $l(\theta)$) the likelihood function $f(x | \theta)$, which we assume is $\mathcal{F}_X \otimes \mathcal{F}$ measurable. Let $\mathcal{P}$ be the space of all probability measures on $(\Theta, \mathcal{F})$ and define

$$\Gamma = \{\pi \in \mathcal{P} : \int_{\Theta} H_i(\theta) \pi(d\theta) \leq \alpha_i, i = 1, \dots, m\} \quad (1)$$

where H_i are integrable with respect to any $\pi \in \mathcal{P}$ and α_i are fixed real constants, $i = 1, \dots, m$. Suppose that Γ is nonempty. We are interested in determining

$$\sup_{\pi \in \Gamma} \frac{\int_{\Theta} g(\theta) l(\theta) \pi(d\theta)}{\int_{\Theta} l(\theta) \pi(d\theta)} \quad (2)$$

where $g : \Theta \rightarrow \mathbb{R}$ is a given function such that $\int g(\theta) \pi(d\theta | x)$ exists for all $\pi \in \Gamma$, $\pi(d\theta | x)$ being

2 Bayesian Robustness: Theory and Computation

the posterior distribution of θ corresponding to the prior π .

The function to be optimized in expression (2) is not linear in π , however it is possible to build up a problem equivalent to the one given by expression (2) in which the objective function is linear. Consider the following map from $\mathcal{P}$ into $\mathcal{M}$, the set of finite measures on Θ : $\nu(A) = \int_A \pi(d\theta) / \int_\Theta l(\theta)\pi(d\theta)$ $A \in \mathcal{F}$, assuming that $0 < \int_\Theta l(\theta)\pi(d\theta) < +\infty$. Accordingly, expression (2) turns into

$$\begin{aligned} \sup_{\nu \in \mathcal{M}_1} \int_\Theta g(\theta)l(\theta)\nu(d\theta) \\ \mathcal{M}_1 = \mathcal{M}_1(\Theta) = \left\{ \nu \in \mathcal{M} : \int_\Theta f_i(\theta)\nu(d\theta) \right. \\ \left. \leq 0, i = 1, \dots, m \right. \\ \left. \int_\Theta l(\theta)\nu(d\theta) = 1 \right\} \\ f_i(\theta) := H_i(\theta) - \alpha_i, i = 1, \dots, m \end{aligned} \quad (3)$$

From now on the transformed problem formulation (3) is considered. For an extension to the non-parametric case see [4].

Application of the Generalized Moment Theory to Bayesian Robustness

Let Θ be some closed subset of $\mathbb{R}^n$ and let $g, l, f_i, i = 1, \dots, m$ in expression (3) be such that the following assumptions hold:

- A1. l is continuous and for $i = 1 \dots m$ f_i is lower semicontinuous;
- A2. g is upper semicontinuous;
- A3. $\forall i = 1 \dots m \exists C_i \in \mathbb{R}$ such that $f_i \geq C_i$;
- A4. l is bounded from above;
- A5. gl is bounded from above;
- A6. $\exists \tilde{\beta}_0 \in \mathbb{R}, \tilde{\beta}_1, \dots, \tilde{\beta}_{m+1} \geq 0 : \forall \theta \in \Theta$ it is $\tilde{\beta}_0 l(\theta) + \sum_{i=1}^m \tilde{\beta}_i f_i(\theta) - \tilde{\beta}_{m+1} g(\theta)l(\theta) > 1$;
- A7. $\forall \epsilon > 0 \exists K_\epsilon \subseteq \Theta, K_\epsilon$ compact, $\exists \beta_0^\epsilon \in \mathbb{R}, \beta_i^\epsilon \geq 0, i = 1, \dots, m+1$ with $|\beta_0^\epsilon| + \sum_{i=1}^{m+1} \beta_i^\epsilon \leq B, B > 0$ such that, for any $s \in K_\epsilon^c$, it is $\beta_0^\epsilon l(\theta) + \sum_{i=1}^m \beta_i^\epsilon f_i(\theta) - \beta_{m+1}^\epsilon g(\theta)l(\theta) > 1/\epsilon$.

According to [4], Theorem 5, the following result holds:

Theorem 1 Under conditions A1–A7, it is

$$\begin{aligned} \sup_{\nu \in \mathcal{M}_1} \int_\Theta g(\theta)l(\theta) d\nu(\theta) \\ = \inf \left\{ \beta_0 : \beta_0 \in \mathbb{R}, \beta_1, \dots, \beta_m \geq 0, \beta_0 l(\theta) \right. \\ \left. + \sum_{i=1}^m \beta_i f_i(\theta) \geq g(\theta)l(\theta), \theta \in \Theta \right\} \end{aligned}$$

when $\mathcal{M}_1$ is $\neq \emptyset$. Moreover the supremum is attained.

A6 can be rewritten as

$$\text{A6'} \quad \exists \tilde{\beta}_0, \tilde{\beta}_1, \dots, \tilde{\beta}_m > 0 : \forall \theta \in \Theta \text{ it is } \tilde{\beta}_0 l(\theta) + \sum_{i=1}^m \tilde{\beta}_i f_i(\theta) \geq g(\theta)l(\theta) + \eta, \eta > 0,$$

which is known in LSIP literature as strong Slater condition (SSC) (see, e.g., [8, p. 128]). It is also worth noticing that A6 is also equivalent to the following more intuitive condition:

$$\text{A6''} \quad \exists \bar{\epsilon} > 0, \exists \tilde{\beta}_1, \dots, \tilde{\beta}_{m+1} \geq 0 : \sum_{i=1}^m \tilde{\beta}_i f_i(\theta) - \tilde{\beta}_{m+1} g(\theta)l(\theta) > 1 \quad \forall \theta : l(\theta) \leq \bar{\epsilon},$$

which states that in the regions where the likelihood l is small (close to 0) some f_i or $-gl$ must be positive and away from 0.

As far as A7 is concerned, it essentially requires that when $\theta \rightarrow \infty$ some $f_i(\theta)$ or $-g(\theta)l(\theta)$ diverges to $+\infty$.

In the case of Θ compact, then Theorem 1 holds under A1, A2, and A6, the other assumptions being true as a consequence of the compactness of Θ .

LSIP Algorithms and Bayesian Robustness

Theorem 1 provides the link between prior robustness under generalized moment conditions and LSIP, which is concerned with optimization problems stated as, under standard notation,

$$(P) \quad I = \inf \{c'x : x \in \mathbb{R}^n, a'(\theta)x \geq b(\theta) \quad \forall \theta \in \Theta\} \quad (4)$$

where Θ is an arbitrary infinite index set.

This enables the numerical treatment of robustness analysis by algorithms developed in this latter context which has been widely considered in the optimization literature (see, e.g., [8] and [9], for comprehensive surveys). Among the algorithms for solving

LSIP problems, and hence for determining the bounds required by robustness analysis via Theorem 1, the classification in [8, p. 253], states that *discretization methods* (by *grids* and by *cutting planes*, *CPs*) have the highest reputation in terms of computational efficiency, according to most experts' opinions. Being also the most popular and easy to implement, they are the natural candidates for the numerical treatment of Bayesian robustness analysis, although algorithms not falling into this category have also been proposed in the literature.

Grid discretization methods are based on sequences of finite grids Θ_r (by grid we mean a finite or countable set of points belonging to Θ , not necessarily regularly displaced) such that $\Theta_r \subset \Theta_{r+1}$ (expansive grids) and dense in Θ . For each grid an ordinary linear programming (LP) program is solved, corresponding to the subproblem (P^r) of (P) obtained substituting Θ by Θ_r , until the solution of (P^r) , x^r , is such that $a'(\theta)x^r - b(\theta) \geq -\varepsilon \forall \theta \in \Theta$ for some prefixed accuracy $\varepsilon > 0$. Convergence is obtained if all the functions defining (P) are continuous, which rules out indicator functions, commonly involved in robustness analysis. The final x^r is not guaranteed to be feasible for (P) (in this case it would also be optimal), so that grid algorithms in general underestimate the optimal solution; when applied to robustness analysis, this means that the posterior range of the quantity of interest will be in general underestimated, leading to an erroneous conclusion about the presence of robustness.

Cutting plane (CP) discretization methods, first proposed in [10], starting from a finite set of constraints and solving the corresponding LP subproblem of (P) , proceed by adding to the current constraint set Θ_r a finite number of constraints of (P) which are violated at the current subproblem solution. Convergence can be proved under more general conditions than the ones required by grid methods, essentially the boundedness of the functions a in (P) , which can always be achieved by normalization.

Within the same scheme of things, but not included in the general setting of the basic CP algorithm is the central cutting plane (CCP) method in [11], originally proposed for general convex programming problems; the method is aimed at providing at each iteration a feasible point (unlike both grid discretization and ordinary CP methods) and at preventing the numerical instability of CP algorithms due to the fact that cuts tend to be parallel near

optimal points. CCP method proceeds by computing at each step the center x^r and the radius of the maximal sphere inscribed into the polytope $\{c'x \leq \alpha_r, a'(\theta)x \geq b(\theta), \theta \in \Theta_r\}$, cutting down α_r to $c'x^r$ if x^r is feasible for (P) (*objective cut*) and enlarging the constraint set to $\Theta_r \cup \theta_r$, where θ_r is any point in Θ giving a violated constraint, otherwise (*feasibility cut*). Convergence is achieved when the functions a are bounded and a SSC condition $a'(\theta)\hat{x} \geq b(\theta) + \eta, \forall \theta \in \Theta$ and some $\eta > 0$ and $\hat{x} \in \mathbb{R}^n$, holds.

In [12] a modification of the CCP algorithm, called ACCP algorithm, was introduced with the aim of accelerating its convergence. The ACCP algorithm shares with the CCP algorithm features that make it attractive for application to robustness analysis, i.e., its applicability under mild conditions (no regularity condition is required on the functions defining the constraints) and the fact that it produces a convergent sequence of points interior to the feasible region (so that the infimum can be approximated from above rather than from below as in the grid methods); its advantage over the CCP method is the superior rate of convergence (see [12, Theorem 3]).

In order to apply the ACCP algorithm to the LSIP problem stated by Theorem 1, all that is needed is to ensure that

1. A SSC holds: this is assumption A6', equivalent to A6.
2. $\sup_{\theta \in \Theta} |f_i(\theta)| < +\infty$ for $i = 1, \dots, m$; if some of the f_i 's are not bounded from above (recall that the f_i 's are bounded from below by assumption A3), then it is possible to transform the problem into an equivalent one in which all required boundedness conditions are satisfied. By the existence of positive $\tilde{\beta}_0, \tilde{\beta}_1, \dots, \tilde{\beta}_{m+1}$ such that $\tilde{s}(\theta) = \tilde{\beta}_0 l(\theta) + \sum_{i=1}^m \tilde{\beta}_i f_i(\theta) - \tilde{\beta}_{m+1} g(\theta) l(\theta) \geq 1 \forall \theta \in \Theta$, the minimization problem of Theorem 1 can be shown to be equivalent to the one $\inf\{\beta_0 : \beta_0 \in R, \beta_1, \dots, \beta_m \geq 0, \beta_0 \tilde{l}(\theta) + \sum_{i=1}^m \beta_i \tilde{f}_i(\theta) \geq g(\theta) \tilde{l}(\theta), \theta \in \Theta\}$, where $\tilde{l}(\theta) = l(\theta)/\tilde{s}(\theta)$ and $\tilde{f}_i(\theta) = f_i(\theta)/\tilde{s}(\theta)$. For this problem too a SSC holds (with coefficients $\tilde{\beta}_i, i = 0, \dots, m+1$); moreover, all the functions involved are now bounded.
3. There exists a suitable finite subset $\Theta_0 \subset \Theta$ such that the corresponding finite subproblem of (P) has nonempty bounded level sets; this is the case when there exists a finite measure $\bar{\nu}$ with finite

4 Bayesian Robustness: Theory and Computation

support such that $\int l d\bar{\nu} > 0$ and $\int f_i d\bar{\nu} \leq -\epsilon_i$, with $\epsilon_i > 0, i = 1, \dots, m$, as can be proved by Corollary 9.3.1 in [8], as restated by Corollary 3 in [13].

A CP algorithm is also introduced in [14] for calculating a Γ -minimax test, where Γ is given by a finite set of generalized moment conditions. The inner maximization problem which is required to solve is a generalized moment problem in the form of expression (3) with $l \equiv 1$, i.e., ν is a probability measure.

An Example

We consider the classical example of Bayesian analysis for failure data of 10 pumps in a nuclear plant reported in [15].

Let $X_i, i = 1, \dots, 10$ be the number of failures of the pump i during the observation period t_i of the pump. The observed values x_i and the respective t_i are reported in Table 1.

X_i is assumed to be distributed according to a Poisson distribution with mean $\lambda_i t_i$, where λ_i is the expected number of failures per unit of time. The pumps are assumed to work independently, so that $X = (X_1, \dots, X_{10})$ has density $f(x|\lambda) = \prod_{i=1}^{10} e^{-\lambda_i t_i} (\lambda_i t_i)^{x_i} / x_i!$.

The rates λ_i are assumed to be independent realizations from a gamma distribution with parameters α and θ , so that λ has density $p(\lambda|\alpha, \theta) = \prod_{i=1}^{10} \theta^\alpha \lambda_i^{\alpha-1} e^{-\theta \lambda_i} / \Gamma(\alpha)$.

We assume α known, $\alpha = 1.8$, and write $p(\lambda|\theta)$ instead of $p(\lambda|\alpha, \theta)$. Let $\pi(d\theta)$ the prior distribution of θ . Then, for the posterior density of λ it is

$$p(\lambda|x) = \frac{f(x|\lambda) \int p(\lambda|\theta) \pi(d\theta)}{\int f(x|\lambda) p(\lambda|\theta) d\lambda \pi(d\theta)} \quad (5)$$

and hence, for a given function of λ , say $g(\lambda)$, it is

$$E(g(\lambda)|x) = \frac{\int g_1(\theta) l(\theta) \pi(d\theta)}{\int l(\theta) \pi(d\theta)} \quad (6)$$

where

$$l(\theta) = \int f(x|\lambda) p(\lambda|\theta) d\lambda, \\ g_1(\theta) = \frac{\int g(\lambda) f(x|\lambda) p(\lambda|\theta) d\lambda}{l(\theta)} \quad (7)$$

After standard computations, we obtain

$$l(\theta) = C \frac{\theta^{10\alpha}}{\prod_{i=1}^{10} (\theta + t_i)^{\alpha+x_i}}, \\ C = \prod_{i=1}^{10} t_i^{x_i} \frac{\Gamma(\alpha + x_i)}{\Gamma(1 + x_i) \Gamma(\alpha)}, \\ g_1(\theta) = \sum_{i=1}^{10} \frac{\alpha + x_i}{\theta + t_i} \quad (8)$$

In order to apply the generalized moment theory, we assume $\theta \in [0, 5]$, so that Θ is compact and hence we need only to verify assumptions A1, A2, A6 (or A6').

We need now to consider some constraints. Suppose that prior information, rather than being reflected into an explicit form for π , is expressed through the marginal probability of no failure of one of the pumps, say pump 1, in a period of length t as a function of t :

$$p_0(t) = P(X_1(t) = 0) \\ = \int P(X_1(t) = 0 | \lambda_1) p(\lambda_1 | \theta) \pi(d\theta) \\ = \int e^{-\lambda_1 t} \frac{1}{\Gamma(\alpha)} \theta^\alpha \lambda_1^{\alpha-1} e^{-\theta \lambda_1} d\lambda_1 \pi(d\theta) \\ = \int \left(\frac{\theta}{\theta + t} \right)^\alpha \pi(d\theta) \quad (9)$$

where $X_1(t)$ represents the number of failures during a period of length t for the pump 1.

Table 1 Failure data in the nuclear plant test case

Pump	1	2	3	4	5	6	7	8	9	10
Failures	5	1	5	14	3	19	1	1	4	22
Period	94.32	15.72	62.88	125.76	5.24	31.44	1.05	1.05	2.10	10.48

Let us assume that lower bounds of $p_0(t)$ are elicited at m values of t , $p_0(\bar{t}_i) \geq \alpha_i$, $i = 1, \dots, m$. Then, $f_i(\theta) = -(\theta/(\theta + \bar{t}_i))^\alpha + \alpha_i$, $i = 1, \dots, m$.

As $f_i(\theta) > 0$ at $\theta = 0$, the only point at which $l(\theta) = 0$, then A6' holds. A1, A2 obviously hold too.

Suppose that $m = 6$, $\bar{t}_1 = 0.001$, $\bar{t}_2 = 0.01$, $\bar{t}_3 = 0.1$, $\bar{t}_4 = 0.5$, $\bar{t}_5 = 1$, $\bar{t}_6 = 3$ and $\alpha_1 = 0.4$, $\alpha_2 = 0.25$, $\alpha_3 = 0.10$, $\alpha_4 = 0.04$, $\alpha_5 = 0.02$, $\alpha_6 = 0.01$.

We remark that the above conditions define a generalized moment class which the usual prior for $\theta \Gamma(0.1, 1)$ belongs to, as can be seen by numerical integration.

The ACCP algorithm gave the following bounds: $4.74415 \leq E(g(\lambda)|x) \leq 11.41814$. The upper bound and the lower bound were obtained, respectively, in 3.5 s and in 0.1 s of CPU time on a computer with an Athlon MP 1600+ processor.

BRUNO BETRÒ

Survival Analysis, Nonparametric

Introduction

Statistical analysis of survival (failure time) data is of great importance in several biomedical and engineering fields. We consider survival data arising from a (continuous) distribution on $\mathbb{R}^+$ (the positive real line), with distribution function $F(t)$ and density function $f(t)$. Inferential objectives involve the survival function, $S(t) = 1 - F(t)$, the cumulative hazard function, $H(t) = -\log S(t)$, or the hazard function, $h(t) = f(t)/S(t)$. Inference approaches need to account for censoring (and/or truncation), the distinguishing feature of survival data. Moreover, several modeling formulations have been explored to incorporate **covariate** information.

There exists a substantial literature on classical (frequentist) semiparametric regression techniques for survival data analysis (see, e.g., [1, 2]). Here, the survival distribution is left unspecified with interest focusing on **estimation** for the regression coefficients. Hence, lacking a likelihood specification, point estimation proceeds through optimization of a particular estimating equation, with further inference relying on asymptotic or **resampling** methods.

Parametric probabilistic modeling for survival analysis applications has also received much attention. Such modeling approaches are in contrast to classical nonparametric methods, since, here, all the unknown functions and/or distributions of the model are described through parametric forms (specified up to a number of unknown parameters). Hence, either likelihood or Bayesian estimation techniques can be utilized for inference. Parametric models for survival data analysis are widely available in statistical packages and are routinely used by practitioners. However, they might yield inaccurate inference or misleading predictions when the postulated distributional assumptions are not supported by the data.

Bayesian nonparametric methods provide the means to enhance the flexibility of standard parametric models retaining a probabilistic framework for inference. Under the Bayesian nonparametric paradigm, the unknown functions or distributions of the model are treated as the random (infinite-dimensional) parameters. Hence, from a theoretical

point of view, Bayesian nonparametric approaches require priors (formally, random probability measures) over spaces of functions or distributions. The area of Bayesian nonparametrics has grown rapidly following the work in [3] on the Dirichlet process (DP), a random probability measure on spaces of distribution functions. As with most research areas in Bayesian statistics, Bayes nonparametrics has benefited enormously from advances in simulation-based model fitting, mainly Markov chain Monte Carlo (MCMC) methods (see **Markov Chain Monte Carlo, Introduction and Convergence and Mixing in Markov Chain Monte Carlo** for background on MCMC posterior simulation methods). With an increasing amount of emphasis on applications over the past 10 years or so, it is now easy to argue for the utility and potential of Bayesian nonparametric modeling. See [4–6] for general reviews of Bayesian nonparametrics.

Bayesian nonparametric methods are, arguably, very well suited for survival data analysis, since they: enable flexible modeling for the unknown survival function, cumulative hazard function, or hazard function; provide techniques to handle censoring under a unifying inferential framework; allow incorporation of prior information; and yield rich inference that does not rely on restrictive parametric specifications or asymptotic approximations for large sample sizes. There is, by now, a relatively large literature on Bayesian nonparametric approaches to survival analysis (and reliability analysis) problems, including different prior models for survival, cumulative hazard, and hazard functions. For related references, see the reviews in [7, 8] as well as articles **Nonparametric and Semiparametric Bayesian Reliability Analysis**; **Lévy Processes, Simulation of**; **Simulation of the Beta-Stacy Process**; **Dirichlet Process, Simulation of**; **Polya Trees and Their Use in Reliability and Survival Analysis**.

In this article, we review Bayesian nonparametric and semiparametric methods for survival analysis using mixture models for distributions. In the next section, we consider DP mixture models for survival distributions in a fully nonparametric setting. In the process, we provide a brief introduction to DPs and DP mixtures. The section titled “Semiparametric Accelerated Failure Time Regression Models” presents practically important extensions to regression settings. Finally, we conclude with a summary.

Dirichlet Process Mixture Models for Survival Distributions

Here, we consider fully nonparametric modeling for survival distributions for problems that do not include a regression component. The objective of such modeling is to increase the flexibility of commonly used parametric models, such as, the gamma, Weibull, or lognormal families of survival distributions.

In looking beyond standard parametric families, one is naturally led to mixture models. In particular, finite mixtures provide flexible modeling and are now feasible to implement using MCMC posterior simulation techniques. For instance, finite Weibull mixtures for survival analysis are studied in [9].

Though it may appear paradoxical, rather than handling the large number of parameters resulting from finite mixtures with a large number of mixture components, it may be easier to work with an infinite-dimensional specification by assuming a random mixing distribution that is not restricted to a specified parametric family. The DP is the most widely used in this context, following [10–12].

Under the DP mixture setting, the random distribution function for the survival distribution can be expressed as

$$F(t; G) = \int K(t; \theta) dG(\theta), \quad t \in \mathbb{R}^+,$$

$$G \sim \text{DP}(\alpha, G_0) \quad (1)$$

Here, the parametric kernel of the mixture, $K(\cdot; \theta)$, is a distribution function on $\mathbb{R}^+$ (with parameter vector θ), and $\text{DP}(\alpha, G_0)$ denotes the DP prior for the random mixing distribution G . The DP prior is specified through two hyperparameters, a positive scalar parameter α , and a distribution function $G_0 \equiv G_0(\psi)$, which, in general, depends on parameters ψ and defines the prior expectation of G . Hence, G_0 plays the role of the center of the DP prior whereas α can be viewed as a precision parameter; the larger α is the *closer* a DP realization is expected to be to G_0 .

A very useful characterization of the DP is given by its *stick-breaking* constructive definition (see [13]). On the basis of this definition, a realization G from $\text{DP}(\alpha, G_0)$ is (almost surely) of the form $G = \sum_{j=1}^{\infty} \omega_j \delta_{\theta_j}$, where δ_x denotes a point mass at x , $\omega_1 = z_1$, $\omega_j = z_j \prod_{s=1}^{j-1} (1 - z_s)$, $j = 2, 3, \dots$, with z_s independent from a $\text{beta}(1, \alpha)$ distribution, and,

independently, θ_j independent from G_0 . Evidently, DP realizations are discrete distributions. In particular, $F(t; G)$ in equation (1) admits the (almost sure) representation $\sum_{j=1}^{\infty} \omega_j K(t; \theta_j)$, that is, it can be expressed as a countable mixture with weights generated according to the stick-breaking scheme above.

The choice of the mixture kernel in equation (1) is discussed in [14], where a Weibull DP mixture is developed. In principle, any other two-parameter kernel, which yields unimodal as well as decreasing density shapes, should provide similar inferences. In particular, that should be the case for the gamma DP mixture proposed in [15].

Illustrating with the model from [14], let $K(t; \gamma, \lambda) = 1 - \exp(-\lambda^{-1} t^\gamma)$ be the Weibull distribution function, with shape parameter $\gamma > 0$ and scale parameter $\lambda > 0$, where $\theta = (\gamma, \lambda)$. For clarity of exposition, we consider right censoring; left and interval censored data can be handled in a similar fashion. Suppose that the study involves n subjects, and let t_i and c_i denote the survival time and a fixed censoring time, respectively, for the i th subject. Hence, the actual i th survival time is observed only if $t_i \leq c_i$, and it is right censored otherwise. The observed data consist of the pairs (y_i, d_i) , $i = 1, \dots, n$, where $y_i = \min\{t_i, c_i\}$ and $d_i = 1$, if $t_i \leq c_i$, with $d_i = 0$, if $t_i > c_i$.

The full Bayesian model can be expressed in a hierarchical form by introducing a latent mixing parameter vector (γ_i, λ_i) associated with each observation. Then, y_i , given (γ_i, λ_i) , are independent with first stage specification $\{\lambda^{-1} \gamma_i y_i^{\gamma_i - 1}\}^{d_i} \exp(-\lambda_i^{-1} y_i^{\gamma_i})$. Next, (γ_i, λ_i) , given G , are independent and identically distributed (i.i.d.) from G , with the $\text{DP}(\alpha, G_0)$ prior assigned to G . The model is completed with hyperpriors for α and for (a subset of) the parameters of G_0 . Thus, the full posterior involves the infinite-dimensional parameter G as well as (γ_i, λ_i) , α , and ψ .

Regarding prior specification, note that the prior expectation for $F(t; G)$ is given by $\int K(t; \theta) dG_0(\theta)$, a result that can be used to drive the choice for G_0 and for the prior on its parameters ψ . Moreover, the choice of the prior for α is facilitated by the role that α plays in the DP-induced clustering of (γ_i, λ_i) (see, e.g. [12]).

We refer to **Dirichlet Process, Simulation of** for a review of MCMC posterior simulation for DP mixtures. We simply note here that MCMC inference is based on the marginalized version of the

model, which results by integrating G over its DP prior. Hence, regardless of the MCMC method that might be used, inference for functionals of the random mixture $F(\cdot; G)$ is limited, especially, in this fully nonparametric survival analysis context. Without obtaining posterior samples for G , one can only estimate the posterior predictive survival function, which, evaluated at $t \in \mathbb{R}^+$, is the posterior expectation of $1 - F(t; G)$. An approach to full inference for any functional of the survival distribution that might be of interest is presented in [14]. The posterior distribution of G is sampled using a key result from [10], which provides the conditional posterior of G , given (γ_i, λ_i) , α , and ψ , as a DP with updated parameters. Samples from this DP can be obtained using its constructive definition with a truncation approximation. Inference for median survival times, survival functions, and hazard functions is illustrated in [14] with right-censored data.

Semiparametric Accelerated Failure Time Regression Models

In this section, we review the literature on Bayesian semiparametric regression approaches for survival data under the accelerated failure time (AFT) setting.

Denote by $\mathbf{x}_i = (x_{i1}, \dots, x_{ip})^T$ the vector of (known) covariates corresponding to survival time t_i , $i = 1, \dots, n$. Under the AFT setting, the covariates act multiplicatively on the survival time, the most common formulation being, $t_i = \exp(-\mathbf{x}_i^T \boldsymbol{\beta}) V_i$, where $\boldsymbol{\beta}$ is the vector of regression coefficients. The error terms V_i are assumed independent from a distribution function $F(\cdot)$ on $\mathbb{R}^+$. To avoid restrictions on the model for the error distribution, one can opt not to include an intercept term in $\boldsymbol{\beta}$.

Early semiparametric work for the AFT regression model was reported in [16] and [17]. This work was based on a DP prior (instead of a DP mixture prior) for $F(\cdot)$. These papers provide a careful study of the posterior distributions resulting from the DP prior. In particular, they highlight the practical difficulties of a fully Bayesian analysis, especially, in the presence of censoring.

More recent Bayesian work in [15, 18–22] utilizes DP mixture priors for $F(\cdot)$, taking advantage of MCMC techniques for DP mixtures. Here, the DP mixture model in equation (1) is used for the errors, that is, $V_i | G$ are assumed i.i.d. from $F(v; G) =$

$\int K(v; \boldsymbol{\theta}) dG(\boldsymbol{\theta})$, $v \in \mathbb{R}^+$, with a DP prior for G . In fact, as discussed below, some of the approaches involve a semiparametric error model with DP mixing on a portion of $\boldsymbol{\theta}$ only. Introducing latent mixing parameters $\boldsymbol{\theta}_i$ for the t_i , the generic DP mixed AFT regression model can be expressed hierarchically as follows:

$$\begin{aligned} t_i &= \exp(-\mathbf{x}_i^T \boldsymbol{\beta}) V_i, \quad V_i | \boldsymbol{\theta}_i \stackrel{\text{i.i.d.}}{\sim} K(v; \boldsymbol{\theta}_i), \\ i &= 1, \dots, n \\ \boldsymbol{\theta}_1, \dots, \boldsymbol{\theta}_n &| G \stackrel{\text{i.i.d.}}{\sim} G, \\ G | \alpha, \psi &\sim \text{DP}(\alpha, G_0(\psi)) \end{aligned} \quad (2)$$

with priors added for $\boldsymbol{\beta}$ and, possibly, for α and/or ψ .

Here, for simpler notation, we do not consider censoring, which, however, can be handled. Indeed, with the exception of [20], all the papers above develop MCMC methods for inference under right censoring. This is accomplished with either data augmentation techniques to impute the latent survival times for the subjects with right-censored observations, or, more efficiently, through direct inclusion of the right-censored times in the first stage specification of equation (2) as discussed in the section titled “Dirichlet Process Mixture Models for Survival Distributions”.

A normal DP mixture for the V_i is used in [18], implemented with a fixed variance for the normal kernel. A general DP mixture for the log V_i is also discussed. For instance, a normal DP mixture in this case would result in a DP mixture of lognormal distributions for the V_i , and might be a more natural choice, since it models the errors on $\mathbb{R}^+$. Moreover, this paper considers the practically important problem of variable selection using a stochastic search algorithm.

Weibull DP mixtures are utilized in [20, 21]. In both cases, the error model is semiparametric, involving DP mixing only on the scale parameter of the Weibull kernel with a common (random) shape parameter. The former paper focuses on applications in reliability analysis. In fact, the model is presented within the proportional hazards regression framework. However, given the choice of the Weibull distribution, it can also be represented as an AFT model. The latter paper studies applications in survival analysis. However, to enable use of existing software, the Weibull DP mixture in [21]

is, in fact, implemented approximately as a finite mixture. This paper also reports results on posterior consistency, albeit under the assumption that the *true* response distribution is a scale Weibull mixture.

Gamma DP mixture models for right-censored survival data are studied in [15] and [22]. Here, DP mixing is with respect to both the shape and scale parameters of the gamma kernel. To facilitate MCMC posterior simulation, G_0 is taken to be the product of two exponentials. In fact, the emphasis in [22] is on comparison of the modeling and resulting inference with an alternative nonparametric mixture model based on a normalized inverse-Gaussian prior (see [23]) for G .

Finally, extensions to median regression and median residual life regression are proposed in [19] and [24], respectively. In both cases, the methodology is based on the AFT setting (on a logarithmic scale) with structured prior models, which yield unimodal error distributions on $\mathbb{R}$ with zero median. Two error models are developed, a semiparametric scale DP mixture of skewed normals, and a more general nonparametric scale DP mixture of uniforms.

Summary

We have reviewed research work on Bayesian nonparametric and semiparametric survival analysis. We have considered approaches that are based on one of the most commonly used classes of nonparametric priors, specifically, DP mixture models. The discussion has focused on nonparametric mixture modeling for univariate survival data, in particular, modeling approaches for the survival distribution (“Dirichlet Process Mixture Models for Survival Distributions”) and for the error distribution under the AFT regression setting (“Semiparametric Accelerated Failure Time Regression Models”).

Decision Search via Simulation

Introduction

Experimental design requires the specification of all aspects of an experiment, for example, the number of experimental units needed, which treatments to study in a **clinical trial**, or what levels of input/control variables should be used. When designing an experiment, decisions are often taken before **data collection**. Sample sizes are usually restricted because of costs, ethics, or other limitations on resources or time, hence making efficient use of all the available resources becomes crucial. The basic idea of experimental design consists of improving the inference on the quantity of interest by appropriately selecting the values of the design variables which are under the control of the investigator within the constraints of the available resources. Decision analysis provides a general framework for solving decision making problems under uncertainty. A major use of statistical inference is its application to decision making under uncertainty. Statistically designed experiments are an important tool for decision makers in all areas including engineers, analysts in planning offices and public agencies, project management consultants, manufacturing process planners, financial and economic analysts, experts supporting medical/technological diagnosis, etc. Since specific information is often available before the experiment is carried out, it can be helpfully used to design it. In this respect, the Bayesian approach can play an important role as it provides a natural framework to incorporate prior information into the design problem and account for various sources of variability [1, 2].

An **optimal design** problem is conceptually simple: we look for a design that maximizes the expected utility in a statistical experiment or equivalently minimizes the expected loss. The maximization is taken over some design parameter $d \in D$. The experiment is defined by a probability model for the observable data y taking a value in a set $\mathcal{Y}$ (sample space). Ultimately, the amount we lose as a result of our decision will depend on the observed quantities y . We denote with $p_d(y | \theta)$ the probability distribution of the observables y conditional on some unknown vector of parameter θ . We denote with Θ the parameter

space. In some applications the model may depend on the decision d and therefore we have introduced a subscript d in the probability model. The model is then completed by a prior distribution $p(\theta)$ on the parameter vector θ and

$$p_d(y, \theta) = p_d(y | \theta)p(\theta) \quad (1)$$

Sample sizes, levels of explanatory variables, or other characteristics of the design to be selected are implicitly captured by $p_d(y | \theta)$. The main goal of the experiment may include **estimation** of θ , or some functions of θ , prediction of future observations, model selection, or hypothesis testing. The purpose and the cost of the experiment are usually reflected in the utility function. A general utility function has the form $u(d, \theta, y)$. For example, the utility could be equal to the negative squared error loss $u = -\{\theta - E(\theta | y, d)\}^2$, or something more problem specific like $u =$ total number of successfully treated patients, etc. The utility function models preferences over consequences. It is fundamental to select a utility function that appropriately captures the goals and the various aspects of a given experiment. A design that is optimal for estimation is not necessarily optimal for prediction. For example, in quality control or in clinical trials prediction of future observations can be of special interest.

In most general types of decision problems, decisions must be taken before data collection, i.e. before observing the experimental data y , consequently we need to maximize the expected utility U , given by the expectation of $u(\cdot)$ with respect to (θ, y) . We can then formalize decision making under uncertainty as choosing $d^* \in D$ which maximizes the expected utility:

$$d^* = \arg \max_{d \in D} U(d), \quad \text{where}$$

$$U(d) = \int u(d, \theta, y) p_d(\theta, y) d\theta dy \quad (2)$$

Therefore, in this framework the optimal way to solve a decision problem is to specify a utility function that describes the essential features of the problem and then to select a design that maximizes the expected utility. While conceptually simple, the actual solution of the design problem may be extremely complex, e.g., model and likelihood are chosen in a way that does not allow for analytic evaluation

of the expected utility, the set of possible alternatives D is continuous, or a sequence of decisions is included (*sequential design*). In these scenarios approximations can be used. Most approximations to expected utility usually require a normal approximation of the posterior distribution $p(\theta | y, d)$. See Chaloner and Verdinelli [2] for a review of Bayesian experimental design, which covers analytical and approximate solutions to the optimal design problem.

A very powerful and widely applicable alternative in complex setups is offered by simulation-based strategies. See, for example, Müller [3] for a review. Recent advances in computing have enabled design and decision analysis based on highly structured, simulation-based stochastic models. In the following sections we present some of the most common simulation schemes.

Optimal Design by Monte Carlo Integration

The most simple scheme to evaluate $U(d)$ is to use straightforward **Monte Carlo** simulations. In many problems it is easy to simulate from $p_d(\theta, y) = p(\theta)p_d(y | \theta)$ using efficient random variate generation. Therefore we can use a sample $\{(\theta_i, y_i), i = 1, \dots, M\}$ generated from $\theta_i \sim p(\theta)$, $y_i \sim p_d(y | \theta)$ to approximate the marginal utility by the empirical average:

$$\hat{U}(d) = \frac{1}{M} \sum_{i=1}^M u(d, \theta_i, y_i) \quad (3)$$

and $\hat{U}(d)$ converges almost surely to $U(d)$ by the strong law of **large numbers**. Using the approximate evaluations, $\hat{U}(d)$, we could proceed using a suitable maximization method to find the optimal design d^* . The use of Monte Carlo integration is common in Bayesian optimal design problems. An appealing feature of Monte Carlo integration is that the probability model $p(\theta)$ is not restricted to any particular form; we only need to be able to simulate from it. For example, Sun *et al.* [4] consider a design problem in quantal response analysis, where an experimenter must choose a set of dose levels and number of independent observations to take at those levels, subject to some total sample size, in order to minimize the expected or predicted posterior variance of some

function ϕ (utility function) of a binary response curve. One of the proposed solutions consists of a combination of simulated outcomes and Monte Carlo integration to evaluate the predicted variance. Carlin *et al.* [5] discuss optimal design in a sequential experiment. In this scenario only up to K observations (data monitoring points) are allowed. The design defines a stopping rule, which gives at each time a decision of whether or not to stop the experiment. The authors offer a fully Bayesian approach to this problem, specifying not only the likelihood and **prior distributions** but appropriate loss functions as well. At each data monitoring point, the available decisions are enumerated. **Monte Carlo simulation** from $p_d(\theta, y)$ is used to evaluate expected utility for a given decision. In the context of sequential design, this approach is referred to as the *forward sampling algorithm*.

Müller and Parmigiani [6] propose numerical methods for stochastic optimization by curve fitting of Monte Carlo samples. The goal is to maximize the marginal utility function $U(d)$ with respect to d , when the evaluation of $U(d)$ requires Monte Carlo integration. Rather than estimating $U(d)$ for a design d , they exploit the smoothness of the expected utility surface and “borrow information” from Monte Carlo simulation at neighboring design points d . This is achieved by simulating draws from $p_d(\theta, y)$ and then evaluating the observed utilities. Fitting a smooth surface $\tilde{U}(d)$ through these simulated points serves as an estimate of $U(d)$. We describe here the basic implementation strategy:

Algorithm 1

1. Select $d_i \in D, i = 1, \dots, N$.
2. Draw (θ_i, y_i) from $p_{d_i}(\theta, y)$ for $i = 1, \dots, N$. Compute $u_i = u(d_i, \theta_i, y_i)$.
3. Fit a smooth k -dimensional curve $\tilde{U}(d)$ to the resulting points (d_i, u_i) , where k is the dimension of the decision space.
4. Find the optimal design d^* deterministically.

Simulation from p_d is usually straightforward and the evaluation of the maximum can be performed through standard optimization methods, as the optimal design is simply the mode of the smooth curve $\tilde{U}(d)$. On the other hand, the choice of the curve fitting method and of the number of design points N is fundamental for the performance of the scheme [6].

Augmented Probability Simulation

The methods described in the previous section evaluate expected utilities for given instantiations of the decision variables d (e.g., on a grid of values for d) and therefore they do not easily accommodate continuous decision variables, unless a discretization is carried out. Moreover, computations become more expensive as the dimensionality of the spaces considered increases. The algorithm described in Müller and Parmigiani [6] partly overcomes this limitation by fitting a continuous surface through the expected utility. An alternative and powerful strategy is to recast the optimal design problem equation (2) as a problem of simulation from an augmented probability model $h(d, \theta, y)$ defined on the product space of the alternatives, parameters, and observables [7, 8]. This method consists of defining a joint probability model on $D \times \Theta \times \mathcal{Y}$ so that the marginal distribution on the space of decisions/alternatives is proportional to the expected utility. Assuming that D is bounded, $u(d, \theta, y)$ is nonnegative and bounded, we can specify an artificial distribution

$$h(d, \theta, y) \propto p_d(\theta, y)u(d, \theta, y) \quad (4)$$

From equation (4), we find that the marginal distribution in d is proportional to the expected utility:

$$h(d) \propto \int h(d, \theta, y) d\theta dy = U(d) \quad (5)$$

Hence the optimal design d^* coincides with the mode of the marginal distribution $h(d)$. The underlying idea behind this approach is simple: to sample designs proportionally to their expected utility, we can construct a **Markov chain** with stationary distribution $h(d, \theta, y)$ and then we use the simulated values as an approximate sample from the desired distribution.

Algorithm 2

1. Start with a design d_0 . Simulate (θ_0, y_0) from $p(\theta)p_{d_0}(y | \theta)$. Evaluate $u_0 = u(d_0, \theta_0, y_0)$.
2. Generate a candidate $\tilde{d}$ from a proposal distribution $g(\tilde{d} | d_0)$.
3. Simulate $(\tilde{\theta}, \tilde{y})$ as in 1 under design $\tilde{d}$. Evaluate $\tilde{u} = u(\tilde{d}, \tilde{\theta}, \tilde{y})$.
4. Compute the acceptance probability

$$\alpha = \min \left\{ 1, \frac{h(\tilde{d}, \tilde{\theta}, \tilde{y})}{h(d_0, \theta_0, y_0)} \frac{g(d_0 | \tilde{d})}{g(\tilde{d} | d_0)} \frac{p_{d_0}(\theta_0, y_0)}{p_{\tilde{d}}(\tilde{\theta}, \tilde{y})} \right\}$$

$$= \min \left\{ 1, \frac{\tilde{u}}{u_0} \frac{g(d_0 | \tilde{d})}{g(\tilde{d} | d_0)} \right\}$$

5. With probability α accept the proposal and set $(d_1, u_1) = (\tilde{d}, \tilde{u})$, otherwise set $(d_1, u_1) = (d_0, u_0)$.
6. Repeat steps 2–5 until convergence.

This algorithm defines a Markov chain Monte Carlo (MCMC) scheme to simulate from $h(d, \theta, y)$, using a Metropolis–Hastings chain to update (d, θ, y) [9]. An independent proposal is used to update (θ, y) , while a proposal distribution $g(\tilde{d} | d)$ to draw d needs to be specified. The choice of a symmetric proposal distribution, i.e. $g(\tilde{d} | d) = g(d | \tilde{d})$, leads to a simple expression for the acceptance probability, $\alpha = \min \{1, \frac{\tilde{u}}{u}\}$. The choice of the proposal distribution affects the speed of convergence of the chain. The sample of simulated $d_i, i = 1, \dots, M$ can be used to estimate the marginal distribution $h(d)$. The mode of $h(d)$ corresponds to the optimal design d^* .

Optimal Design by Inhomogeneous Markov Chain Simulation

Algorithm 2 does not entirely solve the original stochastic optimization problem. Expected utility integration is only one of the computational challenges in optimal design. The other key issue is maximization over the design space. If D is low dimensional, we can find the mode from a density estimate, $\hat{h}(d)$. In the case of high-dimensional design spaces, density estimation becomes impracticable. Moreover, in many applications the expected utility surface is relatively flat over a wide range of designs and the sampler would end up drawing roughly uniformly from the dimension of d and information would accumulate slowly, sometimes requiring unfeasibly large sample sizes to estimate the mode of $h(d)$. In fact, Algorithm 2 works best when the utility function mimics a concentrated probability distribution. Müller *et al.* [10] propose an approach to optimal design based on inhomogeneous Markov chains simulations. The approach builds on simulated annealing algorithms [11] by blending simulated annealing and standard MCMC integration to develop an algorithm that simultaneously addresses maximization and integration. The central idea is to replace $h(d)$ with a

4 Decision Search via Simulation

power transformation $h(d)^J$, for a positive integer J . For sufficiently large J , $h_J(d)$ is tightly concentrated around the mode d^* (note that d^* does not need to be unique). In this setup, an artificial distribution h_J is defined as

$$h_J(d, \theta_1, y_1, \dots, \theta_J, y_J) \propto \prod_{j=1}^J p_d(\theta_j, y_j) \times u(d, \theta_j, y_j) \quad (6)$$

i.e., for each d we generate J experiments (θ_j, y_j) and we then consider the product of the observed utilities. Marginalizing equation (6) over $(\theta_1, y_1, \dots, \theta_J, y_J)$, we obtain

$$h_J(d) \propto \left\{ \int u(d, \theta, y) p_d(\theta, y) d\theta dy \right\}^J = U(d)^J \quad (7)$$

Fixing $J = 1$ leads to Algorithm 2. The algorithm starts by simulating from h ($J = 1$). In subsequent iterations of the MCMC algorithm, $n = 1, 2, \dots$, we increment $J = J_n$ as we proceed hence changing the target distribution to h_J and creating an inhomogeneous Markov chain. The chain is set up in such a way that the stationary distribution for fixed J is h_J . As J increases, $h_J(d)$ becomes more concentrated around the mode. To describe the algorithm we use the alternative state vector (d, v) , where v is the average log observed utility $v = 1/J \sum_{j=1}^J \log u(d, \theta_j, y_j)$.

Algorithm 3

1. Assume that the current state of the chain is $(J, d, \theta_1, y_1, \dots, \theta_J, y_J)$ or (d, v) .
2. Generate a candidate $\tilde{d}$ from a proposal distribution $g(\tilde{d} | d)$. For simplicity of explanation, assume that $g(\tilde{d} | d)$ is symmetric, with $g(\tilde{d} | d) = g(d | \tilde{d})$.
3. Simulate experiments $(\tilde{\theta}_j, \tilde{y}_j)$ from $p_{\tilde{d}}(\theta, y)$ for $j = 1, \dots, J$. Evaluate $\tilde{v} = 1/J \sum \log u(\tilde{d}, \tilde{\theta}_j, \tilde{y}_j)$. Thus the proposed new state of the Markov chain is $(\tilde{d}, \tilde{v})$.
4. Compute the acceptance probability

$$\alpha_J = \min \{1, \exp(J\tilde{v} - Jv)\}.$$

5. With probability α_J accept the proposal and set $(d, v) = (\tilde{d}, \tilde{v})$, otherwise leave (d, v) unchanged.
6. Let J_n denote the current value of J . Increase J to $J_{n+1} \geq J_n$, following a chosen cooling schedule $(J_n, n = 1, 2, \dots)$, such that $J_n \rightarrow \infty$.
7. Repeat steps 2–6 until convergence.

For practical implementation, J can be increased only to the point where $h_J(d)$ is sufficiently peaked. Technical details and proof of convergence of the MCMC scheme are given in Müller *et al.* [10].

In Müller *et al.* [10], the algorithm is applied to choose an optimal design for a network of ground-level ozone monitoring stations in the eastern United States. Figure 1(a) shows the location of the 463 monitoring stations. Each station reports daily maxima for 8 hours running average ozone concentrations. A formal solution to this design problem is complicated by the use of complex spatiotemporal models for the ozone measurements and the need to account for several competing goals in the utility function. The optimal network needs to satisfy some key requirements: (a) we want to identify locations with mean ozone level beyond the air quality standard of 85 parts per billion, (b) we wish to accurately estimate ozone levels at stations that are dropped, (c) we wish to make inference about the response surface of mean ozone level across the eastern United States, and (d) we want to minimize the cost. The optimal design for the ozone network problem is shown in Figure 1(b): 209 stations were selected by maximizing the expected utility.

Discussion

A complex decision problem may preclude the possibility of obtaining an exact solution to the optimal design problem. Therefore in many scenarios we need to consider approximation methods, including simulations. We have described various simulation schemes to implement simulation-based optimal Bayesian design. None of the described algorithms is sufficiently general to allow for routine application without adaptation to the specific problem. Choice of utility functions and probability models remain a key issue in any decision analysis. However, with increased computer power, simulation-based methods for finding optimal designs allow for more realistic model, prior, and utility specifications, although the

Figure 1 (a) Location of monitoring stations. (b) Optimal design: selected stations

main limitation of these strategies still remains the computationally intensive implementation in some scenarios.

Maximum-Likelihood Estimation

Single-Parameter Estimation

Let y be a realization of the random variable Y with probability density $f_Y(y; \theta)$ where θ is an unknown parameter to be estimated. Define the likelihood function $L(\theta) = f_Y(y; \theta)$ as the probability of the observed data y expressed as a function of θ . Although the argument of $f_Y(y; \theta)$ is y , the argument of $L(\theta)$ is θ . When the random variables $Y_1, \dots, Y_n$ are mutually independent, the joint density is equal to the product of the marginal densities, and the likelihood function becomes $L(\theta) = \prod_{j=1}^n f_{Y_j}(y_j; \theta)$.

It is usually more convenient to work with the log-likelihood function $\ell(\theta) = \ln L(\theta)$. Defining the score function $S(\theta) = \partial \ell / \partial \theta$ as the derivative of the log-likelihood, the maximum-likelihood estimate (MLE) $\hat{\theta}$ of θ is the solution to the score equation $S(\theta) = 0$ and is the most plausible value of θ in the sense that it makes the observed sample most probable (see **Estimation; Maximum Likelihood**). We can verify that a solution $\hat{\theta}$ of the equation $S(\theta) = 0$ is actually a maximum by checking that $I(\hat{\theta}) > 0$, where $I(\theta) = -\partial^2 \ell / \partial \theta^2$ is called the *Fisher information function*. The scalar quantity $I(\hat{\theta})$ is referred to as the *observed Fisher information*. A large value of $I(\hat{\theta})$ is associated with a well-defined maximum, indicating less uncertainty about θ .

Example 1: The time to failure T of components has an exponential distribution with mean θ . Suppose that n components are tested for 100 hours and that m components failed at times $t_1, \dots, t_m$, with $n - m$ components surviving the 100-h test. The likelihood function can be written as

$$L(\theta) = \underbrace{\prod_{i=1}^m \frac{1}{\theta} e^{-t_i/\theta}}_{\text{components failed}} \underbrace{\prod_{j=m+1}^n P(T_j > 100)}_{\text{components survived}} \quad (1)$$

Clearly $P(T \leq t) = 1 - e^{-t/\theta}$ implies $P(T > 100) = e^{-100/\theta}$ is the probability of a component surviving

the 100-h test. Then

$$L(\theta) = \left(\prod_{i=1}^m \frac{1}{\theta} e^{-t_i/\theta} \right) (e^{-100/\theta})^{n-m} \quad (2)$$

$$\ell(\theta) = -m \ln \theta - \frac{1}{\theta} \sum_{i=1}^m t_i - \frac{1}{\theta} 100(n-m) \quad (3)$$

$$S(\theta) = -\frac{m}{\theta} + \frac{1}{\theta^2} \sum_{i=1}^m t_i + \frac{1}{\theta^2} 100(n-m) \quad (4)$$

Setting $S(\hat{\theta}) = 0$ suggests the estimator $\hat{\theta} = [\sum_{i=1}^m t_i + 100(n-m)]/m$. Also, $I(\hat{\theta}) = m/\hat{\theta}^2 > 0$, and $\hat{\theta}$ is indeed the MLE. Although failure times were recorded for just m components, this example usefully demonstrates that all n components contribute to the estimation of the mean failure parameter θ . The $n - m$ surviving components are often referred to as *right censored* (see **Reliability Sampling**).

Multiparameter Estimation

Suppose that a statistical model specifies that the data $\mathbf{y}$ has a probability distribution $f(\mathbf{y}; \boldsymbol{\theta})$ depending on a vector of m unknown parameters $\boldsymbol{\theta} = (\theta_1, \dots, \theta_m)$. In this case, the likelihood function is a function of the m parameters $\theta_1, \dots, \theta_m$ and having observed the value of $\mathbf{y}$ is defined as $L(\boldsymbol{\theta}) = f(\mathbf{y}; \boldsymbol{\theta})$ with $\ell(\boldsymbol{\theta}) = \ln L(\boldsymbol{\theta})$.

The MLE of $\boldsymbol{\theta}$ is a value $\hat{\boldsymbol{\theta}}$ for which $L(\boldsymbol{\theta})$, or equivalently $\ell(\boldsymbol{\theta})$, attains its maximum value. For $r = 1, \dots, m$ define $S_r(\boldsymbol{\theta}) = \partial \ell / \partial \theta_r$. Then we can (usually) find the MLE $\hat{\boldsymbol{\theta}}$ by solving the set of m simultaneous equations $S_r(\boldsymbol{\theta}) = 0$ for $r = 1, \dots, m$. The information matrix $\mathbf{I}(\boldsymbol{\theta})$ is defined to be the $m \times m$ matrix whose (r, s) element is given by I_{rs} , where $I_{rs} = -\partial^2 \ell / \partial \theta_r \partial \theta_s$. The conditions for a value $\hat{\boldsymbol{\theta}}$ satisfying $S_r(\hat{\boldsymbol{\theta}}) = 0$ for $r = 1, \dots, m$ to be an MLE are that all the eigenvalues of the matrix $\mathbf{I}(\hat{\boldsymbol{\theta}})$ are positive.

Example 2: A Weibull random variable with “shape” parameter $a > 0$ and “scale” parameter $b > 0$ has density $f_T(t) = (a/b)(t/b)^{a-1} \exp\{-(t/b)^a\}$ for $t \geq 0$. The (cumulative) distribution function is $F_T(t) = 1 - \exp\{-(t/b)^a\}$ on $t \geq 0$. Suppose that

2 Lifetime Distributions, Optimization Methods for

the time to failure T of components has a Weibull distribution and after testing n components for 100 h, m components fail at times $t_1, \dots, t_m$, with $n - m$ components surviving the 100-h test. The likelihood function can be written

$$L(\theta) = \underbrace{\prod_{i=1}^m \frac{a}{b} \left(\frac{t_i}{b}\right)^{a-1} \exp\left\{-\left(\frac{t_i}{b}\right)^a\right\}}_{\text{components failed}} \underbrace{\prod_{j=m+1}^n \exp\left\{-\left(\frac{100}{b}\right)^a\right\}}_{\text{components survived}} \quad (5)$$

Then the log-likelihood function is

$$\ell(a, b) = m \ln(a) - ma \ln(b) + (a-1) \sum_{i=1}^m \ln(t_i) - \sum_{i=1}^n (t_i/b)^a \quad (6)$$

where for convenience we have written $t_{m+1} = \dots = t_n = 100$. This yields score functions

$$S_a(a, b) = \frac{m}{a} - m \ln(b) + \sum_{i=1}^m \ln(t_i) - \sum_{i=1}^n (t_i/b)^a \ln(t_i/b) \quad (7)$$

and

$$S_b(a, b) = -\frac{ma}{b} + \frac{a}{b} \sum_{i=1}^n (t_i/b)^a \quad (8)$$

It is not obvious how to solve $S_a(a, b) = S_b(a, b) = 0$ for a and b .

Newton–Raphson Optimization

When the m equations $S_r(\theta) = 0$, $r = 1, \dots, m$ cannot be solved directly, numerical optimization is required. Let $\mathbf{S}(\theta)$ be the $m \times 1$ vector whose r th element is $S_r(\theta)$. Let $\hat{\theta}$ be the solution to the set of equations $\mathbf{S}(\theta) = \mathbf{0}$ and let θ_0 be an initial guess at

$\hat{\theta}$. Then a first-order Taylor's series approximation to the function S about the point θ_0 is given by

$$S_r(\hat{\theta}) \approx S_r(\theta_0) + \sum_{j=1}^m (\hat{\theta}_j - \theta_{0j}) \frac{\partial S_r}{\partial \theta_j}(\theta_0) \quad (9)$$

for $r = 1, 2, \dots, m$ which may be written in matrix notation as

$$\mathbf{S}(\hat{\theta}) \approx \mathbf{S}(\theta_0) - \mathbf{I}(\theta_0)(\hat{\theta} - \theta_0) \quad (10)$$

Requiring $\mathbf{S}(\hat{\theta}) = \mathbf{0}$, this last equation can be reorganized to give

$$\hat{\theta} \approx \theta_0 + \mathbf{I}(\theta_0)^{-1} \mathbf{S}(\theta_0) \quad (11)$$

Thus given θ_0 this is a method for finding an improved guess at $\hat{\theta}$. We then replace θ_0 by this improved guess and repeat the process. We keep repeating the process until we obtain a value θ^* for which $|S_r(\theta^*)|$ is less than ϵ for $r = 1, 2, \dots, m$ where ϵ is some small number like 0.0001. θ^* will be an approximate solution to the set of equations $\mathbf{S}(\theta) = \mathbf{0}$. We then evaluate the matrix $\mathbf{I}(\theta^*)$ and if all m of its eigenvalues are positive we set $\hat{\theta} = \theta^*$.

Example 2 (continued): For the Weibull distribution

$$I_{aa} = \frac{m}{a^2} + \sum_{i=1}^n (t_i/b)^a [\ln(t_i/b)]^2 \quad (12)$$

$$I_{bb} = -\frac{ma}{b^2} + \frac{a(a+1)}{b^2} \sum_{i=1}^n (t_i/b)^a \quad (13)$$

$$I_{ab} = I_{ba} = \frac{m}{b} - \frac{1}{b} \sum_{i=1}^n (t_i/b)^a \times [\ln(t_i/b) + 1] \quad (14)$$

Given initial values a_0 and b_0 , equation (11) can be used to obtain updated estimates via

$$\begin{pmatrix} a_{\text{new}} \\ b_{\text{new}} \end{pmatrix} = \begin{pmatrix} a_0 \\ b_0 \end{pmatrix} + \begin{pmatrix} I_{aa}(a_0, b_0) & I_{ab}(a_0, b_0) \\ I_{ba}(a_0, b_0) & I_{bb}(a_0, b_0) \end{pmatrix}^{-1} \times \begin{pmatrix} S_a(a_0, b_0) \\ S_b(a_0, b_0) \end{pmatrix} \quad (15)$$

Table 1 Newton–Raphson estimates of the Weibull parameters

a_0	b_0	a^*	b^*	Steps	Eigenvalues
1.8	74.5	1.924941	78.12213	4	All positive

2	100	4.292059	−34.591322	2	Crashed

Having solved for a and b , we check that a maximum has been achieved by calculating $\mathbf{I}(a^*, b^*)$ and verifying that both of its eigenvalues are positive.

Suppose that $n = 10$ and $m = 8$ items fail at times 17, 29, 32, 55, 61, 74, 77, and 93 (in hours) with the remaining two items surviving the 100-h test. Table 1 shows estimates (a^*, b^*) obtained from equation (15) using various starting values (a_0, b_0) along with the number of iteration steps taken until convergence using $\epsilon = 0.000001$. Four of the starting pairs considered converged to estimates $a^* = 1.924941$ and $b^* = 78.12213$ for a and b . The starting pairs (1, 2) and (80, 1) might misleadingly suggest that the algorithm is robust to the choice of starting values. However, the starting pair (2, 100) produced a negative estimate of b , and as $\ln(b)$ is required in the computation of the score function, caused the algorithm to crash. Other starting pairs not reported failed to yield estimates due to a noninvertible $\mathbf{I}(\theta_0)$ matrix being produced during the running of the algorithm. The remainder of this section describes commonly applied modifications of the Newton–Raphson method.

Initial Values

The Newton–Raphson method depends on the initial guess being close to the true value. If this requirement is not satisfied, the procedure might converge to a minimum instead of a maximum, or just simply diverge and fail to produce any estimates at all. Methods of finding good initial estimates depend very much on the problem at hand and may require some ingenuity.

The distribution function of a Weibull random variable T can be linearized as $\log(-\log[1 - F(t)]) = -a \log(b) + a \log(t)$. A regression (see **Mean Square Error; Least-Squares Estimation**) of the empirical distribution function $\hat{F}(t)$ (see **Quantiles**)

on $\log(t)$ can be used to recover initial estimates for a and b . The starting pair (1.8, 74.5) in Table 1 was obtained in this way.

A more general method for finding initial values is the method of moments. This method estimates the k th moment (see **Moments**) about the origin $E(T^k)$ by the sample moment $\tilde{m}_k = n^{-1} \sum t_i^k$. For a Weibull distribution, the k th moment about the origin equals $b^k \Gamma(1 + k/a)$ where $\Gamma(c) = \int_0^\infty u^{c-1} e^{-u} du$ is the usual gamma function satisfying $\Gamma(c) = (c-1)\Gamma(c-1)$. It is easy to show that $E(T^2)/[E(T)]^2 = 2a\Gamma(2/a)/[\Gamma(1/a)]^2$. An estimate, a_0 , of a can be obtained by solving $\tilde{m}_2^2/(\tilde{m}_1)^2 = 2a\Gamma(2/a)/[\Gamma(1/a)]^2$ for a . The corresponding estimate of b is then $b_0 = \tilde{m}_1/\Gamma(1 + 1/a_0)$. The starting pair (2.36, 72) in Table 1 was obtained in this way.

Fisher’s Method of Scoring

One modification to the Newton–Raphson method is to replace the matrix $\mathbf{I}(\theta)$ in equation (11) with $\bar{\mathbf{I}}(\theta) = E[\mathbf{I}(\theta)]$. The matrix $\bar{\mathbf{I}}(\theta)$ is positive definite, thus overcoming many of the problems regarding matrix inversion. Like Newton–Raphson, there is no guarantee that Fisher’s method of scoring will avoid producing negative parameter estimates or converging to local minima. Unfortunately, calculating $\bar{\mathbf{I}}(\theta)$ can often be mathematically difficult.

The Profile Likelihood

Setting $S_b(a, b) = 0$ from equation (8) we can solve for b in terms of a as

$$b = \left[\frac{1}{m} \sum_{i=1}^n t_i^a \right]^{1/a} \quad (16)$$

This reduces our two-parameter problem to a search over the “new” one-parameter *profile* log-likelihood

$$\begin{aligned} \ell_a(a) &= \ell(a, b(a)) \\ &= m \ln(a) - m \ln \left(\frac{1}{m} \sum_{i=1}^n t_i^a \right) \\ &\quad + (a-1) \sum_{i=1}^m \ln(t_i) - m \end{aligned} \quad (17)$$

4 Lifetime Distributions, Optimization Methods for

Given an initial guess a_0 for a , an improved estimate a_1 can be obtained using a single-parameter Newton–Raphson updating step $a_1 = a_0 + S(a_0)/I(a_0)$, where $S(a)$ and $I(a)$ are now obtained from $\ell_a(a)$. The estimates $\hat{a} = 1.924941$ and $\hat{b} = 78.12213$ were obtained by applying this method to the Weibull data using starting values $a_0 = 0.001$ and $a_0 = 5.8$ in 16 and 13 iterations, respectively. However, the starting value $a_0 = 5.9$ produced the sequence of estimates $a_1 = -5.544163$, $a_2 = 8.013465$, $a_3 = -16.02908$, $a_4 = 230.0001$ and subsequently crashed.

Reparameterization

Negative parameter estimates can be avoided by reparameterizing the profile log-likelihood in equation (17) using $\alpha = \ln(a)$. Since $a = e^\alpha$ we are guaranteed to obtain $a > 0$. The reparameterized profile log-likelihood becomes

$$\begin{aligned} \ell_\alpha(\alpha) = m\alpha - m \ln \left(\frac{1}{m} \sum_{i=1}^n t_i^{e^\alpha} \right) \\ + (e^\alpha - 1) \sum_{i=1}^m \ln(t_i) - m \end{aligned} \quad (18)$$

implying score function

$$\begin{aligned} S(\alpha) = m - \frac{me^\alpha \sum_{i=1}^n t_i^{e^\alpha} \ln(t_i)}{\sum_{i=1}^n t_i^{e^\alpha}} \\ + e^\alpha \sum_{i=1}^m \ln(t_i) \end{aligned} \quad (19)$$

and information function

$$I(\alpha) = \frac{me^\alpha}{\sum_{i=1}^n t_i^{e^\alpha}} \times \left[\sum_{i=1}^n t_i^{e^\alpha} \ln(t_i) - \frac{e^\alpha \left[\sum_{i=1}^n t_i^{e^\alpha} \ln(t_i) \right]^2}{\sum_{i=1}^n t_i^{e^\alpha}} + e^\alpha \sum_{i=1}^n t_i^{e^\alpha} [\ln(t_i)]^2 \right] - e^\alpha \sum_{i=1}^m \ln(t_i) \quad (20)$$

The estimates $\hat{a} = 1.924941$ and $\hat{b} = 78.12213$ were obtained by applying this method to the Weibull data using starting values $a_0 = 0.07$ and $a_0 = 76$ in 103 and 105 iterations, respectively. However, the starting values $a_0 = 0.06$ and $a_0 = 77$ failed due to division by computationally tiny ($1.0e^{-300}$) values.

The Step-Halving Scheme

The Newton–Raphson method uses the (first and second) derivatives of $\ell(\theta)$ to maximize the function $\ell(\theta)$, but the function itself is not used in the algorithm. The log-likelihood can be incorporated into the Newton–Raphson method by modifying the updating step to

$$\theta_{i+1} = \theta_i + \lambda_i \mathbf{I}(\theta_i)^{-1} \mathbf{S}(\theta_i) \quad (21)$$

where the search direction has been multiplied by some $\lambda_i \in (0, 1]$ chosen so that the inequality

$$\ell(\theta_i + \lambda_i \mathbf{I}(\theta_i)^{-1} \mathbf{S}(\theta_i)) > \ell(\theta_i) \quad (22)$$

holds. This requirement protects the algorithm from converging toward minima or saddle points. At each iteration, the algorithm sets $\lambda_i = 1$, and if equation (22) does not hold, λ_i is replaced with $\lambda_i/2$. The process is repeated until the inequality in equation (22) is satisfied. At this point, the parameter estimates are updated using equation (21) with the value of λ_i for which equation (22) holds. If the function $\ell(\theta)$ is concave and unimodal, convergence is guaranteed. Finally, when $\bar{\mathbf{I}}(\theta)$ is used in place of $\mathbf{I}(\theta)$, convergence to a (local) maxima is guaranteed, even if $\ell(\theta)$ is not concave.

Approximate Standard Errors

Let $\hat{\theta} = (\hat{\theta}_1, \dots, \hat{\theta}_m)$ be the MLE of $\theta = (\theta_1, \dots, \theta_m)$. Let V_r^* and V_r be, respectively, the r th

diagonal elements of the matrices $[\tilde{\mathbf{I}}(\hat{\theta})]^{-1}$ and $[\mathbf{I}(\hat{\theta})]^{-1}$. The quantities $\sqrt{V_r^*}$ and $\sqrt{V_r}$ are often used as approximate standard errors of the MLE $\hat{\theta}_r$. Thus an approximate, 95% confidence interval (see **Confidence Intervals**) for θ_r is given by $[\hat{\theta}_r - 1.96\sqrt{V_r^*}, \hat{\theta}_r + 1.96\sqrt{V_r^*}]$. Another approximate, 95% confidence interval for θ_r is given by $[\hat{\theta}_r - 1.96\sqrt{V_r}, \hat{\theta}_r + 1.96\sqrt{V_r}]$.

Regression Problems

The time to failure T_i of electric fuse i , for $i = 1, \dots, n$ is thought to have a γ density $f_{T_i}(t_i; \omega, \lambda_i) = \lambda_i(\lambda_i y)^{\omega-1} e^{-\lambda_i y} / \Gamma(\omega)$ whose mean is given by $E(T_i) = \omega/\lambda_i = \mu_i = \beta_0 + \beta_1 x_i$ where x_i is the voltage applied across the fuse, and the parameter ω is constant across all i . The density of T_i can also be written as $f_{T_i}(t_i; \omega, \theta_i) = \exp\{\omega[t_i \theta_i + \ln(-\theta_i)] + c(t_i, \omega)\}$ for $t_i > 0$, where $\theta_i = -1/\mu_i$ and $c(t_i, \omega) = (\omega - 1) \ln y_i - \ln \Gamma(\omega) + \omega \ln \omega$. For the purposes of this example we will not consider inferences about ω .

A probability distribution is said to belong to the exponential family (of distributions) if its density function $f_Y(y; \theta)$ can be written in the form $f_Y(y; \theta) = \exp\{(\omega/\phi)[y\theta - b(\theta)] + c(y, \phi)\}$, where θ, ϕ are scalar parameters and ω is a known constant. Clearly this is satisfied by the gamma distribution with $\phi = 1$ and $b(\theta) = -\ln(-\theta)$. The exponential family of distributions give rise to a wide class of regression problems, collectively known as *generalized linear models* (see **Generalized Linear Models**). These have three components: (a) a parent distribution for the response variable Y , which in our example is gamma, having expected value $E(Y_i) = \mu_i$; (b) a linear predictor $\eta_i = \mathbf{x}_i^T \boldsymbol{\beta}$, which in our example is $\eta_i = \beta_0 + \beta_1 x_i$; and (c) a link function $g(\mu_i) = \eta_i$, which in our example is $g(\mu_i) = -1/\mu_i$. Using this formulation, a general method can be derived for fitting the models using MLE and Fisher's scoring algorithm, which further reduce to fitting using iterative weighted least squares.

Stochastic Search

Although the Newton–Raphson method is sufficient for most problems, it does not perform well in the

presence of likelihood functions containing multiple optima. Stochastic search routines (for example, see **Hierarchical Markov Chain Monte Carlo (MCMC) for Bayesian System Reliability; Genetic Algorithms in Reliability**) should be considered in such circumstances. One such routine, simulated annealing, works on the basis that at each iteration step the search makes a random jump to a different part of the likelihood function. Downward jumps are always possible, thus allowing the algorithm to escape from local maxima, but such jumps become less likely as the updated value of the estimated maximum increases.

Concluding Remarks

This article gives only a brief account of optimization methods in statistics. For more details see any of the texts [1–4].

The popular statistical software package R contains a general-purpose optimization function `optim()` that implements Newton–Raphson, quasi-Newton, and conjugate gradient algorithms. It also includes an option for simulated annealing. Alternatively, FORTRAN and C code can be obtained from [5] and [6].

KEVIN HAYES AND DON BARRY

Bootstrap and Jackknife, Overview

Introduction

About a quarter of a century ago, the age of fast, cheap computing dawned. Now, with ever faster computers on the desktop, we live in an age of which previous generations of scientists can only have dreamed. The classical ways of the past now seem rather restrictive – the reliance on simplifying distributional (usually normal) assumptions fails a basic test of usability as the conditions on which they depend do not seem to hold in many important real-world problems. Supported by the advent of unprecedented computational power, new, computer-intensive approaches were developed based on the simple idea that the sample data itself must hold more information than is explicitly used by classical methods, particularly when classical assumptions fail – so-called sample reuse or “resampling” was born. Several types of resampling are now commonplace, with whimsical names like *jackknife* and *bootstrap* capturing the imaginations of statisticians and non-statisticians alike. These methods replace the overt use of tools like central limit theorems to approximate sampling distributions of certain statistics by “generating” these distributions on the basis of the behavior of a statistic under “resampled data” derived from the original data using a resampling rule. In many cases of practical interest, the distributions so generated converge to the true, unknown sampling distributions as sample size grows.

Some sample reuse methods were proposed well before the advent of fast, modern computing. Permutation procedures were developed as early as the 1930s by Fisher and others [1], but their widespread use was delayed by the lack of available computing power. The jackknife was first proposed in 1949 by Quenouille [2] as a method for **bias** reduction in a **time series estimation** context, and it was later popularized by Tukey in a famous 1958 abstract [3] promoting its use beyond its original, restricted setting to variance estimation (see **Variance**). The bootstrap, a method now virtually synonymous with the term *resampling*, was introduced by Efron in 1979 [4], and leveraged the explosion of computational power occurring at the time to allow thousands

of bootstrap resamples to be used in generating the sampling distributions of complex statistics. Efron’s realization in marrying an “old” idea, that of using the empirical cumulative distribution function (CDF) (see **Cumulative Distribution Function (CDF)**) in place of the true unknown CDF in thinking about the sampling distribution of a statistic of interest, with the means to carry out the necessary calculations – resampling from the data with replacement – was a watershed moment in modern statistics.

The predominant resampling methods in common usage are the jackknife, the bootstrap, and permutation tests. Apart from the bootstrap, which is the most utilitarian of the techniques, other techniques have attracted use for specific purposes, the jackknife primarily for bias and variance estimation, and permutation tests for assessing the equality of two distributions. In this article, we will describe some common and important uses for the jackknife and the bootstrap. Another article, *Sampling from Virtual Populations* (see **Sampling from Virtual Populations**) places the jackknife and the bootstrap more generally in the context of sampling algorithms. In the context of statistical reliability, see **Resampling for Lifetime Distributions**, which focuses in particular on the theory behind resampling methods specifically in a lifetime data setting.

The Jackknife

Quenouille [2] introduced the jackknife as a method to correct for bias in time series estimation (see **Time Series Analysis**). Tukey [3] popularized the idea and coined its name in perhaps statistics’ most famous abstract (there was no paper). The basic idea of the jackknife is to mimic a kind of repeated sampling by creating so-called jackknife samples, and then to use the values of the relevant statistic calculated for those samples in forming bias (see **Bias of an Estimator**) and variance estimates. Specifically, given a sample $\mathbf{X} = (X_1, \dots, X_n)$ and an estimator $\hat{\theta} = \hat{\theta}(X) = \hat{\theta}(X_1, \dots, X_n)$ that is symmetric in the data, define jackknife (leave-1-out) samples:

$$\begin{aligned}\mathbf{X}_1 &= (X_2, \dots, X_n), \dots, \\ \mathbf{X}_i &= (X_1, \dots, X_{i-1}, X_{i+1}, \dots, X_n), \dots, \\ \mathbf{X}_n &= (X_1, \dots, X_{n-1})\end{aligned}\tag{1}$$

Now, define the jackknife replicates $\hat{\theta}_{(i)} = \hat{\theta}(X_1, \dots, X_{i-1}, X_{i+1}, \dots, X_n)$, the value of $\hat{\theta}$ computed using the i th jackknife sample. Define $\hat{\theta}_{(\bullet)} = n^{-1} \sum_{i=1}^n \hat{\theta}_{(i)}$. Then, the jackknife estimate of the bias of $\hat{\theta}$ in estimating θ is $\hat{b}_{\text{Jack}}(\hat{\theta}) = (n-1)[\hat{\theta}_{(\bullet)} - \hat{\theta}]$, and so a bias-corrected estimate of θ is $\hat{\theta}_{\text{corrected}} = \hat{\theta} - \hat{b}_{\text{Jack}}(\hat{\theta}) = n\hat{\theta} - (n-1)\hat{\theta}_{(\bullet)}$. For the sample mean, $\hat{\theta}_{(\bullet)}$ is equal to the sample mean, and the jackknife estimate of bias is zero. For the (biased) estimate $\hat{\theta} = n^{-1} \sum_{i=1}^n (X_i - \bar{X})^2$ of a variance, it turns out that $\hat{\theta}_{(\bullet)} = (n-1)^{-2}(n-2) \sum_{i=1}^n (X_i - \bar{X})^2$, and so $\hat{\theta}_{\text{corrected}} = (n-1)^{-1} \sum_{i=1}^n (X_i - \bar{X})^2$, the usual unbiased variance estimator. Basically, the jackknife removes the first-order ($O(n^{-1})$) term in the bias expansion of the original estimator. In the case of the variance discussed above, it removes *all* of the bias, and, indeed, it always does so for quadratic functionals of the underlying distribution function.

In suggesting its use beyond bias estimation, Tukey [3] developed an alternative way to view the jackknife, in terms of so-called pseudovalues, $\tilde{\theta}_i = n\hat{\theta} - (n-1)\hat{\theta}_{(i)}$, based on the jackknife replicates. In terms of the pseudovalues, the jackknife bias-corrected estimate of θ is simply the average of the pseudovalues $\hat{\theta}_{\text{corrected}} = n^{-1} \sum_{i=1}^n \tilde{\theta}_i = n\hat{\theta} - (n-1)\hat{\theta}_{(\bullet)}$. The pseudovalues were constructed so that in the case of the mean, the pseudovalues were just the original data points and the jackknife estimator returned the sample mean. Informally, the i th pseudovalue is a measure of the “influence” the i th data point has on the estimator $\hat{\theta}$, and so the pseudovalues act as “data points” on the same scale as the parameter estimate.

Tukey further reasoned that if pseudovalues act like data points, their use may be generalized to include variance estimation: $\hat{V}_{\text{Jack}}(\hat{\theta}) = n^{-1}(n-1) \sum_{i=1}^n (\hat{\theta}_{(i)} - \hat{\theta}_{(\bullet)})^2$, or, in terms of pseudovalues, $\hat{V}_{\text{Jack}}(\hat{\theta}) = \{n(n-1)\}^{-1} \sum_{i=1}^n (\tilde{\theta}_i - \hat{\theta}_{\text{corrected}})^2$, the latter formula reminiscent of the case of the variance estimator of the sample mean, $\hat{V}(\bar{X}) = \{n(n-1)\}^{-1} \sum_{i=1}^n (X_i - \bar{X})^2 = s^2/n$. Uses of the jackknife beyond bias correction and variance estimation have been disappointing. For example, its use in constructing confidence intervals (see **Confidence Intervals**) has been limited and generally resulted in intervals with poor coverage properties.

Permutation Tests

Permutation tests are the oldest resampling method, introduced in the 1930s by Fisher [1] but essentially shelved until recent times when computing power became sufficient to allow their regular use. Suppose that we have data $X_1, X_2, \dots, X_n$ and $Y_1, Y_2, \dots, Y_m$, m not necessarily equal to n . We wish to test whether X and Y arise from the same distribution (so if F is the distribution function of X , and G is the distribution of Y , we want to test $F = G$). Under the hypothesis that F and G are the same, then we can think of $X_1, X_2, \dots, X_n$ and $Y_1, Y_2, \dots, Y_m$ as a single sample of size $n+m$ from the common distribution. The idea is to sample from all $n+m$ data points at random without replacement, allocating the first n points to an “ X ” sample, and the remaining m points to a “ Y ” sample. This process simulates repeated sampling *under the assumption that the parent distributions are the same*. Now for each permutation, compute the value of some test statistic which measures disparity between the distributions of X and Y . Obviously, there are many possible choices for such a statistic, for example, $\bar{X} - \bar{Y}$, (close to 0 if $F = G$), $\bar{X}/\bar{Y}$, (close to 1 if $F = G$), or $\text{median}(X) - \text{median}(Y)$. Extreme values of the test statistic support the hypothesis that the two distributions differ, and “extreme” is defined in terms of the null distribution of the test statistic. The null distribution is generated using the simulated “repeated sampling” – that is, the permutations. For each permutation, the value of the chosen test statistic is calculated, and the Actual Significance Level (ASL), defined as the proportion of permutation values not exceeding the observed test statistic, is computed. A two-sided α -level test rejects the null hypothesis if $\min\{\text{ASL}, (1 - \text{ASL})\} < \alpha/2$.

The Bootstrap

The bootstrap, introduced by Efron in 1979 [4], has become almost synonymous with the term *resampling*, mainly because of its wide applicability and the flexibility it offers in allowing practitioners to avoid restrictive parametric assumptions in their analyses. Efron’s genius lay in his realization that the simple idea of using the empirical distribution function in place of the unknown population distribution function in estimating a parameter of interest could be implemented through a computationally intensive scheme

of sampling from the data itself. Efron also coined the term *bootstrap*, perhaps referring to the legendary Baron von Munchausen of German folklore, who was said to have saved himself from drowning by hoisting himself up by his own bootstraps! Many statistics of interest are functionals of the underlying CDF (see **Cumulative Distribution Function (CDF)**): $\theta = \theta(F)$. For example, the mean, $\mu = \int x dF$. A natural “plug-in” estimator of θ replaces F by the empirical CDF $\hat{F}(x) = n^{-1}\{\#(X_i \leq x)\}$ for data $X_1, \dots, X_n$, the proportion of observed data not exceeding x . The “bootstrap estimator” of θ is $\hat{\theta} = \theta(\hat{F})$, the same functional of $\hat{F}$. For independent and identically distributed (i.i.d.) data and under mild conditions, $|\hat{F}(x) - F(x)| = O_p(n^{-1/2})$, and $\hat{F}(x)$ estimates the true underlying distribution F well (in “normal deviations” regions) even for small values of n . Informally, because $\hat{F} \rightarrow F$, provided θ is a reasonably smooth functional, then $\hat{\theta} \rightarrow \theta$. The bootstrap paradigm involves sampling from $\hat{F}(x)$ in order to simulate repeated sampling from F . Resamples $X_1^*, \dots, X_n^*$ are drawn from $X_1, \dots, X_n$ using the rule $P(X_i^* = X_j) = 1/n$, for all i, j . Bootstrap resampling involves sampling *with* replacement from n equally likely data points. By contrast, permutation tests use sampling without replacement. Each resample, conditional on the data, has distribution function $\hat{F}$, so “repeated sampling” versions of $\hat{\theta} = \theta(\hat{F}) = \theta(X_1, \dots, X_n)$ are $\hat{\theta}^* = \theta(X_1^*, \dots, X_n^*)$, and the bootstrap distribution of $\hat{\theta}$ (the empirical distribution of the $\hat{\theta}^*$ values, conditional on the original data) estimates the sampling distribution of $\hat{\theta}$.

The nature of bootstrap resampling makes clear the importance of two assumptions: in resampling,

the points sampled can appear *in any order* and *in roughly equal proportions*. *In any order* suggests that independence (at least exchangeability) is an important assumption; *in roughly equal proportions* suggests that the data arise from a common distribution. As a result, the basic assumption is that the data is i.i.d. Both assumptions can be relaxed, but doing so requires significant modification to the bootstrap algorithm to allow for resampling independent “units” with like structure.

In principle, “repeated sampling” in the traditional sense reflects an *ad infinitum* thought experiment. But the finite nature of the data means that bootstrapping cannot be conducted this way. The total number of possible distinct resamples is $\binom{2n-1}{n}$ (assuming distinct data), but exhaustive bootstrap sampling is rarely used. In practice, a random sample of resamples is drawn, and the number of resamples required for reasonable performance varies depending on the application. Hundreds of resamples are typically sufficient for point estimation (bias, variance), while thousands of resamples are necessary for interval estimation where tail information is needed.

Figure 1 illustrates the bootstrap paradigm, the idea that the constructed relationship relating the sample and resample “worlds” can be effectively transplanted to allow inferences about model parameters, thereby eliminating the need for classical distributional assumptions through the use of computational effort.

The bootstrap has found wide usage for bias and variance estimation and in the construction of confidence intervals and hypothesis tests (see **Hypothesis Testing**). It has also been applied much

Figure 1 A schematic diagram for the bootstrap

more broadly, for example to setting confidence bands for curvilinear relationships using nonparametric curve estimators, and to problems such as spatial kriging. In a reliability context, bootstrap methods have been employed for setting tolerance intervals for process capability indices (*see Process Capability Indices, Nonnormal*; and Chernick [5, p. 134]) for a discussion of this and other uses in this area, with bootstrap confidence interval construction a key element. Here, we will describe the major uses of the bootstrap, leaving specific discussion to related, more specific articles (*see Resampling for Lifetime Distributions*).

Bootstrap Bias and Variance Estimation

The bias of an estimator $\hat{\theta}$, $b(\hat{\theta}) = E_F(\hat{\theta}) - \theta = E_F\{\theta(\hat{F})\} - \theta(F)$ is a functional of the underlying distribution and of the empirical CDF. Under the bootstrap paradigm, replacing population quantities by sample quantities and sample quantities by resample quantities,

$$\begin{aligned}\hat{b}_{\text{Boot}}(\hat{\theta}) &= E_{\hat{F}}(\hat{\theta}^*) - \hat{\theta} \\ &= E_{\hat{F}}\{\theta(\hat{F}^*)\} - \theta(\hat{F}) \\ &= E_{\hat{F}}\{\theta(X_1^*, \dots, X_n^*)\} - \theta(X_1, \dots, X_n)\end{aligned}\quad (2)$$

where $\hat{F}^*$ is the empirical CDF of a resample $(X_1^*, \dots, X_n^*)$. The bootstrap bias formula involves the quantity $E_{\hat{F}}(\hat{\theta}^*)$, which could be calculated exactly using all possible resamples. In practical terms, we resort to a Monte Carlo algorithm (*see Monte Carlo Methods*) to approximate it: resample $\{X_1^*, \dots, X_n^*\}$ B times from $\{X_1, \dots, X_n\}$ and compute $\hat{\theta}^* = \hat{\theta}(X_1^*, \dots, X_n^*)$ to obtain B values $\hat{\theta}_1^*, \dots, \hat{\theta}_B^*$. The approximation for $E_{\hat{F}}(\hat{\theta}^*)$ is the average $\hat{E}_{\hat{F}}(\hat{\theta}^*) = B^{-1} \sum_{b=1}^B \hat{\theta}_b^*$. The bootstrap bias estimate is $B^{-1} \sum_{b=1}^B \hat{\theta}_b^* - \hat{\theta}$ and the bootstrap bias-corrected estimate is $2\hat{\theta} - B^{-1} \sum_{b=1}^B \hat{\theta}_b^*$, which typically has bias an order of magnitude lower than that of $\hat{\theta}$.

For variance estimation, note that the variance of $\hat{\theta}$ is $V(\hat{\theta}) = E_F(\hat{\theta}^2) - \{E_F(\hat{\theta})\}^2$. The bootstrap estimator of $V(\hat{\theta})$ is thus $\hat{V}_{\text{Boot}}(\hat{\theta}) = E_{\hat{F}}\{(\hat{\theta}^*)^2\} - \{E_{\hat{F}}(\hat{\theta}^*)\}^2$. A Monte Carlo approach can be employed using “bootstrap values” $\hat{\theta}_1^*, \hat{\theta}_2^*, \dots, \hat{\theta}_B^*$

to approximate expectations under $\hat{F}$. Then, $\hat{V}_{\text{Boot}}(\hat{\theta}) = B^{-1} \sum_{b=1}^B \{\hat{\theta}_b^*\}^2 - \left(B^{-1} \sum_{b=1}^B \hat{\theta}_b^*\right)^2 = B^{-1} \sum_{b=1}^B (\hat{\theta}_b^* - \bar{\theta}^*)^2$, where $\bar{\theta}^* = B^{-1} \sum_{b=1}^B \hat{\theta}_b^*$. Note that $\hat{V}_{\text{Boot}}(\hat{\theta})$ is biased for the true variance as it uses divisor B rather than $B-1$. An unbiased, bootstrap variance estimator is $\hat{V}_{\text{Boot}}(\hat{\theta}) = (B-1)^{-1} \sum_{b=1}^B (\hat{\theta}_b^* - \bar{\theta}^*)^2$, the sample variance of the bootstrap quantities $\hat{\theta}_1^*, \hat{\theta}_2^*, \dots, \hat{\theta}_B^*$.

Bootstrap Confidence Intervals

One of the major uses of the bootstrap is confidence interval construction (*see Confidence Intervals*). The standard $100(1-\alpha)\%$ normal theory confidence interval for a parameter θ , $\hat{\theta} \pm z_{1-\alpha/2} \text{s.e.}(\hat{\theta})$, makes the assumption that the standardized quantity $(\hat{\theta} - \theta) / \text{s.e.}(\hat{\theta})$ has a standard normal distribution (*see Normal Distribution*). Our description of bootstrap confidence intervals is based on the concept of pivots, quantities whose (asymptotic) distributions do not depend on unknown parameters. The various bootstrap methods replace the standard normal assumption by bootstrap estimates of the sampling distributions of various “pivots”. We will describe several kinds of bootstrap confidence intervals, each based on different approximate “pivots”: percentile method, percentile- t method (or bootstrap- t), and Efron’s accelerated bias-corrected BC_a method.

The percentile method is based on the premise that the bootstrap distribution of $\hat{\theta}^*$ (that is, the distribution of $\hat{\theta}^*$ under repeated sampling from $\hat{F}$) is close to the distribution of $\hat{\theta}$ under F . **Quantiles** of the bootstrap distribution of $\hat{\theta}^*$ are then used as interval endpoints: if $\hat{G}$ represents the CDF of the bootstrap distribution of $\hat{\theta}^*$, then the interval $[\hat{G}^{-1}(\alpha/2), \hat{G}^{-1}(1-\alpha/2)]$ is a $100(1-\alpha)\%$ percentile method interval for θ . In principle, the percentile interval performs no better than the standard interval, at least in terms of coverage accuracy. It does, however, allow for asymmetry, which means its shape may be more appropriate than that of the standard interval. If there exists a monotone transformation g of $\hat{\theta}$ for which $\hat{\phi} = g(\hat{\theta}) \sim N(\phi, \tau^2)$, where $\phi = g(\theta)$ and τ is a known constant, then the percentile method works well. In this case, we can think of the percentile method as being based on the pivot $(\hat{\phi} - \phi) / \tau$. Moreover, the percentile method is transformation respecting, so the practitioner need

not know what the right transformation is, just that one exists. This property is a major improvement on the standard interval. An excellent example where this phenomenon applies, at least approximately, is the correlation coefficient (see **Correlation**), where Fisher's $\tanh^{-1}$ function effectively normalizes the correlation to a constant variance scale.

To construct a percentile method interval for a parameter θ given data $X_1, \dots, X_n$ and an estimator $\hat{\theta}$ of θ , resample B times $\{X_1^*, \dots, X_n^*\}$ from $\{X_1, \dots, X_n\}$ each time computing $\hat{\theta}^* = \hat{\theta}(X_1^*, \dots, X_n^*)$ to obtain B values $\hat{\theta}_1^*, \dots, \hat{\theta}_B^*$. The $100(1 - \alpha)\%$ equal-tailed percentile interval for θ is $[\hat{\theta}_{[\alpha B/2+1]}^*, \hat{\theta}_{[(1-\alpha)B/2+1]}^*]$, where $\hat{\theta}_{[1]}^* \leq \dots \leq \hat{\theta}_{[B]}^*$ denote the ordered $\hat{\theta}^*$ values.

The percentile- t method is based on the premise that the bootstrap distribution of $(\hat{\theta}^* - \hat{\theta})/s^*$ is close to the distribution of $(\hat{\theta} - \theta)/s$, where $s = s(X_1, \dots, X_n)$ is an estimate of the **standard error** of $\hat{\theta}$ and $s^* = s(X_1^*, \dots, X_n^*)$ is its bootstrap version. Quantiles of the bootstrap distribution of $(\hat{\theta}^* - \hat{\theta})/s^*$ are then used to construct interval endpoints. Formally, if $\hat{K}$ represents the CDF of the bootstrap distribution of $(\hat{\theta}^* - \hat{\theta})/s^*$, then the interval $[\hat{\theta} - s\hat{K}^{-1}(1 - \alpha/2), \hat{\theta} - s\hat{K}^{-1}(\alpha/2)]$ is a $100(1 - \alpha)\%$ percentile- t method interval for θ .

The percentile- t interval performs well provided an adequate estimate of the standard error (see **Standard Error**) of $\hat{\theta}$ is available. Nevertheless, the interval endpoints produced by the percentile- t method are *second-order correct*, meaning that they agree with theoretically “correct” endpoints to terms of order $O(n^{-1})$. In contrast, the percentile method interval is only first-order correct, as is the classical “standard interval”.

If the scale estimate s is not stable enough, especially in small samples, the percentile- t method can go awry. For example, in the case of the correlation coefficient, percentile- t intervals can extend well outside the $[-1, 1]$ range of the parameter. Unfortunately, like the standard interval, the percentile- t interval is not range respecting. It is also not transformation respecting, so it does not share the advantage of the percentile interval in automatically benefiting from the existence of an appropriate normalizing transformation.

To construct a percentile- t method interval for a parameter θ given data $X_1, \dots, X_n$ and an estimator $\hat{\theta}$ of θ and an estimator s of the

standard error of $\hat{\theta}$, resample B times $\{X_1^*, \dots, X_n^*\}$ from $\{X_1, \dots, X_n\}$, each time computing $\hat{\tau}^* = \{\hat{\theta}(X_1^*, \dots, X_n^*) - \hat{\theta}(X_1, \dots, X_n)\}/(s(X_1^*, \dots, X_n^*))$ to obtain B values $\hat{\tau}_1^*, \hat{\tau}_2^*, \dots, \hat{\tau}_B^*$. The $100(1 - \alpha)\%$ equal-tailed percentile- t interval for θ is $[\hat{\theta} - s\hat{\tau}_{[(1-\alpha)B/2+1]}^*, \hat{\theta} - s\hat{\tau}_{[\alpha B/2+1]}^*]$, where $\hat{\tau}_{[1]}^* \leq \hat{\tau}_{[2]}^* \leq \dots \leq \hat{\tau}_{[B]}^*$ denote the ordered $\hat{\tau}^*$ values.

BC_a intervals modify percentile method intervals to improve their coverage accuracy. The percentile method tacitly assumes that there exists a monotone transformation g of $\hat{\theta}$ for which $\hat{\phi} = g(\hat{\theta}) \sim N(\phi, \tau^2)$, where $\phi = g(\theta)$ and τ is a known constant. The BC_a interval assumes that a normalizing transformation g exists, but that the resultant model is potentially biased and has nonconstant variance. Instead, it allows that $(\hat{\phi} - \phi)/(\tau(1 + a\phi)) \sim N(-z_0, 1)$ for constants z_0 (biasing constant) and a (acceleration constant, called so because it measures the rate of change of the standard error with respect to the normalized parameter). The BC_a method adjusts the quantiles of the distribution of $\hat{\theta}^*$ to account for the bias and accelerated variance of this normal approximation. The resultant BC_a interval is

$$\left[\hat{G}^{-1} \left(\Phi \left\{ \hat{z}_0 + (1 - \hat{a}(\hat{z}_0 + z_{\alpha/2}))^{-1} (\hat{z}_0 + z_{\alpha/2}) \right\} \right), \right. \\ \left. \hat{G}^{-1} \left(\Phi \left\{ \hat{z}_0 + (1 - \hat{a}(\hat{z}_0 + z_{(1-\alpha)/2}))^{-1} \right. \right. \right. \\ \left. \left. \left. \times (\hat{z}_0 + z_{(1-\alpha)/2}) \right\} \right) \right] \quad (3)$$

Efron [6] developed the BC_a interval as an adjustment to the percentile interval to allow for a more flexible model for the distribution of $(\hat{\phi} - \phi)/\tau$. Thought of in this way, the BC_a method is an attempt to approximate the distribution of this “pivot” better than the percentile method does by allowing the limiting distribution to incorporate appropriate bias and variance terms. A key part of implementing the BC_a interval is the estimation of the biasing and acceleration constants. The biasing constant is estimated as $\hat{z}_0 = \Phi^{-1}\{\hat{G}(\hat{\theta})\}$, while the acceleration constant is estimated as $\hat{a} = \sum_{i=1}^n (\hat{\theta}_{(i)} - \hat{\theta}_{(i)})^3 / [6\{\sum_{i=1}^n (\hat{\theta}_{(i)} - \hat{\theta}_{(i)})^2\}^{3/2}]$. DiCiccio and Efron [7] developed an analytical approximation to BC_a intervals, called the *ABC method*, designed to avoid the need for significant resampling. The algorithm replaces bootstrap quantities in the BC_a algorithm

by Taylor series approximations. The ABC method shares the advantages of the BC_a method, but can be computed in a small fraction of the time that BC_a intervals require.

Use of the bootstrap has also been proposed in a variety of contexts beyond those already described here. Bootstrap **hypothesis testing** has been developed both as an extension of bootstrap confidence interval methods and also in specific contexts where resampling under relevant hypotheses has been developed. A particularly important use of the bootstrap has been in the contexts of regression and time series models. For regression models, two main approaches have been developed: residual-based resampling, where i.i.d. model residuals (*see Residuals*) are resampled and the fitted model is added back to the resampled residuals to create resampled data; and case-based resampling, where individual cases (**covariate**/response pairs) are resampled under the notion that they represent i.i.d. variates drawn from an appropriate multivariate distribution. Time series settings pose particularly difficult questions for the bootstrap, as serial dependence (*see Dependence*) in data contravenes the exchangeability assumption required by the basic bootstrap. Again, two approaches have been developed to deal with this problem, the first based on resampling residuals from an appropriate Autoregressive Integrated Moving Average (ARIMA) (*see Large Autoregressive Integrated Moving Average (ARIMA) Modeling*), or other, model, and the second based on resampling “blocks” of contiguous data points under the notion that while data may suffer short-range dependence, data points sufficiently far apart (that is, in different blocks) should be close to independent.

Where to Look for More Information

In an article of this length, it is only possible to skim the surface of a topic as broad as resampling, and only a very limited set of references is possible. A number of excellent monographs provide much additional detail. Efron and Tibshirani [8] is an excellent starting point, providing a very good, accessible account of the bootstrap in practice. Davison and Hinkley [9] gives a very thorough overview of resampling in a very broad set of contexts. More theoretical

accounts are given by Shao and Tu [10] and Hall [11], while Chernick [5] gives an exhaustive bootstrap bibliography with about 1600 references. Young [12] offers an excellent article outlining the achievements of, and the challenges for, the bootstrap.

MICHAEL A. MARTIN AND STEVEN ROBERTS

Asymptotic Reliability Analysis of Very Large Structural Systems

Introduction

Uncertainties need to be taken into account for optimal and reliable design of complex safety-critical structural systems such as aircraft, helicopters, and marine vehicles. Such uncertainties include, but are not limited to, uncertainties in specifying material properties, geometric parameters, boundary conditions, and applied loadings. Other articles in this encyclopedia that deal with related problems are **Fault Tree Analysis for Large Systems**, **Quadrature and Numerical Integration**, and **Normal Distribution**, respectively. Suppose that the random variables describing the uncertainties in the structural properties and loading are considered to form a vector $\mathbf{x} \in \mathbb{R}^n$ where n is the number of random variables. The statistical properties of the system are fully described by the joint **probability density function** $p(\mathbf{x}) : \mathbb{R}^n \mapsto \mathbb{R}$. For a given set of variables $\mathbf{x}$, the structure will either fail under the applied (random) loading or be safe. The condition of the structure for every $\mathbf{x}$ can be described by a safety margin $g(\mathbf{x}) : \mathbb{R}^n \mapsto \mathbb{R}$ such that the structure fails if $g(\mathbf{x}) \leq 0$ and is safe if $g(\mathbf{x}) > 0$. Thus, the probability of failure is given by

$$P_f = \int_{g(\mathbf{x}) \leq 0} p(\mathbf{x}) d\mathbf{x} \quad (1)$$

The function $g(\mathbf{x})$ is also known as the *limit-state function* and the $(n - 1)$ -dimensional surface $g(\mathbf{x}) = 0$ is known as the *failure surface*. The central theme of a structural reliability analysis is to evaluate the multidimensional integral (1). The exact evaluation of this integral, either analytically or numerically, is not possible for most practical problems because n is usually large and $g(\mathbf{x})$ is a highly nonlinear function of $\mathbf{x}$ which may not be available explicitly. Over the past three decades, there has been extensive research (see, e.g., the books [1–4]) to develop approximate numerical methods for the efficient calculation of the reliability integral. The approximate reliability methods can be broadly grouped into (a) first-order reliability method

(FORM) and (b) second-order reliability method (SORM). In FORM and SORM, it is assumed that all the basic random variables are transformed and scaled so that they are uncorrelated Gaussian random variables, each with zero mean and unit standard deviation.

The difficulty in computing the failure probability using classical FORM and SORM increases rapidly with the number of variables or “dimension”. There are two main reasons behind this. The first is the increase in computational time with the increase in the number of random variables. In principle, this problem can be handled with superior computational tools and powerful computing machines. The second, which is perhaps more fundamental, is that there are some conceptual difficulties associated typically with high dimensions. In the context of FORM, using the Tchebysheff bound, Veneziano [5] has shown that the probability of failure depends on the dimension n although the reliability index does not explicitly depend on n . In the context of SORM, using the χ^2 distribution, Fiessler *et al.* [6] have shown that there can be a significant difference in the probability of failure in higher dimensions for a fixed value of the reliability index. This means that even if one manages to carry out the necessary computations, the application of existing FORM and SORM may still lead to incorrect results in high dimensions. In this chapter, two asymptotic approximations are derived for the case when the number of random variables $n \rightarrow \infty$.

Asymptotic Distribution of Quadratic Forms

We suppose that the random variables are scaled so that $\mathbf{x}$ is a standard n -dimensional Gaussian random vector. Using classical SORM (see, e.g., [2, 7, 8]), the failure surface can be approximated as

$$\tilde{g} \approx -y_n + \beta + \mathbf{y}^T \mathbf{A} \mathbf{y} \quad (2)$$

Here $\mathbf{y}$ is an $(n - 1)$ -dimensional standard Gaussian random vector, y_n is a standard Gaussian random variable, and $\mathbf{A}$ is a symmetric, positive definite matrix. The scalar β is known as the *reliability index* [9], which is the minimum distance of the failure surface from the origin in $\mathbb{R}^n$. The eigenvalues of $\mathbf{A}$ can be related to the principal curvatures of the failure surface at the design point. With the

2 Asymptotic Reliability Analysis of Very Large Structural Systems

approximation in equation (2), the failure probability is given by

$$\begin{aligned} P_f &\approx \text{Prob}[\tilde{g} \leq 0] \approx \text{Prob}[y_n \geq \beta + \mathbf{y}^T \mathbf{A} \mathbf{y}] \\ &= \text{Prob}[y_n \geq \beta + U] \end{aligned} \quad (3)$$

where

$$U : \mathbb{R}^{n-1} \mapsto \mathbb{R} = \mathbf{y}^T \mathbf{A} \mathbf{y} \quad (4)$$

is a central quadratic form in standard Gaussian random variables.

Using quadratic approximation of the failure surface together with asymptotic analysis, Breitung [10] proved that

$$\begin{aligned} P_f &\longrightarrow \Phi(-\beta) \|\mathbf{I}_{n-1} + 2\beta \mathbf{A}\|^{-1/2} \\ \text{when } \beta &\longrightarrow \infty \end{aligned} \quad (5)$$

Here $\Phi(\bullet)$ is the standard Gaussian cumulative distribution function. Later, Hohenbichler and Rackwitz [11] proposed the following formula

$$P_f \approx \Phi(-\beta) \left\| \mathbf{I}_{n-1} + 2 \frac{\varphi(\beta)}{\Phi(-\beta)} \mathbf{A} \right\|^{-1/2} \quad (6)$$

where $\varphi(\bullet)$ is the standard Gaussian probability density function. This expression is more accurate than equation (5) for lower values of β (although both are asymptotically equivalent). In FORM, the failure surface is approximated by a hyperplane at the design point and consequently the probability of failure is approximated as

$$P_f \approx \Phi(-\beta) \quad (7)$$

This is the simplest approximation to the integral (1). Breitung's formula (5) and the formula by Hohenbichler and Rackwitz (6) can be viewed as corrections to the FORM formula (7) to take into account the curvature of the failure surface at the design point.

If n is very large, the computation of P_f using any available methods will be computationally expensive. Nevertheless, it is of interest to know if we can expect the same level of accuracy from the classical FORM/SORM formula in high dimensions as we do in low dimensions. Moreover, what we exactly mean by "high dimension" is also an open question. We tried to address these issues using the asymptotic distribution of the quadratic form (4) as $n \rightarrow \infty$.

Overview of SORM Approximations

Discussions on asymptotic distribution of quadratic forms may be found in [12, Section 4.6b]. The moment generating function of U is given by

$$\begin{aligned} M_U(s) &= E[e^{sU}] = E[e^{s\mathbf{y}^T \mathbf{A} \mathbf{y}}] \\ &= \|\mathbf{I}_{n-1} - 2s\mathbf{A}\|^{-1/2} \end{aligned} \quad (8)$$

Suppose n is large such that

$$\begin{aligned} \sum_{k=1}^{n-1} \frac{(2a_k/\sqrt{n})^2}{2} &< \infty \\ \text{or } \frac{2}{n} \text{Trace}(\mathbf{A}^2) &< \infty \end{aligned} \quad (9)$$

$$\begin{aligned} \text{and } \sum_{k=1}^{n-1} \frac{(2a_k/\sqrt{n})^r}{r} &\longrightarrow 0 \\ \text{or } \frac{2^r}{n^{r/2}} \text{Trace}(\mathbf{A}^r) &\longrightarrow 0, \quad \forall \quad r \geq 3 \end{aligned} \quad (10)$$

Under these assumptions, using the series expansion of the logarithm of the moment generating function, it can be shown that U asymptotically approaches a Gaussian random variable with mean $\text{Trace}(\mathbf{A})$ and variance $2 \text{Trace}(\mathbf{A}^2)$; that is, when $n \rightarrow \infty$

$$\begin{aligned} U &\simeq \mathbb{N}_1(m, \sigma^2), \quad \text{with } m = \text{Trace}(\mathbf{A}) \\ \text{and } \sigma &= \sqrt{2 \text{Trace}(\mathbf{A}^2)} \end{aligned} \quad (11)$$

Suppose ϵ is the allowable error for the asymptotic approximation. Using the error in neglecting more than quadratic order terms in the Taylor series of $\ln(M_q(s))$, it can be shown that we should have

$$\begin{aligned} \left| \frac{1}{r} \frac{(-2\beta)^r}{n^{r/2}} \text{Trace}(\mathbf{A}^r) \right| &< \epsilon \\ \text{or } n^{r/2} &> \frac{(2\beta)^r}{r\epsilon} \text{Trace}(\mathbf{A}^r) \end{aligned} \quad (12)$$

$$\text{or } n_{\min} = \frac{4\beta^2}{\sqrt[3]{9\epsilon^2}} \left(\sqrt[3]{\text{Trace}(\mathbf{A}^3)} \right)^2 \quad (13)$$

Since $\mathbf{A}$ is a positive definite matrix, the critical value of n is obtained for $r = 3$. From equation (13), the following points may be observed: (a) the minimum number of random variables required would be more if ϵ (error) is considered to be small (as expected)

and $n_{\min} \propto \frac{1}{\epsilon^{2/3}}$ and (b) if β is large, more random variables are needed to achieve a desired accuracy and $n_{\min} \propto \beta^2$.

Failure Probability Using Strict Asymptotic Formulation

In the strict asymptotic formulation we start with equation (3). The probability of failure can be rewritten as

$$P_f \approx \text{Prob}[y_n \geq \beta + U] = \text{Prob}[y_n - U \geq \beta] \quad (14)$$

Since the asymptotic pdf of U is Gaussian, the variable $z = y_n - U$ is also a Gaussian random variable with mean $(-\text{Trace}(\mathbf{A}))$ and variance $(1 + 2 \text{Trace}(\mathbf{A}^2))$. The probability of failure can be obtained from equation (14) as

$$P_{f\text{Strict}} \longrightarrow \Phi(-\beta_1), \quad \beta_1 = \frac{\beta + \text{Trace}(\mathbf{A})}{\sqrt{1 + 2 \text{Trace}(\mathbf{A}^2)}} \quad (15)$$

when $n \longrightarrow \infty$

This is the exact asymptotic expression of P_f after making the parabolic failure surface assumption and it cannot be improved or changed asymptotically. If the failure surface is close to linear and the number of random variables is not very large, then it is expected that $\text{Trace}(\mathbf{A}) = \text{Trace}(\mathbf{A}^2) \rightarrow 0$, and it is easy to see that equation (15) reduces to the classical FORM formula (7). Therefore, the expressions derived here can be viewed as the “correction” that needs to be applied to the classical FORM formula when a large number of random variables are considered.

The value of n given by equation (13) can be viewed as the borderline between the low and high dimension. Beyond this value of n , significant “trace effect” can be observed and consequently the modified reliability index β_1 should be used instead of β .

Failure Probability Using Weak Asymptotic Formulation

The expression of P_f given by equation (15) cannot be improved asymptotically. However, there is scope for improvements if one does not strictly apply the asymptotic condition $n \rightarrow \infty$. The advantage of such nonasymptotic approximations is that

the approximations may work well even when the asymptotic condition is not met. The disadvantage is that a nonasymptotic approximation will have unquantified errors and one cannot, in general, prove that such errors will vanish when the asymptotic condition is fulfilled. Nevertheless, it is worth perusing a nonasymptotic approximation since real-life structural systems have a finite number of random variables.

Rewriting equation (3), the failure probability can be expressed as

$$P_f \approx \text{Prob}[y_n \geq \beta + U] = \int_{\mathbb{R}} \left\{ \int_{\beta+u}^{\infty} \varphi(y_n) dy_n \right\} \times p_U(u) du = E[\Phi(-\beta - U)] \quad (16)$$

where $p_U(u)$ is the probability density function of U and $E[\bullet]$ is the expectation operator. From the definition of U in equation (4), note that $u \in \mathbb{R}^+$ since $\mathbf{A}$ is a positive definite matrix. We rewrite equation (16) as

$$P_f \approx \int_{\mathbb{R}^+} \Phi(-\beta - u) p_U(u) du = \int_{\mathbb{R}^+} e^{\ln[\Phi(-\beta - u)] + \ln[p_U(u)]} du \quad (17)$$

The aim here is to expand the integrand in a first-order Taylor series about the most probable point or optimal point, say $u = u^*$. The optimal point is the point where the integrand in equation (17) reaches its maxima in $u \in \mathbb{R}^+$. The asymptotic approximation of $p_U(u)$ will be used only to find the maxima of the integrand and will *not* be used subsequently to calculate the expectation. The expectation operation will be carried out exactly by utilizing the expression of the moment generating function in equation (8). For this reason this approach is called *weak asymptotic formulation*.

For the maxima of the integrand in equation (17), we must have

$$\frac{\partial}{\partial u} \{ \ln[\Phi(-\beta - u)] + \ln[p_U(u)] \} = 0 \quad (18)$$

Recalling that

$$p_U(u) = (2\pi)^{-1/2} \sigma^{-1} e^{-(u-m)^2/(2\sigma^2)} \quad (19)$$

4 Asymptotic Reliability Analysis of Very Large Structural Systems

where m and σ are given in equation (11), equation (18) results in

$$\frac{\varphi(\beta + u)}{\Phi(-(\beta + u))} = \frac{m - u}{\sigma^2} \quad (20)$$

Because this relationship holds at the optimal point u^* , we define a constant η as

$$\eta = \frac{\varphi(\beta + u^*)}{\Phi(-(\beta + u^*))} = \frac{m - u^*}{\sigma^2} \quad (21)$$

Taking a first-order Taylor series expansion of $\ln[\Phi(-\beta - u)]$ about $u = u^*$ and simplifying, we have

$$\Phi(-\beta - u) \approx \Phi(-\beta_2)e^{\eta u^*} e^{-\eta u} \quad (22)$$

where

$$\beta_2 = \beta + u^* \quad (23)$$

Taking the expectation of equation (22) and utilizing the expression of the moment generating function in equation (8), the probability of failure can be expressed as

$$P_f \approx \Phi(-\beta_2)e^{\eta u^*} \|\mathbf{I}_{n-1} + 2\eta\mathbf{A}\|^{-1/2} \quad (24)$$

The optimal point u^* should be obtained by solving the nonlinear equation (21). An exact closed-form solution of this equation does not exist. By considering the asymptotic expansion of the ratio $\varphi(\beta + u^*)/\Phi(-(\beta + u^*))$, equation (21) can be solved approximately and β_2 in equation (23) can be obtained as

$$\begin{aligned} \beta_2 &\approx \eta \approx \beta + u^* \approx \beta + \frac{m - u^*}{\sigma^2} \\ &\approx \frac{\beta + m}{1 + \sigma^2} = \frac{\beta + \text{Trace}(\mathbf{A})}{1 + 2 \text{Trace}(\mathbf{A}^2)} \end{aligned} \quad (25)$$

Now substituting η and β_2 in equation (24), the failure probability using weak asymptotic formulation can be obtained as

$$P_{f\text{Weak}} \longrightarrow \frac{\Phi(-\beta_2)e^{-(2\beta_2^2\text{Trace}(\mathbf{A}^2) - \beta_2\text{Trace}(\mathbf{A}))}}{\sqrt{\|\mathbf{I}_{n-1} + 2\beta_2\mathbf{A}\|}}, \quad (26)$$

when $n \longrightarrow \infty$

where β_2 is defined in equation (25). If the number of random variables is not very large, then it is expected that $\text{Trace}(\mathbf{A}) = \text{Trace}(\mathbf{A}^2) \rightarrow 0$. In that case, it is easy to see that $\beta_2 \rightarrow \beta$ and equation (26)

reduces to the classical SORM formula (5). Therefore, equation (26) can be viewed as the “correction” that needs to be applied to the classical SORM formula when a large number of random variables are considered. Unlike the strict formulation, a simple geometric explanation of this expression cannot be given. Also note that the modified reliability indices β_1 and β_2 for the two formulations are not identical.

A Numerical Example

We consider a problem for which the failure surface is *exactly* parabolic in the normalized space, as given by equation (2). In numerical calculations, we have fixed the number of random variables n and the trace of the coefficient matrix $\mathbf{A}$. It is assumed that the eigenvalues of $\mathbf{A}$ are uniform positive random numbers. Figure 1 shows the probability of failure (normalized by dividing with $\Phi(-\beta)$) for values of β ranging from 3 to 6 and values of n ranging from 10 to 1000. Results obtained from the expressions derived here are compared with two existing expressions given in equations (5) and (6). The following points may be noted for these results:

- For a fixed value of β and $\mathbf{A}$, the weak asymptotic formulation is more accurate for smaller values of n compared to the strict asymptotic formulation.
- For a fixed value of $\mathbf{A}$ and n , the results from both approaches will be more accurate if β is small.

Conclusions

The demands of modern engineering design have led structural engineers to model a structure using random variables in order to handle uncertainties. Two approximations to calculate the probability of failure of an engineering structure when the number of random variables used for mathematical modeling, $n \rightarrow \infty$ are provided. It is assumed that the basic random variables are Gaussian and the failure surface is approximated by a parabolic hypersurface in the neighborhood of the design point. The new approximations are based on the asymptotic distribution of a central quadratic form in Gaussian random variables. Two formulations, namely, *strict asymptotic formulation* and *weak asymptotic formulation* are presented. Both approximations result in simple

Figure 1 Normalized failure probability for different values of β when $\text{Trace}(\mathbf{A}) = 1$

closed-form expressions in terms of the trace of the curvature matrix. For a small number of variables, the trace effects may not be significant, and in such cases the proposed formulas reduce to the classical FORM and SORM formulas, respectively. A closed-form expression for the minimum number of random variables required to apply these asymptotic formulas is derived. Beyond this value of n , the reliability problem can be considered high dimensional since the trace effects become significant. The proposed approximations are compared with some existing approximations and **Monte Carlo** simulations using numerical examples. The results obtained from both asymptotic formulations match well with the Monte Carlo simulation results in high dimensions. Numerical studies show that the weak formulation is in

general applicable for a small number of variables compared to the strict formulation. In many real-life problems, the number of random variables is expected to be large. In such situations, the asymptotic results derived here will be useful.

Perfect Sampling

Introduction

A common requirement of many problems in a variety of disciplines is for a sample to be drawn from some probability distribution π on a space $\mathcal{X}$. Often this distribution cannot be specified completely: for example, it may only be known up to a normalization constant. One widely used method for doing this is Markov chain **Monte Carlo** (MCMC). Such an approach involves designing an ergodic Markov chain X , which has π as its stationary distribution, and then running a simulation of X until it is near equilibrium (see **Markov Chain Monte Carlo, Introduction; Convergence and Mixing in Markov Chain Monte Carlo**).

However, an obvious problem with MCMC is the following: for how long should we run the chain before sampling (in other words, what is an appropriate burn-in time)? If we sample from X when it is not ‘close enough’ to equilibrium then the algorithm output may be from a distribution that is far from π .

An attractive alternative to estimating a sufficient burn-in period is to adapt the MCMC algorithm to form a *perfect simulation* algorithm. Such a procedure has two desirable features:

1. The algorithm determines for itself when it should stop.
2. If the algorithm is successful, then it returns a sample drawn *exactly* from π .

In [1], an algorithm known as *coupling from the past* (CFTP) was introduced and used to sample from the exact equilibrium distribution of the critical Ising model on a finite lattice. Although there do exist other perfect simulation algorithms (such as the FMMR algorithm [2]), in this article we shall principally present the CFTP algorithm, and a variant of this method named *dominated CFTP* (also called *CIAFTP*).

A friendly warning: perfect simulation is a technical area that has mainly evolved in the stochastic process literature, and which involves a lot of stochastic process theory. Unfortunately, there’s no escaping from this fact, but hopefully the simple examples below will help newcomers to this field gain some insight into the beauty of the approach.

Coupling from the Past

As the name suggests, CFTP is based on the idea of coupling Markov chains together (see [3] for a comprehensive introduction). For our purpose, a coupling of two chains X and X' (with common transition kernel) is a prescription for specifying their joint transition kernel such that if the two chains meet, then they stay together thereafter.

A general method of producing such a coupling is to define the updates of X and X' using a common update function. More specifically, it is possible to describe the transitions of X using a deterministic function $f : \mathcal{X} \times [0, 1] \rightarrow \mathcal{X}$ and a sequence of *Uniform*[0, 1] random variables $\{\xi_n\}$, such that

$$X_{n+1} = f(X_n, \xi_n) \quad (1)$$

(This construction is known as a *stochastic recursive sequence*.) Using this representation we can couple X and X' such that they stay together once they agree: define their updates by

$$X_{n+1} = f(X_n, \xi_n), \quad X'_{n+1} = f(X'_n, \xi_n) \quad (2)$$

The beauty of this representation is that it enables us to couple *any number* of chains in this way, using the same f and the same randomness $\{\xi_n\}$ for all the chains.

The basic concept behind CFTP is the following: Consider a hypothetical copy of our chain of interest, say $\tilde{X}$, which has been running since time $-\infty$. At time zero this chain will be in equilibrium, i.e., $\tilde{X}_0 \sim \pi$. This would be of obvious use if we could determine $\tilde{X}_0$, but clearly we cannot run a chain from time $-\infty$ in practice! However, it may be possible to determine $\tilde{X}_0$ by looking back only a *finite number of steps* into the past of $\tilde{X}$.

To describe the algorithm, suppose that we have available to us an independent and identically distributed (i.i.d.) sequence $\{\xi_n\}_{-\infty}^0$ of *Uniform*[0, 1] random variables and a deterministic update function f . For $v \geq -u$, define the random composite *input-output* map $F_{(-u,v]}(x) : \mathcal{X} \rightarrow \mathcal{X}$ by

$$F_{(-u,v]}(x) = f(f(\dots f(f(x, \xi_{-u}), \xi_{-u+1}) \dots, \xi_{v-2}), \xi_{v-1}) \quad (3)$$

Thus if X is begun at time $-u$ with the value $X_{-u} = x$, then we may set $X_v = F_{(-u,v]}(x)$. We write

2 Perfect Sampling

$X_v^{x,-u}$ for the value of the chain X at time v , when X is started at time $-u$ from state x .

Definition 1 For a given update function f , the *backwards coalescence time* T^* of the chain X is the random variable defined by

$$T^* = \min\{n \geq 0 : F_{(-t,0]}(x) = F_{(-s,0]}(y), \\ \text{for all } x, y \in \mathcal{X} \text{ and for all } s, t \geq n\} \quad (4)$$

Now consider starting chains $X^{x,-n}$ from *all* states $x \in \mathcal{X}$ at time $-n$. Using f we can couple all of these chains, as well as the hypothetical $\tilde{X}$, using the same source of randomness $\{\xi_n\}_{n=0}^\infty$. If $n \geq T^*$ then $X_0^{x,-n} =: X_0$ is the same for all x , and so $X_0 = \tilde{X}_0 \sim \pi$. That is, if we start our chains $X^{x,-n}$ far enough back into the past that they have all coalesced by time zero, then their common value at zero is an exact draw from π , as required! Of course, we do not know the value of T^* , and so the CFTP algorithm simply repeats the above procedure for larger and larger n until $n \geq T^*$ is achieved:

CFTP Algorithm

```

set  $n \leftarrow 1$ 
while  $F_{(-n,0]}(\mathcal{X})$  not constant
   $n \leftarrow 2n$ 
return  $F_{(-n,0]}(\mathcal{X})$ 

```

The most important aspect of the algorithm is that the random sequence $\{\xi_n\}$ is *reused* in each execution of the `while` loop. This implies a possible issue with computer memory in practice, but there is a trick that avoids this, known as *read-once CFTP* [4]. The use of binary search for T^* contained within the `while` loop is also noteworthy: we are free to increase n in any way we like, but the binary search means that the total number of simulated Markov chain steps is linear in T^* , whereas if we used $n \leftarrow n + 1$ (for example) it would grow quadratically. Furthermore, this strategy means that the number of simulation steps comes within a factor of 4 of the true value of T^* [1, 4].

Theorem 1 *If the backward coalescence time T^* is almost surely finite, then CFTP samples from equilibrium.*

The proof of Theorem 1 is very simple [1, 5]. Note that if $\mathcal{X}$ is finite, then T^* is almost surely finite (but very large) for the trivial independence coupling, where chains evolve independently until they meet, after which they agree forever. In fact, $\mathbb{P}(T^* < \infty)$ is always either zero or one, whatever the choice of f [6]. A good CFTP algorithm uses a function f that has a high probability of making target chains coalesce quickly.

A Simple Example

The following example was considered in [7], with variants appearing in [1, 8]. Consider a symmetric reflecting random walk X on $\mathcal{X} = \{1, 2, 3, 4\}$, satisfying $\pi(i) = 1/4$ for all $i \in \mathcal{X}$ (see Figure 1).

For our update function f we may choose the following:

$$f(x, u) = \begin{cases} \min(x + 1, 4) & \text{if } u \leq 1/2 \\ \max(x - 1, 1) & \text{if } u > 1/2 \end{cases} \quad (5)$$

Figure 2 demonstrates the CFTP algorithm for this example. The gray arrows indicate the transitions determined by f and the sequence $\{\xi_n\}$. The algorithm runs chains $X^{x,-n}$ started from all states x , with $n = 1, 2, 4, \dots$. When $n = 8$ is reached, all of

Figure 1 Simple symmetric reflecting random walk

Figure 2 CFTP for a simple symmetric reflecting random walk

Figure 3 Output of 10 000 runs of the CFTP algorithm for the random walk described above: (a) a proper implementation, reusing randomness; (b) not reusing randomness; (c) reusing randomness, but with simulations with “long” run times interrupted and discarded

the target chains have the same value at time zero: $X_0^{x,-8} = 2$ for this realization (for which $T^* = 7$). The shaded circles highlight the possible values of the chains $X^{x,-8}$ at each step: coalescence occurs the first time that $X^{1,-n}$ hits four or $X^{4,-n}$ hits one.

Implementation of CFTP for this example is trivial, and Figure 3(a) shows a histogram of the results of 10 000 runs of the algorithm. A χ^2 test to compare this output to π yields a p value of 0.79: it is clear that the algorithm is drawing from the correct distribution. In contrast, Figure 3(b) shows the output of a wrongly implemented algorithm, in which the random sequence $\{\xi_n\}$ is not reused when the chains are restarted further into the past. Here a definite departure from uniformity is visible, and indeed a χ^2 test gives a tiny p value of 2×10^{-16} . The reader may like to see if his/her intuition can explain this bias toward a distribution with more mass at the extremal states! For more examples of such bias see [1, 4, 8]. Finally, Figure 3(c) shows another possible source of bias: that which is introduced by *user impatience*. This happens when simulations with long run times are interrupted and discarded. Since the output of the CFTP algorithm is in general not independent of the algorithm run time, this introduces a bias. In this implementation, any simulation that had not coalesced when starting chains from time -8 were discarded. The p value for this sample is again very small: $p = 2.6 \times 10^{-11}$. It should be noted that the FMMR algorithm (under suitable implementation) does not suffer from this bias [9].

Although this is clearly a toy example, it does highlight the ease with which CFTP may be applied to state spaces with a partial order. More specifically, suppose that $\mathcal{X}$ admits a partial order $\leq$, which is respected by the update function f . That is,

$$x \leq y \quad \Rightarrow \quad f(x, u) \leq f(y, u) \quad \text{for all } x, y \in \mathcal{X} \quad (6)$$

Furthermore, suppose that $\mathcal{X}$ contains maximal and minimal elements, $x^{\max}$ and $x^{\min}$, satisfying $x^{\min} \leq x \leq x^{\max}$ for all $x \in \mathcal{X}$. With this setup it becomes simple to check for coalescence in the CFTP algorithm, since the monotonicity of f guarantees that

$$\begin{aligned} F_{(-n,0]}(x^{\min}) &= F_{(-n,0]}(x^{\max}) \\ &\implies F_{(-n,0]}(\mathcal{X}) \text{ is constant} \end{aligned} \quad (7)$$

Thus, instead of running target chains, $X^{x,-n}$, starting from all states $x \in \mathcal{X}$ at time $-n$, we now only need to simulate chains started from $x^{\min}$ and $x^{\max}$. This is exactly the case in our example above, where f is monotonic (using the normal ordering on the integers): coalescence occurs exactly when the two chains $X^{1,-n}$ and $X^{4,-n}$ meet.

Evading Monotonicity

Monotonicity, while useful for CFTP, is by no means essential. Consider modifying the random walk above by setting $\mathbb{P}(X_{n+1} = 2 \mid X_n = 1) = 1$, and leaving all other transitions the same. This chain, say $\hat{X}$, is no longer reversible, and there is no monotonic update function under the usual ordering on the integers (although a different ordering, or the use of subsampling, may reintroduce monotonicity). However, a CFTP algorithm for this chain can be constructed using the *crossover trick* [7]: this first appeared in [10] to deal with *antimonotone chains*, and is also used in [11].

A variant of this approach is to use the original monotonic random walk X as an *envelope process* for $\hat{X}$. Suppose we define an update function $\hat{f}$ as follows:

$$\begin{aligned} \hat{f}(1, u) &= 2, \quad \text{and} \\ \hat{f}(x, u) &= \begin{cases} \min(x+1, 4) & \text{if } u \leq 1/2 \\ \max(x-1, 1) & \text{if } u > 1/2 \end{cases} \quad \text{for } x = 2, 3, 4 \end{aligned} \quad (8)$$

4 Perfect Sampling

Note that $\hat{f}$ is a valid update function for $\hat{X}$, and that $f(x, u) \leq \hat{f}(x, u)$ for all $x \in \mathcal{X}$ and $u \in [0, 1]$ (where f is defined in equation 5). This suggests the following perfect simulation algorithm:

- run a target chain $X^{1,-n}$ using the update function f and random sequence $\{\xi_i\}$, until the first time $S \leq 0$ that state 4 is hit (if $S \not\leq 0$, increase n and repeat, reusing $\{\xi_i\}$);
- due to the ordering of f and $\hat{f}$, $X_S^{1,-n} = \hat{X}_S^{x,-n} = 4$ for all x , and so all target chains $\hat{X}^{x,-n}$ have coalesced by time S ;
- run the chain $\hat{X}^{4,S}$ up to time zero, using $\hat{f}$ and the same $\{\xi_i\}$. Return $\hat{X}_0^{4,S}$.

The idea of using an envelope process was studied in more depth, under the name *bounding chains*, in [12]: the technique can be used in situations which are neither monotonic nor antimonotonic, and can also give bounds on the expected run time of CFTP. This trick, along with the crossover trick mentioned above, increases the possibility of efficient implementation of CFTP for a variety of chains. Furthermore, there are other variants of CFTP, which make the technique applicable to even more general chains, even those on infinite state spaces. For example, the method of *small set CFTP* [13] uses the idea of small set regeneration to determine when target chains have coalesced.

Dominated CFTP

The classic CFTP algorithm of [1] has a major drawback: a successful CFTP algorithm for X exists if and only if X is *uniformly ergodic* [6]. However, there does exist a major extension of CFTP, known as *dominated CFTP* [14, 15], or *coupling into and from the past* (CIAFTP), which can be applied to chains not satisfying this restriction. Indeed, dominated coupling from the past (domCFTP) can (in principle) be implemented for any *geometrically ergodic* chain [16], and a class of *subgeometrically ergodic* chains for which a domCFTP algorithm exists is introduced in [17], greatly extending the possible applicability of perfect simulation.

Whereas CFTP works by checking for *vertical* coalescence (target chains started from all states have coalesced by time zero), domCFTP checks for *horizontal* coalescence (all sufficiently early starts

from a specific state lead to the same result at time zero). A second chain Y is used to identify how far into the past one has to go to determine that this coalescence has occurred. To describe the algorithm in the simplest possible way, we consider here only a monotonic chain X on $\mathcal{X} = [0, \infty)$: see [18] for a much more general formulation.

Suppose that copies of X can be coupled such that, for each $x, t, u \geq 0$, and $s \geq -t$, we can construct $X^{x,-t}$ (begun at state x at time $-t$) satisfying

$$X_s^{x,-t} \leq X_s^{x,-u} \implies X_{s+1}^{x,-t} \leq X_{s+1}^{x,-u} \quad (9)$$

Suppose too that we can construct a dominating process Y on $\mathcal{X}$ which is stationary, defined for all time, and may be coupled to the target chains X such that

$$X_s^{x,-t} \leq Y_s \implies X_{s+1}^{x,-t} \leq Y_{s+1} \quad (10)$$

The domCFTP algorithm then proceeds as follows:

1. Draw Y_0 from its stationary distribution.
2. Simulate Y backwards to time $-n$.
3. Set $y = Y_{-n}$. Simulate $X^{y,-n}$ and $X^{0,-n}$ forwards to time zero (coupled to each other and to Y so that equations (9) and (10) are satisfied).
4. If $X_0^{y,-n} = X_0^{0,-n}$, then return this value as a perfect draw from π . If not, extend the realization of Y back to time $-2n$, set $n \leftarrow 2n$, and go to step 3.

A proof that this algorithm returns a perfect draw from π (so long as it terminates almost surely) may be found in [5, 15]. A consequence of the coupling in equation (9) is that the target processes are *funneled*: the earlier the two target chains (X^0 and X^y) are started, the closer they will be at time zero. As a simple example of the algorithm in practice, consider a birth–death process X with transitions $x \rightarrow x+1$ at rate $\alpha_x \leq \alpha < \infty$, and $x \rightarrow x-1$ at rate μx . This chain is clearly monotonic, and may be dominated by the birth–death chain Y , which has births at rate α and deaths at rate μ . It is easy to see that Y is reversible and has a *Poisson*(α/μ) equilibrium distribution. A realization of the domCFTP algorithm for this chain when $\alpha_x = 10 - \log(x+1)/(x+1)$ and $\mu = 1$ is shown in Figure 4. This algorithm can also be made to work if multiple simultaneous deaths are allowed to occur, or if the birth rate μ varies with x , as is the case with many problems in stochastic geometry [10, 15].

Figure 4 Implementation of domCFTP for a birth-death process. The topmost line shows the evolution of the dominating process into the past, and the shaded regions demonstrate the funneling of target processes. In this realization, all target chains started beneath the dominating process at time -64 have coalesced by time zero

Summary

Perfect simulation algorithms are both a useful practical tool and an exciting area of research. Unlike with MCMC, there is no issue of estimating a burn-in time, and the algorithm output is an exact draw from the required distribution. We have seen above how to apply CFTP and domCFTP to a couple of toy examples: generalization to more interesting chains will often require little additional theory. However, for complicated Markov chains such algorithms are typically harder to implement than MCMC, mainly due to the potential difficulty in finding an efficient method of coupling target chains together. That said, since the arrival of CFTP, more and more variants on this and other techniques mean that there is now a wide range of perfect simulation algorithms available. A comprehensive resource for further investigation of perfect simulation is the on-line bibliography of David Wilson: <http://research.microsoft.com/~dbwilson/exact/>.

STEPHEN B. CONNOR

Resampling for Lifetime Distributions

Noncensored Lifetimes

Data with lifetimes are common in engineering where it is important to evaluate the reliability of technical systems, [1], and in medical sciences where data with lifetimes are collected during observations of patients, [2]. Various statistical methods are used in the analysis of such data. We consider the resampling methods. They can be used if certain assumptions are valid. It is especially important to know these assumptions because otherwise we will obtain erroneous decisions. We start with the following example. Let $\mathbf{dat}_n = \{t_1, \dots, t_n\}$ be different failure times of n similar elements that are tested. Suppose that we can consider them as values of *independent identically distributed* (i.i.d.) *random variables* (r.v.'s) $T_1, \dots, T_n$. We use capital letters for r.v.'s and small letters for their values. The *survival function* (s.f.) $S_0(t) = P[T_i > t]$ is the probability that the failure time of the i th element occurs after time t . Assume that the mean time and the variance of T_i are finite. The mean time $\mu_0 = E[T_i]$ and the α -quantile q_α are useful characteristics. They are defined by the relations $\mu_0 = \int_0^\infty S_0(t) dt$ and $S_0(q_\alpha) = 1 - \alpha$. One can use the estimators $\hat{\mu}_n = 1/n \sum_{i=1}^n T_i$ and $\hat{q}_{\alpha n} = T_{(k_{\alpha n})}$, where $k_{\alpha n} = \min_{1 \leq k \leq n} (k : \alpha \leq (k/n + 1))$, $T_{(k)} = T_{i_k}$ is the k th value in the list of ordered failure times $T_{i_1} < T_{i_2} < \dots < T_{i_n}$. Accuracy of the estimators can be characterized by the distributions of their deviations from their true values. We are interested in estimating the distributions of $\hat{\mu}_n - \mu_0$ and $\hat{q}_{\alpha n} - q_\alpha$. We need to have a sufficiently good random number generator, which can generate independent, (pseudo)random numbers J_{in}^* that are uniformly distributed on $\{1, 2, \dots, n\}$, i.e. $P^*[J_{in}^* = h] = 1/n$, $h = 1, \dots, n$, (see **Sampling from Virtual Populations**). We use “*” to stress the values related to the usage of the random number generator. Let $\mathbf{J}_n^* = \{J_{1n}^*, J_{2n}^*, \dots, J_{nn}^*\}$ and $M_{hn}^* = \sum_{i=1}^n I(J_{in}^* = h)$. $I(\cdot)$ is the indicator function. M_{hn}^* is the number of events $J_{in}^* = h$ in the list $\mathbf{J}_n^*$. We simulate independent lists $\mathbf{j}_n^{*b} = \{j_{1n}^{*b}, \dots, j_{nn}^{*b}\}$, $b = 1, \dots, B$, where j_{in}^{*b} and $m_{hn}^{*b} = \sum_{i=1}^n I(j_{in}^{*b} = h)$ are the simulated values of the r.v.'s J_{in}^* and M_{hn}^* , respectively. We obtain the b th resampled copy $\mathbf{dat}_n^{*b} = \{t_{j_{1n}^{*b}}, \dots, t_{j_{nn}^{*b}}\}$

of the original $\mathbf{dat}_n$. Let us for each $\mathbf{dat}_n^{*b}$ calculate the “copy” – estimate $\hat{\mu}_n^{*b} = 1/n \sum_{i=1}^n t_{j_{in}^{*b}} = 1/n \sum_{h=1}^n m_{hn}^{*b} t_h$ and $\hat{q}_{\alpha n}^{*b} = t_{(k_{\alpha n}^{*b})}$ which is the $k_{\alpha n}^{*b}$ failure time in the list of ordered resampled failure times $\mathbf{dat}_n^{*b}$. If certain assumptions hold as $n \rightarrow \infty$, then the numbers in the following two lists

$$\mathbf{dev}_\mu^* = \{\mu_n^* - \mu_n, \dots, \mu_n^{*B} - \mu_n\},$$

$$\mathbf{dev}_q^* = \{\hat{q}_{\alpha n}^{*1} - \hat{q}_{\alpha n}, \dots, \hat{q}_{\alpha n}^{*B} - \hat{q}_{\alpha n}\} \quad (1)$$

can be used as if they are values of i.i.d. deviations of the estimators $\hat{\mu}_n$ and $\hat{q}_\alpha$ from their true values. Efron was the first to recognized this universal utility of resampling methods [3]. We consistently estimate the distributions of deviations $\hat{\mu}_n - \mu_0$ and $\hat{q}_\alpha(n) - q_\alpha$ because then

$$\frac{1}{B} \sum_{b=1}^B I(\sqrt{n}(\mu_n^{*b} - \hat{\mu}_n) \leq x) - P[\sqrt{n}(\hat{\mu}_n - \mu_0) \leq x] \xrightarrow{P} 0 \quad (2)$$

$$\frac{1}{B} \sum_{b=1}^B I(\sqrt{n}(\hat{q}_{\alpha n}^{*b} - \hat{q}_{\alpha n}) \leq x) - P[\sqrt{n}(\hat{q}_{\alpha n} - q_\alpha) \leq x] \xrightarrow{P} 0 \quad (3)$$

for any real x as $n \rightarrow \infty$ and $B \rightarrow \infty$. The notation $\xrightarrow{P} 0$ means convergence to zero in probability.

The following variant of the central limit resampling theorem (CLRT) can be applied to justify relations (2) and (3).

Let $\{X_{in}, i = 1, \dots, n, n = 1, 2, 3, \dots\}$ be a triangular array of r.v.'s. For each $n = 2, 3, \dots$ $\{X_{1n}, \dots, X_{nn}\}$ are independent real-valued r.v.'s with finite second moments $E[X_{in}^2] < \infty$. Suppose that for any small $\varepsilon > 0$ and a number $C < \infty$,

- (i) $\sum_{i=1}^n E[(X_{in}/\sqrt{n})^2] \leq C < \infty$,
- (ii) $\sum_{i=1}^n E[(X_{in}/\sqrt{n})^2 I(|X_{in}/\sqrt{n}| > \varepsilon)] \rightarrow 0$, and
- (iii) $\sum_{i=1}^n (E[X_{in}/\sqrt{n}])^2 \rightarrow 0$ as $n \rightarrow \infty$

Then for each real number x

$$\frac{1}{B} \sum_{b=1}^B I\left(\frac{1}{\sqrt{n}} \sum_{h=1}^n (m_{hn}^{*b} - 1)x_{hn} \leq x\right) - P\left[\frac{1}{\sqrt{n}} \sum_{i=1}^n (X_{in} - E[X_{in}]) \leq x\right] \xrightarrow{P} 0 \quad (4)$$

2 Resampling for Lifetime Distributions

along a sequence of values x_{hn} of r.v.'s X_{hn} as $n \rightarrow \infty$ and $B \rightarrow \infty$.

A close variant of the CLRT is given in [4] where the more general notion of weakly approaching distributions is used. The CLRT with necessary and sufficient assumptions for consistency of resampling is proved in [5]. The sufficient for relation (2) assumptions (i)–(iii) hold with $x_{in} = t_i - \mu_0$ if r.v.'s T_i have finite variance. Relation (3) holds if the s.f. $S_0(t)$ has continuous nonzero derivative around $t = q_\alpha$. The influence functions for **quantiles** can be found by the δ -method [6]. The CLRT can be applied to the list of influence functions to justify relation (3). The convergence in probability to zero in relation (3) is rather slow but can be improved [7]. The Edgeworth expansions can be used if $\hat{\mu}_n$ is the statistic of interest. The above resampling method is inconsistent in assessing the accuracy of $\hat{\mu}_n$ if **dat**_n are n values of i.i.d. r.v.'s with infinite variance [8].

Nonparametric Estimators for Censored Lifetimes

Often lifetimes are not completely observed, i.e., their exact values T_i are not known. We say that these lifetimes are censored. There are several types of censoring. We consider right-censored lifetimes. Suppose that $T_1, \dots, T_n$ and the censoring times $U_1, \dots, U_n$ are i.i.d. r.v.'s., T_i and U_i are independent and may have different distributions. Observations are stopped at times $Y_i = U_i \wedge T_i = \min\{U_i, T_i\}$. The right-censored data **dat**_n = $\{\{Y_1, \delta_1\}, \dots, \{Y_n, \delta_n\}\}$, where $\delta_i = 1$ if and only if $T_i \leq U_i$, otherwise $\delta_i = 0$. To simplify some of the relations, we suppose that the s.f. $S_0(t)$ is continuous. Then there are no ties in the noncensored lifetimes and the *cumulative hazard function* (c.h.f.) $H_0(t) = -\log(S_0(t))$. $H_0(t)$ is often used in applications because its differential $dH_0(t)$ is the conditional probability $P[t \leq T_i < t + dt \mid t \leq T_i \wedge U_i]$.

Let us introduce the random processes $D_i(z) = I(T_i \leq z \wedge u_i)$, $R_i(z) = I(z \leq T_i \wedge u_i)$, $D_{\cdot n}(z) = \sum_{i=1}^n D_i(z)$, and $R_{\cdot n}(z) = \sum_{i=1}^n R_i(z)$. $D_{\cdot n}(z)$ is the number of lifetimes that have occurred before or at time z . $R_{\cdot n}(z)$ is the number of lifetimes which are not less z and have not been censored before z . One says that at the time z , there are $R_{\cdot n}(z)$ elements at risk. These processes have stepwise realizations. $D_{\cdot n}(z)$ is a counting process [9] and all its jumps

$\Delta D_{\cdot n}(z) = \Delta D_i(z) = 1$ if $z = T_i \leq u_i$. The conditional maximum-likelihood (ML) estimators of $S_0(t)$ and $H_0(t)$ given the censoring times $U_i = u_i$, $i = 1, \dots, n$ are

$$\hat{S}_n(t) = \prod_{z \leq t} \left(1 - \frac{\Delta D_i(z)}{R_{\cdot n}(z)}\right),$$

$$\hat{H}_n(t) = \sum_{i=1}^n \int_0^t \frac{dD_i(z)}{R_{\cdot n}(z)} = \sum_{z \leq t} \frac{\Delta D_{\cdot n}(z)}{R_{\cdot n}(z)} \quad (5)$$

$\hat{S}_n(t)$ is called the *product-limit* (PL) estimator or the *Kaplan–Meier estimator*, and $\hat{H}_n(t)$ is called the *A–estimator* or the *Aalen–Nelson estimator*. There is a one-to-one relation between these estimators. If $Q(t) = S_0(t)P[U_i \geq t] > 0$ then the estimators given in equations (5) are consistent as $n \rightarrow \infty$ [10]. A clear and short introduction to the theory of counting processes and related martingales is given in [11]. The Aalen identity holds

$$\hat{H}_n(t) = H_0(t) + \int_0^t \frac{dM_{\cdot n}(z)}{R_{\cdot n}(z)} - \int_0^t I(R_{\cdot n}(z) = 0) dH_0(z) \quad (6)$$

where $M_{\cdot n}(z) = \sum_{i=1}^n M_i(z)$, $M_i(z) = D_i(z) - \int_0^t R_i(z) dH_0(z)$ are martingales. From identity (6) it follows that $\hat{H}_n(t)$ has a negligible negative **bias** because $n \int_0^t I(R_{\cdot n}(z) = 0) dH_0(z) \xrightarrow{P} 0$ as $n \rightarrow \infty$.

Then from equation (6) and $\sum_{i=1}^n (M_{in}^* - 1) = 0$ it follows that

$$\sqrt{n}(\hat{H}_n(t) - H_0(t)) - \frac{1}{\sqrt{n}} \sum_{i=1}^n \left(\int_0^t \frac{dD_i(z)}{Q(z)} - H_0(t) \right) \xrightarrow{P} 0 \quad \text{as } n \rightarrow \infty \quad (7)$$

$$\sqrt{n} \sum_{i=1}^n (M_{in}^* - 1) \int_0^t \frac{dD_i(z)}{R_{\cdot n}(z)} - \frac{1}{\sqrt{n}} \sum_{i=1}^n (M_{in}^* - 1) \times \int_0^t \frac{dD_i(z)}{Q(z)} \xrightarrow{P} 0 \quad \text{as } n \rightarrow \infty \quad (8)$$

All assumptions in the CLRT hold for the last sum in relation (8). Hence, from relations (7) and (8) we obtain that values of the left sums in relation (8)

will have asymptotically the same distributions as $\sqrt{n}(\hat{H}_n(t) - H_0(t))$, $n \rightarrow \infty$.

Let us consider the generalized ML estimator $\hat{H}_n^{*b}(t) = \int_0^t (dD_n^{*b}(z)/R_n^{*b}(z))$, where $D_n^{*b}(z) = \sum_{i=1}^n M_{in}^{*b} D_i(z)$ and $R_n^{*b}(z) = \sum_{i=1}^n M_{in}^{*b}(z) R_i(z)$, $b = 1, \dots, B$. Then for any real x

$$\frac{1}{B} \sum_{i=1}^B \mathbb{I}(\sqrt{n}(\hat{H}_n^{*b}(t) - \hat{H}_n(t)) \leq x) - \mathbb{P}[\sqrt{n}(\hat{H}_n(t) - H_0(t)) \leq x] \xrightarrow{P} 0 \text{ as } n \rightarrow \infty, B \rightarrow \infty \quad (9)$$

These results can be applied in assessing the accuracy of the PL estimator $\hat{S}_n(t)$ given in equation (5). In a similar way we evaluate the accuracy of the nonparametric ML estimators of the s.f.'s and the c.h.f.'s of renewal times when independent renewal processes are observed during a series of times intervals. We assume that the ends of the time intervals and the renewal times are independent. Here, we have to resample from the subsets of data containing renewals which occurred during the same time interval. Evaluation of the accuracy of estimated reliability characteristics is actual in constructing some mechanical systems with redistributions of applied loads between survived system elements. Cables with many fibers are examples of such systems [12]. Applications of resampling methods to such mechanical systems are given in [13].

Parametric Families of Lifetime Distributions

Parametric families of distributions in lifetime analysis can be useful in obtaining approximated estimators of reliability or survival characteristics and in assessing their accuracy with data containing explanatory variables. Let the elements $\{y_i, \delta_i\}$ of $\mathbf{dat}_n$ be values of independent r.v.'s $\{Y_i, \delta_i\}$ the probability densities $p(y_i, \delta_i, \theta_0)$ of which are known functions of the unknown true parameter $\theta_0 \in \Theta \subseteq \mathbb{R}^k$, then the log-likelihood function [14] is

$$\begin{aligned} \text{lik}(\theta | \mathbf{dat}_n) &= \sum_{i=1}^n l_i(\theta | y_i, \delta_i), \\ l_i(\theta | y_i, \delta_i) &= \log(p(y_i, \delta_i, \theta)) \end{aligned} \quad (10)$$

Suppose that a consistent and asymptotically unbiased ML estimator $\hat{\theta}_n$ of the true parameter θ_0 exists and is defined by the equation

$$\text{lik}(\hat{\theta}_n | \mathbf{dat}_n) = \max(\text{lik}(\theta | \mathbf{dat}_n) : \theta \in \Theta) \quad (11)$$

It is possible to consider resampled copies of the log-likelihood defined by the relations

$$\text{lik}^{*b}(\theta | \mathbf{dat}_n) = \sum_{h=1}^n m_{hn}^{*b} l_h(\theta | \mathbf{dat}_n), \quad b = 1, \dots, B \quad (12)$$

$\{m_{hn}^{*b}\}$ were introduced in the section titled “Noncensored Lifetimes”. The resampled ML estimators $\hat{\theta}_n^{*b}$ are defined by the equations

$$\begin{aligned} \text{lik}^{*b}(\hat{\theta}_n^{*b} | \mathbf{dat}_n) &= \max(\text{lik}^{*b}(\theta | \mathbf{dat}_n) : \theta \in \Theta), \\ b &= 1, \dots, B \end{aligned} \quad (13)$$

The k -dimensional distributions of the components in the list $\{\hat{\theta}_n^{*1} - \hat{\theta}_n, \dots, \hat{\theta}_n^{*B} - \hat{\theta}_n\}$ asymptotically approach the distributions of deviations $\hat{\theta}_n - \theta_0$ under nearly usual regularity assumptions [15] as $n \rightarrow \infty$.

The resampling methods can be efficiently applied to evaluate the accuracy of estimators of lifetime parameters if the data with lifetimes are sufficiently large. The resampling methods can also be used to construct parameter **confidence intervals** (see **Bootstrap and Jackknife, Overview**).

Related influence functions, the CLRT and the functional CLRT can be used in proofs. Two variants of the functional CLRT theorems are given in [13] and [16].

Lévy Processes, Simulation of

Lévy Processes

Lévy processes arise in many areas of applied probability. (See, e.g., relevant articles **Monte Carlo Methods, Univariate and Multivariate; Markov Chain Monte Carlo, Introduction; Survival Analysis, Nonparametric; Dirichlet Process, Simulation of; Convergence and Mixing in Markov Chain Monte Carlo; Simulation of the Beta-Stacy Process.**) For theory of Lévy processes the reader is referred to books of Bertoin [1] and Sato [2], which are the classical references on this topic. A stochastic process $\{X(t)\}_{t \geq 0}$ is said to be a *Lévy process* if it has stationary and independent increments and satisfies $X(0) = 0$. One may always assume that sample paths of a Lévy process are right continuous and have left limits.

Standard **Brownian motion** $\{B(t)\}$ is a Lévy process, so is a linear Brownian motion $\{\mu t + \sigma B(t)\}$. A **Poisson process** $\{N(t)\}$ with rate λ is a Lévy process, so is a compound Poisson process. A linear combination of independent Lévy processes is again a Lévy process. In particular, the sum of a linear Brownian motion and a compound Poisson process

$$X(t) = \mu t + \sigma B(t) + \sum_{j=1}^{N(t)} V_j \quad (1)$$

is a Lévy process, where V_j are independent and identically distributed (i.i.d.) and $\{B(t)\}$, $\{N(t)\}$, and $\{V_j\}$ are independent of each other.

The key to understanding a Lévy process $\{X(t)\}$ is the structure of its jumps $J(t) = X(t) - X(t-)$. It occurs that for any Borel subset B of $\mathbb{R} \setminus \{0\}$, the counting process of B , $N^B(t) = \text{Card}\{s \leq t : J(s) \in B\}$ is a Poisson process with rate $\nu(B)$, where ν is a measure satisfying $\nu(\{0\}) = 0$ and

$$\int \min\{x^2, 1\} \nu(dx) < \infty \quad (2)$$

ν is called the *Lévy measure* of $\{X(t)\}$. Thus $\nu(dx)$ is the intensity of jumps of size x . The *Lévy-Itô*

representation reveals the path structure of a Lévy process:

$$X(t) = at + \sigma B(t) + \lim_{\epsilon \downarrow 0} \left\{ \sum_{s \leq t} J(s) \mathbf{1}_{\{|J(s)| > \epsilon\}} - t \int_{\epsilon < |x| \leq 1} x \nu(dx) \right\} \quad (3)$$

where $\{B(t)\}$ is a standard Brownian motion independent of the process of jumps $\{J(t)\}_{t \geq 0}$. The convergence on the right-hand side holds almost surely (a.s.) uniformly in t on each finite interval. When $\nu(\mathbb{R}) < \infty$, equation (3) reduces to equation (1) with $\mu = a - \int_{|x| \leq 1} x \nu(dx)$. If

$$\int \min\{|x|, 1\} \nu(dx) < \infty \quad (4)$$

then $\sum_{s \leq t} |J(s)| < \infty$ a.s. and equation (3) reduces to

$$X(t) = \mu t + \sigma B(t) + \sum_{s \leq t} J(s) \quad (5)$$

where μ is as above. Sample paths of $\{X(t)\}$ have *bounded variation* on each finite interval if and only if $\sigma = 0$ and equation (4) holds. If additionally $\mu \geq 0$ and $\nu((-\infty, 0)) = 0$, then $\{X(t)\}$ has nondecreasing sample paths and is called a *subordinator*.

The characteristic function of $X(t)$ is of the form $E e^{iuX(t)} = \exp(t\psi(u))$, where $\psi(u)$ is the cumulant of $X(1)$ given by the *Lévy-Khintchine formula*

$$\psi(u) = iau - \frac{\sigma^2 u^2}{2} + \int_{-\infty}^{\infty} (e^{iux} - 1 - iux \mathbf{1}_{\{|x| \leq 1\}}) \nu(dx) \quad (6)$$

where (a, σ^2, ν) are the same as in equation (3).

The *generating triplet* (a, σ^2, ν) or the cumulant $\psi(u)$ of $X(1)$ are usually used as identifiable parameterizations of Lévy processes.

Simulation Methods: An Overview

Simulation of a Brownian motion and/or of a compound Poisson process can be found in many textbooks and will not be discussed here. In view of the representation in equation (3), Brownian

2 Lévy Processes, Simulation of

and Poissonian-type components of a Lévy process can be generated independently of each other. The main problem is to simulate a Poissonian-type component of a Lévy process having infinite Lévy measure.

If the Lévy measure is infinite, then by equation (3) sample paths of $\{X(t)\}$ have infinitely many jumps in each finite interval. Exact simulation of such process is obviously impossible. A process that is close to the original one is generated instead. The following methods will be considered:

1. random walk approximation
2. series representations of Lévy processes
3. Poisson and Gaussian approximations.

1. A discrete skeleton $\{X(jh) : j = 0, 1, \dots\}$ is a random walk. Therefore, if a simulation method (at least an approximate one) of $X(h)$ is available, then one can simulate $\{X(t)\}$ approximately. A disadvantage of such a method is that one cannot precisely identify the location and magnitude of the large jumps. Large jumps are important, especially in the heavy-tailed case, because they determine various functionals of a Lévy process. Another complication may be that a simulation of $X(h)$ may be numerically tedious (e.g., when its density involves special functions).

2. Series representations provide uniform approximations of Lévy processes along the sample paths. They are often easy to simulate. Usually the largest jumps of a Lévy process are included in the first few terms of the series. A disadvantage of this method is that some series may converge slowly. Therefore, one may need a huge number of terms in a series to reach a desired accuracy of the approximation. On the other hand, with ever increasing computational speed, a slow convergence may not be an issue of practical importance for some applications.

3. If one discards small jumps from the right-hand side of equation (5) or if one replaces them by their mean value on the right-hand side of equation (3), then the resulting process is a compound Poisson process with a drift ($\sigma = 0$). This is a Poisson approximation of a Lévy process. It converges uniformly in t on each finite interval, as the size of the discarded jumps tends to zero. The large jumps are precisely simulated. Series representations of Lévy processes provide a consistent way to construct

such approximations. However, when the intensity of small jumps is high, discarding them may produce a substantial error. In such case, instead of discarding a small-jump part of a Lévy process, one can often approximate it by a Brownian motion with a small variance. This approximation complements method 2 because it is applicable when the series converges slowly.

Methods based on 1, 2, and 3 will be discussed in the following sections. Further information on simulation of Lévy processes and related topics can be found in the books of Cont and Tankov [3] and Asmussen and Glynn [4]. The author is grateful to Professor Søren Asmussen for making the manuscript of his forthcoming book available [4].

Random Walk Approximation

Suppose $\{X(t)\}$ is a Lévy process determined by equation (6) with $\sigma = 0$ and an infinite Lévy measure ν . Fix the time domain $[0, T)$, $n \geq 1$, and put $h = T/n$. Generate the increments $\Delta_j^h X = X(jh) - X((j-1)h)$ as i.i.d. random variables with the distribution $P_h(\cdot) = \mathbb{P}(X(h) \in \cdot)$, $j = 1, \dots, n-1$, and let

$$X^h(t) = \begin{cases} 0 & \text{if } 0 \leq t < h \\ \Delta_1^h X + \dots + \Delta_j^h X & \text{if } jh \leq t < (j+1)h \end{cases} \quad (7)$$

Process $\{X^h(t)\}_{0 \leq t < T}$ is a random walk approximation to $\{X(t)\}_{0 \leq t < T}$.

Example 1: Gamma process If $X(t) \sim \Gamma(\alpha t, \lambda)$, then $\{X(t)\}$ is called a *gamma process* with shape parameter $\alpha > 0$ and scale $\lambda > 0$. The density of $X(h)$ is given by

$$p_h(x) = \frac{\lambda^{\alpha h}}{\Gamma(\alpha h)} x^{\alpha h - 1} e^{-\lambda x} \quad (8)$$

There exist many algorithms for generating $\Delta_j^h X$'s with this density e.g., Johnk's and Best's algorithms; see the book of Devroye [5] for a survey on this topic.

Example 2: Stable process A stable process is determined by its cumulant function $\psi(u)$ in equa-

tion (6) of the form

$$\psi(u) = \begin{cases} -\theta^\alpha |u|^\alpha \left(1 - i\beta \operatorname{sgn} u \tan \frac{\pi\alpha}{2}\right) + i\mu u & \text{if } 0 < \alpha < 2, \alpha \neq 1 \\ -\theta |u| \left(1 + i\beta \frac{2}{\pi} \operatorname{sgn} u \log |u|\right) + i\mu u & \text{if } \alpha = 1 \end{cases} \quad (9)$$

where $0 < \alpha < 2$, $\theta > 0$, and $-1 \leq \beta \leq 1$. Densities $p_h(x)$ are known in only a few cases of α . However, the increments $\Delta_j^h X$ can be simulated using an algorithm due to Chambers *et al.* [6] (see also [7] and [8]). In the symmetric case, i.e. $\psi(u) = -\theta^\alpha |u|^\alpha$, this algorithm has a specially simple form

$$\Delta_j^h X = \theta h^{1/\alpha} \frac{\sin \alpha U_j}{(\cos U_j)^{1/\alpha}} \left(\frac{\cos((1-\alpha)U_j)}{V_j} \right)^{(1-\alpha)/\alpha} \quad (10)$$

where U_j are i.i.d. Uniform $(-\pi/2, \pi/2)$ random variables independent of i.i.d. standard exponential random variables V_j .

Example 3: Damien, Laud, and Smith algorithm

This algorithm provides an approximation to an infinitely divisible random variable. Let ν be a Lévy measure and define $\theta(dx) = x^2/(1+x^2) \nu(dx)$, $c = \int_{-\infty}^{\infty} \theta(dx)$. Fix $m \geq 1$ and let (U_i, V_i) , $i = 1, \dots, m$, be i.i.d. pairs such that U has distribution $\theta(dx)/c$ and given $U = u$, $V \sim \text{Poisson}(\lambda_m(u))$, where $\lambda_m(u) = c(1+u^2)/(mu^2)$. Then, as $m \rightarrow \infty$,

$$\sum_{i=1}^m \left(U_i V_i - \frac{c}{n U_i} \right) \quad (11)$$

converges in distribution to an infinitely divisible random variable with the generating triplet $(\int (x \mathbf{1}_{\{|x| \leq 1} - (x/1+x^2)) \nu(dx), 0, \nu)$. The random centers in equation (11) are not needed when equation (4) holds; see [9] for the proofs and further details. Using this algorithm for an approximate simulation of a Lévy process $\{X(t)\}$, one needs to fix n , the number of partitions of the time domain $[0, T]$ and m , the number of terms in equation (11) to approximately generate the increment $\Delta_j^h X$. Two types of errors are committed, one from using a discrete skeleton and another one from each approximation at a grid point.

Series Representations of Lévy Processes

Series representations provide uniform approximations of Lévy processes along sample paths. It occurs that any Lévy process $\{X(t)\}$ with the generating triplet $(a, 0, \nu)$ can be represented almost surely as uniform in t convergent series of the form

$$X(t) = \sum_{j=1}^{\infty} [H(\Gamma_j, V_j) \mathbf{1}_{\{U_j \leq t\}} - t a_j], \quad 0 \leq t \leq T \quad (12)$$

where $\{\Gamma_j\}$ are the arrival times in a Poisson process with rate one, $\{V_j\}$ are i.i.d. random vectors taking values in some Euclidean space, $\{U_j\}$ are i.i.d. uniform on $[0, T]$ variables and the sequences $\{\Gamma_j\}$, $\{V_j\}$, and $\{U_j\}$ are independent of each other. Here H is a jointly measurable real-valued function such that $r \mapsto |H(r, v)|$ is nonincreasing and $a_j \in \mathbb{R}$. The choice of H and V is not unique; they have to satisfy the condition

$$\int_{-\infty}^{\infty} f(x) \nu(dx) = T^{-1} \int_0^{\infty} \mathbb{E} f(H(r, V)) dr \quad (13)$$

for any nonnegative Borel function f with $f(0) = 0$. See [10] for a historical survey on methods of selection of (H, V) , the relation of equation (12) to the Lévy–Itô representation in equation (3), and further details on representation in equation (12). In the following examples the time domain $[0, T]$ will be fixed and $\{\Gamma_j\}$, $\{U_j\}$ will be as above. Then H, V will be specified. $\{V_j\}$ are assumed to be independent of $\{\Gamma_j\}$ and $\{U_j\}$.

Example 4: Gamma process We use the notation of Example 1. Let $\{V_j\}$ be an i.i.d. sequence of exponential random variables with parameter λ . Then

$$X(t) = \sum_{j=1}^{\infty} e^{-\Gamma_j/(\alpha T)} V_j \mathbf{1}_{\{U_j \leq t\}}, \quad 0 \leq t \leq T \quad (14)$$

4 Lévy Processes, Simulation of

represents a gamma process with parameters α, λ . Such representation for gamma random variables is due to Bondesson [11], an extension to gamma processes is immediate. Since $e^{-\Gamma_j/(\alpha T)} V_j = O(e^{-j/(\alpha T)} \log j)$, the series converges very fast and its generation is a good alternative to the simulation of a discrete skeleton discussed in Example 1.

Example 5: Stable process Here we will only present the symmetric case. Representations for non-symmetric cases can be found in [7] and [8]. Let $\{V_j\}$ be an i.i.d. sequence such that $\mathbb{P}(V_j = \pm 1) = 1/2$. Then

$$X(t) = \theta T^{1/\alpha} c_\alpha \sum_{j=1}^{\infty} V_j \Gamma_j^{-1/\alpha} \mathbf{1}_{\{U_j \leq t\}}, \quad 0 \leq t \leq T \quad (15)$$

represents a stable process with the cumulant function $\psi(u) = \exp(-\theta^\alpha |u|^\alpha)$, where $0 < \alpha < 2$, $c_\alpha = |\Gamma(1 - \alpha) \cos \frac{\pi\alpha}{2}|^{-1/\alpha}$ when $\alpha \neq 1$, and $c_1 = \pi/2$. This is the so-called LePage representation.

Example 6: Tempered stable process A Lévy process $\{X(t)\}$ with a generating triplet $(a, 0, \nu)$ is said to be *tempered α -stable* if $\nu(dx) = |x|^{-\alpha-1} g(x) dx$, where $(-1)^n D^n g(x) \geq 0$ for $x > 0$, $D^n g(x) \geq 0$ for $x < 0$, $n = 0, 1, \dots$ and $\lim_{|x| \rightarrow \infty} g(x) = 0$. A typical example is $g(x) = \kappa_1 e^{-\lambda_1 x}$ for $x > 0$ and $g(x) = \kappa_2 e^{\lambda_2 x}$ for $x < 0$. In this case $\{X(t)\}$ is also called a *CGMY process* ($\kappa_1, \kappa_2 \geq 0$, $\lambda_1, \lambda_2 > 0$). Series representations of tempered α -stable processes are attributable to Rosiński [12]. Here we will present a special case as an example.

Suppose that $\nu(dx) = \kappa |x|^{-\alpha-1} e^{-\lambda|x|} dx$. Let $\{\epsilon_j\}$, $\{\eta_j\}$, and $\{\xi_j\}$ be sequences of i.i.d. random variables such that $\mathbb{P}(\epsilon_j = \pm 1) = 1/2$, $\eta_j \sim \text{Exponential}(\lambda)$, and $\xi_j \sim \text{Uniform}(0, 1)$. All random sequences $\{\Gamma_j\}$, $\{U_j\}$, $\{\epsilon_j\}$, $\{\eta_j\}$, and $\{\xi_j\}$ are assumed to be independent of each other. Then

$$X(t) = \sum_{j=1}^{\infty} \epsilon_j \left(\left(\frac{\alpha \Gamma_j}{2\kappa T} \right)^{-1/\alpha} \wedge \eta_j \xi_j^{1/\alpha} \right) \mathbf{1}_{\{U_j \leq t\}}, \quad 0 \leq t \leq T \quad (16)$$

represents a symmetric tempered α -stable process with Lévy measure as above.

One can couple sample paths of an α -stable and a tempered α -stable process via equations (15)–(16). As an illustration we show in Figure 1 a simulation of both processes having $\alpha = 1.3$, θ, κ satisfying $\theta c_\alpha = (2\kappa)^{1/\alpha} = 1$, $\lambda = 1$, and $T = 1$ (see Examples 5 and 6). We used continuous lines instead of dots to draw (discontinuous!) sample paths for a better clarity of the plot. It is quite instructive to see how the tempering occurs and diminishes high variability of a stable sample path.

Poisson and Gaussian Approximations

Any Lévy process $\{X(t)\}$ with the generating triplet $(a, 0, \nu)$ can be decomposed into a sum of two independent Lévy processes

$$X(t) = X^\epsilon(t) + X_\epsilon(t) \quad (17)$$

Figure 1 Trajectories of coupled stable and tempered stable processes

where $\{X^\epsilon(t)\}$ is a compound Poisson process with a drift and the distribution of jumps proportional to $\nu^\epsilon = \nu_{|\{x|>\epsilon\}}$ and the process $\{X_\epsilon(t)\}$ has mean zero and the Lévy measure $\nu_\epsilon = \nu_{|\{x|\leq\epsilon\}}$; $\epsilon > 0$ is fixed. We refer to $\{X_\epsilon(t)\}$ as a *small-jump part* of $\{X(t)\}$. When ϵ is small one can consider

$$X(t) \approx X^\epsilon(t) \quad (18)$$

and simulate the right-hand side as an approximation to $\{X(t)\}$. However, when the intensity of small jumps is high (as for a stable process with $\alpha > 1$), this method may require simulating of an enormous number of jumps to obtain a reasonable accuracy of the approximation. In that case it was proposed to replace X_ϵ in equation (17) by a Brownian motion with a variance $\sigma_\epsilon^2 = \text{Var}(X_\epsilon(1))$. Asmussen and Rosiński [13] rigorously discussed this approximation and showed that $\sigma_\epsilon^{-1}X_\epsilon$ converges in distribution to W , where W is a standard Brownian motion, if and only if $\sigma_{c\sigma_\epsilon \wedge \epsilon} \sim \sigma_\epsilon$ for each $c > 0$ as $\epsilon \downarrow 0$. A close sufficient condition for the latter one is $\sigma_\epsilon/\epsilon \rightarrow \infty$ as $\epsilon \downarrow 0$. Using this Gaussian approximation of X_ϵ we get

$$X(t) \approx X^\epsilon(t) + \sigma_\epsilon W(t) \quad (19)$$

where $\{W(t)\}$ is assumed to be independent of $\{X^\epsilon(t)\}$.

To select ϵ experimentally, one needs a consistent procedure for generating $\{X^\epsilon(t)\}$ as $\epsilon \downarrow 0$. This is possible when a series representation (equation 12) is available. One can choose, for example,

$$X^\epsilon(t) = \sum_{j: \Gamma_j \leq \epsilon^{-1}} [H(\Gamma_j, V_j)\mathbf{1}_{\{U_j \leq t\}} - ta_j] \quad (20)$$

The resulting decomposition $X = X^\epsilon + X_\epsilon$ is not exactly the same as in equation (17) (see for instance Example 6) but the terms of it are independent and the same criterion as above for Gaussian approximation of X_ϵ applies (see [14]).

Stable and tempered stable processes admit Gaussian approximation of small jumps (*cf.* Examples 5 and 6) but a gamma process does not. As discussed in Example 4, a (compound) Poisson approximation of a gamma process is very fast in this case, consequently the small-jump part can be neglected.

Lévy processes are rarely available. This essentially rules out an approximation by a random walk from a discrete skeleton. However, in the multidimensional case one can still use Poisson and Gaussian approximations combined with series representations (see [14]) or use Lévy copulas (see [3] and references therein).

Life Distributions, Simulation of

Sampling Random Values from a Probability Distribution

Let X be a random variable (rv) obeying a cumulative distribution function (cdf) $F_X(x)$ defined as follows:

$$\text{Prob}\{X \leq x\} = F_X(x); F_X(-\infty) = 0; F_X(\infty) = 1 \quad (1)$$

In the following, if the rv X obeys a cdf $F_X(x)$ we shall write $X \sim F_X(x)$.

From the definition it follows that $F_X(x)$ is a nondecreasing function and we further assume that it is continuous and differentiable as well. The corresponding **probability density function** (pdf) is then

$$f_X(x) = \frac{dF_X(x)}{dx}; f_X(x) \geq 0; \int_{-\infty}^{\infty} f_X(x) dx = 1 \quad (2)$$

We now aim at sampling numbers from the cdf $F_X(x)$. This amounts to obtaining a sequence of $N \gg 1$ values $\{X\} \equiv \{X_1, X_2, \dots, X_N\}$ that satisfy the following conditions:

1. The number n of sampled values within an interval $\Delta x \ll X_{\max} - X_{\min}$, where $X_{\min}$ and $X_{\max}$ are the minimum and maximum values in $\{X\}$, should be such that

$$\frac{n}{N} \approx \int_{\Delta x} f_X(x) dx \quad (3)$$

In other words, we require that the histogram of the sampled data should approximate $f_X(x)$.

2. The X_i values should be uncorrelated.
3. If the sequence $\{X\}$ is periodic, the period after which the numbers start repeating should be as large as possible.

Among all the distributions, the uniform distribution in the interval $[0, 1)$, denoted as $U[0, 1)$ or more simply $U(0, 1)$, plays a role of fundamental importance since sampling from this distribution allows obtaining rv's obeying any other distribution.

Sampling from the Uniform Distribution $U[0, 1)$

The cdf and pdf of the distribution $U[0, 1)$ are as follows:

$$U_R(r) = r; u_R(r) = 1 \quad 0 \leq r < 1 \quad (4)$$

The generation of random numbers R uniformly distributed in $[0, 1)$ has represented, and still represents, an important subject of active research. In the beginning, the outcomes of intrinsically random phenomena were used (e.g. throwing a coin or dice, spinning the roulette, counting of radioactive sources of constant intensity, etc.), but soon it was realized that, apart from the disuniformity due to imperfections of the mechanisms of generation or detection, the frequency of data thus obtained was too low and the sequences could not be reproduced, so that it was difficult to find and fix the errors in the computer codes in which the sampled random numbers were used.

To overcome these difficulties, the next idea was to fill tables of random numbers to store in the computers (in 1955, RAND corporation published a table with 10^6 numbers), but the access to the computer memory decreased the calculation speed and, above all, the sequences that had been memorized were always too short with respect to the growing necessities.

Finally, in 1956, von Neumann proposed to have the computer directly generate the "random" numbers by means of an appropriate function $g(\cdot)$, which should allow one to find the next number R_{k+1} from the preceding one R_k , i.e. $R_{k+1} = g(R_k)$.

The sequence thus generated is inevitably periodic: in the course of the sequence, when a number is obtained that had been obtained before, the subsequence between these two numbers repeats itself cyclically, i.e. the sequence enters a loop. Furthermore, the sequence itself can be reproduced so that it is obviously not "random", but rather deterministic. However, if the function $g(\cdot)$ is chosen correctly, it can be said to have a pseudorandom character if it satisfies a number of randomness tests.

In particular, von Neumann proposed to obtain R_{k+1} by taking the central digits of the square of R_k . For example, for a computer with a four digit word, if $R_k = 4567$, then $R_k^2 = 20857489$ and $R_{k+1} = 8574$, $R_{k+2} = 5134$, and so on. This function turns out to be lengthy to calculate and to give rise to rather short periods; furthermore, if one obtains

2 Life Distributions, Simulation of

$R_k = 0000$, then all the following numbers are also zero.

Presently, the most commonly used methods for generating sequences $\{R\}$ of numbers from a uniform distribution are inspired by the Monte Carlo roulette game [1–6].

In a real roulette game, the ball, thrown with high initial speed, performs a large number of revolutions around the wheel and finally it comes to rest within one of the numbered compartments. In an ideal machine nobody would doubt that the final compartment, or its associated number, is actually uniformly sampled among all the possible compartments or numbers. In the domain of the real numbers, within the interval $[0, 1)$, the game could be modeled by throwing a point on the positive x axis very far from the origin, utilizing a method having an intrinsic dispersion much larger than unity. The difference between the value so obtained and the largest integer smaller than this value may then be reasonably assumed as sampled from $U[0, 1)$. Obviously this statement is true if a *suitable* method is utilized for throwing the point. In a computer, the above procedure is performed by means of a mixed congruential relationship of the kind

$$R_{k+1} = (aR_k + c) \bmod m \quad (5)$$

In words, the new number R_{k+1} is the remainder, modulo m (a positive integer), of an affine transform of the old R_k , with nonnegative integer coefficients a and c . The above expression in some way resembles the uniform sampling in the roulette game, $aR_k + c$ playing the role of the distance traveled by the ball and m that of the wheel circumference. The sequence so obtained is made up of numbers $R_k < m$ and is periodic with period $p < m$. For example, if we choose $R_0 = a = c = 5$ and $m = 7$, the sequence is $\{5, 2, 1, 3, 6, 0, 5, \dots\}$, with a period $p = 6$. The sequences generated with the method described above are actually deterministic so that the sampled numbers are more appropriately called *pseudorandom* numbers. However, the constants a , c , and m may be selected so that:

- the sequence satisfies essentially all randomness tests;
- the period p is very large.

Clearly the numbers generated by the above procedure are always smaller than m so that, when divided by m , they lie in the interval $[0, 1)$.

It is important to note that for the generation of pseudorandom numbers $U[0, 1)$ many computer codes do not make use of machine subroutines, but use congruential subroutines which are part of the program itself. Thus, for example, it is possible that an excellent program executed on a machine with a word of length different from the one it was written for, gives absurd results. In this case, it should not be concluded that the program is “garbage”, but it would be sufficient to appropriately modify the subroutine that generates the random numbers.

Sampling by the Inverse Transform Method: Continuous Distributions

Let $X \in (-\infty, +\infty)$ be an rv with cdf $F_X(x)$ and pdf $f_X(x)$, i.e.

$$F_X(x) = \int_{-\infty}^x f_X(x') dx' = \Pr\{X \leq x\} \quad (6)$$

Since $F_X(x)$ is a nondecreasing function, for any $y \in [0, 1)$, its inverse may be defined as

$$F_X^{-1}(y) = \inf\{x : F_X(x) \geq y\} \quad (7)$$

With this definition, we take into account the possibility that in some interval $(x_s, x_d]$ $F_X(x)$ is constant (and $f_X(x)$ zero), that is

$$F_X(x) = \gamma \quad \text{for } x_s \leq x \leq x_d \quad (8)$$

In this case, from the definition in equation (1) it follows that corresponding to the value γ , the minimum value x_s is assigned to the inverse function $F_X^{-1}(\gamma)$. This is actually as if $F_X(x)$ were not defined in $(x_s, x_d]$; however, this does not represent a disadvantage, since values in this interval can never be sampled because the pdf $f_X(x)$ is zero in that interval. Thus, in the following, we will suppose that the intervals $(x_s, x_d]$ (open to the left and closed to the right), in which $F_X(x)$ is constant, are excluded from the definition domain of the rv X . By so doing, the $F_X(x)$ will always be increasing (instead of nondecreasing).

We now show that it is always possible to obtain values $X \sim F_X(x)$ starting from values R sampled

Figure 1 Inverse transform method: continuous distributions $R \sim U_R(r) = r$ in $[0, 1) \Rightarrow X \sim F_X(x)$ [©Lilole-Verlag GmbH, 2002.]

from the uniform distribution $U_R[0, 1)$ [1–6]. In fact, if R is uniformly distributed in $[0, 1)$, we have

$$\Pr\{R \leq r\} = U_R(r) = r \quad (9)$$

Corresponding to a *number* R extracted from a $U_R(r)$, we calculate the *number* $X = F_X^{-1}(R)$ and wonder about its distribution. As it can be seen in Figure 1, for the variable X we have

$$\Pr\{X \leq x\} = \Pr\{F_X^{-1}(R) \leq x\} \quad (10)$$

Because F_X is an increasing function, by applying F_X to the arguments at the rhs of equation (6), the inequality is conserved and from equation (8) we have

$$\Pr\{X \leq x\} = \Pr\{R \leq F_X(x)\} = F_X(x) \quad (11)$$

It follows that $X = F_X^{-1}(R)$ is extracted from $F_X(x)$. Furthermore, because $F_X(x) = r$,

$$\Pr\{X \leq x\} = \Pr\{R \leq r\} \quad (12)$$

In terms of the cdf,

$$U_R(R) = F_X(X) \quad \text{and} \quad R = \int_{-\infty}^X f_X(x') dx' \quad (13)$$

This is the fundamental relationship of the inverse transform method, which for any R value sampled from the uniform distribution U_R $[0, 1)$ gives the corresponding X value sampled from the $F_X(x)$ distribution (Figure 1). However, it often occurs that

the cdf $F_X(x)$ is noninvertible analytically, so that from equation (13) it is not possible to find $X \sim F_X(x)$ as a function of $R \sim U[0, 1)$. An approximate procedure that is often employed in these cases is the interpolation of $F_X(x)$ with a polygonal function and the inversion of equation (13) using the polygonal. Clearly, the precision of this procedure increases with the number of points of $F_X(x)$ through which the polygonal passes. The calculation of the polygonal is performed as follows:

- If the interval of variation of x is infinite, it is approximated by the finite interval (x_a, x_b) in which the values of the pdf $f_X(x)$ are sensibly different from zero: for example in case of the univariate **s-normal distribution** $N(\mu, \sigma^2)$ with mean value μ and variance σ^2 , this interval may be chosen as $(\mu - 5\sigma, \mu + 5\sigma)$.
- The interval $(0, 1)$ in which both $F_X(x)$ and $U_R(r)$ are defined is divided into n equal subintervals of length $1/n$ and the points $x_0 = x_a, x_1, x_2, \dots, x_n = x_b$ such that $F_X(x_i) = i/n$, ($i = 0, 1, \dots, n$) are found, e.g. by a numerical procedure.

At this point the sampling may start: for each R sampled from the distribution $U_R[0, 1)$ we compute the integer $i^* = \text{Int}(R \cdot n)$ and then obtain the corresponding X value by interpolating between the points $(x_{i^*}, (i^*/n))$ and $(x_{i^*+1}, (i^* + 1/n))$. For example, in case of a linear interpolation we have

$$X = x_{i^*} + (x_{i^*+1} - x_{i^*})(R \cdot n - i^*) \quad (14)$$

4 Life Distributions, Simulation of

For a fixed number n of points x_i upon which the interpolation is applied, the described procedure can be improved by interpolating with arcs of parabolas in place of line segments. The arcs can be obtained by imposing continuity conditions of the function and its derivatives at the points x_i (cubic **splines**). The expression of X as a function of R is in this case more precise, but more burdensome to calculate. Currently, given the ease with which it is possible to increase the RAM of the computers, to increase the precision it is possibly preferable to increase the number n of points and to use the polygonal interpolation: as a rule of thumb, a good choice is often $n = 500$.

Examples of Applications of the Sampling Methods

Uniform Distribution in the Interval (a, b)

An rv X is uniformly distributed in the interval (a, b) if

$$\begin{aligned} F_X(x) &= \frac{x-a}{b-a} & f_X(x) &= \frac{1}{b-a} & \text{for } a \leq x \leq b \\ &= 0 & &= 0 & \text{for } x < a \\ &= 1 & &= 0 & \text{for } x > b \end{aligned} \quad (15)$$

Substitution in equation (13) and solving with respect to X yields

$$X = a + (b - a)R \quad (16)$$

Exponential Distribution

An rv $X \in (0, \infty)$ is said to be exponentially distributed if its cdf $F_X(X)$ and pdf $f_X(X)$ are

$$\begin{aligned} F_X(x) &= 1 - e^{-\int_0^x \lambda(u) du}; \\ &= 0 \\ f_X(x) &= \lambda(x) e^{-\int_0^x \lambda(u) du} & \text{for } 0 \leq x \leq \infty \\ &= 0 & \text{otherwise} \end{aligned} \quad (17)$$

where $\lambda(\cdot)$ is the transition rate.

In the following, we shall refer to the exponential distribution of the random variable T , representing the *time to failure* of a component, with cdf $F_T(t)$

and pdf $f_T(t)$. In this case, the transition rate $\lambda(t)$ is called *hazard function* or *failure rate*.

With regard to sampling a realization t of the exponentially distributed random variable T , this can be obtained by solving equation (13), i.e.

$$\int_0^t \lambda(u) du = -\log(1 - R) \quad (18)$$

where the realization $R \sim U[0, 1)$.

Let us first consider the time homogeneous case, i.e. with constant λ . This situation corresponds to the *useful life* for which the component has been designed to operate and during which failures occur at random with no influence from the usage time. Correspondingly, equation (17) becomes

$$F(T) = 1 - e^{-\lambda t}; \quad f(T) = \lambda e^{-\lambda t} \quad (19)$$

Realizations of the associated exponentially distributed rv T are easily obtained from the inverse transform method. The sampling of a given number $N \gg 1$ of realizations is performed by repeating N times the following procedure:

- sample a realization of $R \sim U[0, 1)$
- compute $t = -(1/\lambda) \log(1 - R)$.

Weibull Distribution

A generalization of the above case in the time domain consists in assuming that the probability density of the occurrence of an event (e.g. the failure of a component), is time dependent. A case, commonly considered in practice is that in which the transition rate is of the kind

$$\lambda(t) = \beta \alpha t^{\alpha-1} \quad (20)$$

with $\beta > 0, \alpha > 0$. The corresponding distribution is called *Weibull's distribution* and was proposed in the 1950s by Weibull in the course of his studies on the strength of materials. The cdf and pdf of the Weibull distribution are as follows:

$$F(T) = 1 - e^{-\beta t^\alpha}, \quad f(T) = \alpha \beta t^{\alpha-1} e^{-\beta t^\alpha} \quad (21)$$

In the particular case of $\alpha = 1$, the Weibull distribution reduces to the exponential distribution with constant transition rate $\lambda = \beta$.

In practice, a realization t of the random variable T is sampled from the Weibull distribution through the following steps:

- sampling of a realization of the random variable $R \sim U[0, 1)$
- computation of $t = (-1/\beta) \ln(1 - R))^{1/\alpha}$.

Simulation of the Beta-Stacy Process

Introduction

In Bayesian nonparametric inference, the parameter space consists of the class of all probability measures and the aim is to estimate a random distribution function or some of its functionals of statistical relevance. A common tool for constructing random distribution functions is represented by suitable transformations of stochastic processes. In particular, survival analysis is concerned with the estimation of lifetime distributions and, hence, one needs to define a process $\{F(t), t \in \mathbb{R}_+\}$ such that $F(0) = 0$ almost surely (a.s.), F is a.s. nondecreasing, a.s. right continuous, and $\lim_{t \rightarrow \infty} F(t) = 1$ a.s. A large section of the Bayesian nonparametric literature has considered the problem of *right-censored* data, which is a particular type of incomplete information: instead of observing the actual lifetime T^0 , one observes $T = \min(T^0, C)$ for some censoring time C taken independent of T^0 . The aim is to construct and make inference on random lifetime distributions which are suitable for application to this type of data. Typically, two requirements are in order: a mathematically tractable form for the posterior distribution of F given the observations and a simulation algorithm for drawing samples from the prior and the posterior distribution. As for the first point, a desirable property is the conjugacy of F with respect to right-censored data, which means that the posterior distribution belongs to the same class of random distribution functions as the prior. Conjugacy implies that, if we know how to sample from the prior, then the same type of algorithm can be used for the posterior, thus remarkably alleviating the computational burden.

This chapter is concerned with a class of priors termed *neutral-to-the-right* (NTR) processes, introduced by [1]. Other classes of stochastic processes for survival analysis are discussed in other articles (see **Survival Analysis, Nonparametric; Polya Trees and Their Use in Reliability and Survival Analysis**). NTR processes include the Dirichlet process (see [2]) as a special case and have conjugacy to right-censored observations as a distinctive feature. If we set Z to be the cumulative hazard

$Z(t) = -\log(1 - F(t))$, then an appealing characterization of NTR processes is that F is NTR if and only if Z has independent increments with $Z(0) = 0$ a.s., is nondecreasing a.s., right continuous a.s., and $\lim_{t \rightarrow \infty} Z(t) = \infty$ a.s. (see [3]). For such a process Z , there exist at most countably many fixed points of discontinuity $t_1, t_2, \dots$ with corresponding jumps $J_1, J_2, \dots$ in $\mathbb{R}_+$ having densities $f_{t_1}, f_{t_2}, \dots$. Then the process $Z_c(t) = Z(t) - \sum_{t_j \leq t} J_j$ has Lévy–Khinchine representation (see [4]):

$$-\log E \exp(-\phi Z_c(t)) = \int_0^\infty (1 - e^{-\phi z}) \nu_t(dz) \quad (1)$$

for every $\phi \geq 0$, where $\{\nu_t : t \geq 0\}$ is a family of Lévy measures on $\mathbb{R}_+$ satisfying

- L.1** $\nu_0 \equiv 0$ and $\int_0^\infty \min(1, z) \nu_t(dz) < \infty$ holds true for every $t > 0$;
- L.2** for every measurable B , $\nu_t(B)$ is nondecreasing and continuous in t .

The distribution of F is then completely characterized by the set of jump times $M = \{t_1, t_2, \dots\}$, the corresponding densities of the jumps $f_{t_1}, f_{t_2}, \dots$ and the Lévy measure $\nu_t(\cdot)$.

We consider a particular NTR process, namely the *beta-Stacy* process, introduced in [5], whose corresponding Lévy measure has the form

$$\nu_t(dz) = \frac{1}{1 - e^{-z}} \int_0^t e^{-z\beta(s)} \alpha(ds) dz \quad (2)$$

where $\beta(\cdot)$ is a nonnegative function, $\alpha(\cdot)$ is an absolutely continuous measure, and $\int_0^\infty \alpha(ds)/\beta(s) = \infty$. It is possible to give formulas for the beta-Stacy process in the presence of fixed points of discontinuities by means of a noncontinuous measure $\alpha(\cdot)$ (see [5]); however, for ease of exposition we do not consider this case and take $M = \emptyset$.

In the next section, we describe the properties of the beta-Stacy process and develop the posterior distribution given the right-censored data. In the section titled “Simulation of the Posterior Process”, we review methods to simulate from a general NTR process and, then, tailor them to the beta-Stacy case and conclude with some final remarks.

Property and Posterior of the Beta-Stacy

The beta-Stacy process is well suited for applications in survival analysis since it enjoys the conjugacy property and encompasses various NTR processes proposed in the literature. In fact, the Dirichlet process is a special case with $\alpha(\mathbb{R}_+) < \infty$ and $\beta(t) = \alpha[t, \infty)$, whereas the simple homogeneous process (see [6]) is obtained when $\beta(\cdot)$ is constant. Moreover, the beta-Stacy process is closely related to the celebrated beta-process (see [7]) used for modeling cumulative hazards: indeed the Lévy measure of the beta-process can be obtained from the one of the beta-Stacy in equation (2) via the transformation $v_t \circ g^{-1}(dz)$, where $g(z) = 1 - e^{-z}$.

The prior parameters $\alpha(\cdot)$ and $\beta(\cdot)$ have a straightforward interpretation in terms of the mean and the variance of F : if we set $\mu(t) = -\log[E(1 - F(t))]$ and $\lambda(t) = -\log[E(1 - F(t))^2]$, then

$$\begin{aligned} d\mu(t) &= \alpha(ds)/\beta(s), \quad \text{and} \\ d\lambda(t)/d\mu(t) &= 2 - [1 + \beta(t)]^{-1} \end{aligned} \quad (3)$$

This allows us to explicit prior opinions about the location and the uncertainty in terms of the Lévy measure, see [5]. As for the functionals of the beta-Stacy process, it is worth noting that the random mean $\int_0^\infty t dF(t)$ is studied in [8]: indeed, the random mean can be represented as the exponential functional of the corresponding cumulative hazard, $\int_0^\infty \exp[-Z(t)] dt$, and has the interpretation of the random expected lifetime.

We now provide the description of the posterior distribution of the beta-Stacy process, where we use a star as superscript to denote posterior quantities. Consider a sample $T_1^0, \dots, T_n^0$ of exchangeable observations directed by the beta-Stacy process, that is they are independent and identically distributed (i.i.d.) given F . Assume that $(T_1, \delta_1), \dots, (T_n, \delta_n)$ is observed, where $T_i = \min(T_i^0, C_i)$, $\delta_i = I\{T_i^0 \leq C_i\}$ and $C_1, \dots, C_n$ are the censoring times. Define the counting process $N(t)$, $t \in \mathbb{R}_+$, and the left-continuous at-risk process $Y(t)$, $t \in \mathbb{R}_+$, by

$$\begin{aligned} N(t) &= \sum_{i=1}^n I\{T_i \leq t \text{ and } \delta_i = 1\}, \\ Y(t) &= \sum_{i=1}^n I\{T_i \geq t\} \end{aligned} \quad (4)$$

In particular, $N\{t\}$ is the number of observed T_i^0 's at time point t . Given the data, the posterior distribution of $F(t)$, denoted by $[F(t) | \text{data}]$, is a beta-Stacy process with fixed jumps at $M^* = \{t_i : \delta_i = 1, i = 1, \dots, n\}$ with density given by

$$\begin{aligned} f_{t_i}^*(z) &\propto (1 - e^{-z})^{N\{t_i\}-1} \\ &\times e^{-z[\beta(t_i) + Y(t_i) - N\{t_i\}]} I\{z \in \mathbb{R}_+\} \end{aligned} \quad (5)$$

Alternatively, $f_{t_i}^*(z)$ can be described as the density of a jump random variable $J_{t_i}^*$ satisfying

$$1 - \exp\{-J_{t_i}^*\} \sim \text{beta}(N\{t_i\}, \beta(t_i) + Y(t_i) - N\{t_i\}) \quad (6)$$

where we write $\text{beta}(a, b)$ for a beta random variable of parameter a and b . The continuous component of the posterior process has Lévy measure:

$$v_t^*(dz) = \frac{1}{1 - e^{-z}} \int_0^t e^{-z[\beta(s) + Y(s)]} \alpha(ds) dz \quad (7)$$

which is still of the form in equation (2) with updated parameter $\beta^*(\cdot) = \beta(\cdot) + Y(\cdot)$. If we use the notation $\alpha^*(dt) = \alpha(dt) + dN(t)$, the Bayes estimate of F can be written as:

$$\begin{aligned} \widehat{F}(t) &= E(F(t) | \text{data}) \\ &= 1 - \prod_{[0, t]} \left(1 - \frac{\alpha^*(ds)}{\beta^*(s) + \alpha^*\{s\}} \right) \end{aligned} \quad (8)$$

where $\prod$ stands for the product integral, see [9]. For further details, see [5].

Simulation of the Posterior Process

In this section we review simulation schemes proposed in the literature for NTR processes, with a view toward simulating the posterior distribution of the beta-Stacy process. For the case of the Dirichlet process, see **Dirichlet Process, Simulation of**.

We consider a prior NTR process F with no fixed points of discontinuity. Furthermore, we consider a process for which $v_t(\mathbb{R}_+) = \infty$ for every $t > 0$, which is tantamount to requiring the process to jump infinitely often on any time interval. This clearly happens for the beta-Stacy process. Assume that the Lévy measure admits density, that is

$$v_t(dz) = dz \int_0^t k(z, s) ds \quad (9)$$

and recall that $k(z, s) ds = (1 - e^{-z})^{-1} e^{-z\beta(s)} \alpha(ds)$ for the beta-Stacy process.

In the posterior $Z_c^*(t)$ has updated Lévy density

$$k^*(s, z) = e^{-zY(s)} k(s, z) \quad (10)$$

while there are fixed jumps $J_{t_i}^*$ at noncensored observations with density given by

$$f_{t_i}^*(z) \propto (1 - e^{-z})^{N\{t_i\}} e^{-z[Y(t_i) - N\{t_i\}]} k(z, t) \quad (11)$$

see [3]. It is easy to show that this leads to the formulas for the posterior beta-Stacy process as described in the previous section.

Since simulating an NTR process F is equivalent to simulating the cumulative hazard process Z , sampling from $[F(t) | \text{data}]$ consists of two tasks: (a) simulate from an independent-increment process $Z_c^*(t)$ with Lévy density $k^*(z, s)$ and (b) draw random jump variates $\{J_{t_i}^* : \delta_i = 1, i = 1, \dots, n\}$ from densities given in equation (11). Note that (a) and (b) can be done separately because of the independent-increment property.

Simulation of the Continuous Component

Simulation methods based on the Lévy measure have been the object of major developments (see **Lévy Processes, Simulation of**). In the present setting, they have been used essentially in two ways: generation of the infinitely divisible increments of $Z_c^*(t)$ for a given time partition or a series representation of the whole process $\{Z_c^*(t), t \in \mathbb{R}_+\}$.

As for the first approach, we consider the *Damien, Laud, and Smith algorithm* (DLS95) in [10] and the *Walker and Damien algorithm* (WD98) in [11]. Methods that follow the second approach are the *Ferguson and Klass algorithm* (FK74) in [12] and the *Wolpert and Ickstadt algorithm* (WI98) in [13].

The idea behind DLS95 and WD98 is that, to simulate from the posterior distribution of an interval probability $[F(b) - F(a) | \text{data}]$, one ultimately needs to sample from the jumps $\{J_{t_i}^* : \delta_i = 1, t_i \in [a, b]\}$ and from the increments of $Z_c^*(t)$ for a given partition of the interval $[a, b]$. Let Z_Δ denote the increment of $Z_c^*(t)$ in a given time interval. The random variable Z_Δ is infinitely divisible with log-Laplace transform given by

$$-\log E[\exp(-\phi Z_\Delta)] = \int_0^\infty (1 - e^{-\phi z}) \nu_\Delta(dz) \quad (12)$$

where $\nu_\Delta(dz) = dz \int_\Delta k^*(s, z) ds$. It is a well-known result that each infinitely divisible distribution can be represented as a stochastic integral with respect to a Poisson process, in the present setting

$$Z_\Delta = \int_0^\infty z dP(z) \quad (13)$$

where $P(\cdot)$ stands for a **Poisson process** with intensity measure $\nu_\Delta(dz)$. Note that $\nu_\Delta(B)$, for $B \in \mathcal{B}(\mathbb{R}_+)$, may be interpreted as the Poisson arrival rate of increments for the process $Z_c^*(t)$ in the interval Δ of sizes in B . Since $\nu_\Delta(dz)$ is not a finite measure, in general it is not possible to simulate exactly from the correct distribution of $P(\cdot)$: $P(\cdot)$ has infinitely many jumps in any neighborhood of zero. The two algorithms obviate this by resorting to different approximation techniques, but both require simulation from a jump-size distribution recovered from the measure $\nu_\Delta(dz)$.

The DLS95 method generates a finite number m of jump levels $\{z_i\}$ from the distribution $\gamma(dz) \propto h(z) \nu_\Delta(dz)$, where $h(z)$ is a nonnegative function such that $\gamma = \int_0^\infty h(z) \nu_\Delta(dz) < \infty$. Note that, by property (L. 1), it is sufficient that $h(z) \leq \min(1, z)$. Then, for $i = 1, \dots, m$, take a Poisson variate q_i with rate $\lambda_i = \gamma/[m h(z_i)]$ and approximate Z_Δ by $\sum_{i=1}^m z_i q_i$. This entails an approximation of $P(\cdot)$ with another Poisson process concentrated on the singletons $\{z_i\}$ with intensity measure $\frac{1}{m} \sum_i \delta_{z_i}(dz) \lambda_i$. For details see Damien *et al.* [10], who implemented it for the gamma-process, the simple homogeneous and the Dirichlet process, whereas the case of the beta-process was considered in [14]. We next give the algorithm for the beta-Stacy process, following [5]. In the sequel let $\text{Pois}(\lambda)$ denote a Poisson random variable of rate λ .

DLS95 Algorithm

- Take $h(z) = 1 - e^{-z}$ so that $\gamma = \int_0^\infty \int_\Delta e^{-z[\beta(s) + Y(s)]} \alpha(ds) dz$.
- Generate m independent draws $\{z_i\}$ from the distribution

$$G(dz) = \gamma^{-1} \int_\Delta e^{-z[\beta(s) + Y(s)]} \alpha(ds) dz \quad (14)$$

- For $i = 1, \dots, m$, generate q_i from $Q_i \sim \text{Pois}(\gamma/m(1 - e^{-z_i}))$.
- Set $Z_\Delta \approx \sum_{i=1}^m z_i q_i$. □

4 Simulation of the Beta-Stacy Process

The WD98 method consists in cutting off the part of small jumps from the Poisson integral in equation (13), following an idea that first appeared in [15, Section 2]. For $\epsilon > 0$ such that $\lambda_\epsilon = \nu_\Delta(\epsilon, \infty) < \infty$, consider $Z_\Delta = X_\epsilon + Y_\epsilon$ where X_ϵ is the sum of the jump times of $P(\cdot)$ in (ϵ, ∞) and Y_ϵ is the sum of the jump times in $(0, \epsilon]$. Then, X_ϵ has a.s. a finite number of jumps that can be simulated exactly by generating jump levels from a density proportional to $\frac{d}{dz} \nu_\Delta((\epsilon, z])$ for $z \in (\epsilon, \infty)$. Finally, approximate Z_Δ with X_ϵ , treating Y_ϵ as variable error. In fact, Y_ϵ can be taken as small as needed for small ϵ . The algorithm for the beta-Stacy process is as follows:

WD98 Algorithm

- Take $\lambda_\epsilon = \int_\epsilon^\infty \int_\Delta e^{-z[\beta(s)+Y(s)]} \alpha(ds)$ and $G_\epsilon(z) = \lambda_\epsilon^{-1} \int_\epsilon^z \int_\Delta e^{-z[\beta(s)+Y(s)]} \alpha(ds)$.
- Generate q from $Q \sim \text{Pois}(\lambda_\epsilon)$.
- Generate q independent draws $\{z_i\}$ from c.d.f. $G_\epsilon(z)$.
- Set $Z(\Delta) \approx \sum_{i=1}^q z_i$. $\square$

For details, see [11], which shows how to simulate the z_i 's variates by using a Gibbs sampler with auxiliary variables, and how to calculate the normalizing constant λ_ϵ .

Consider now the second class of simulation methods, based on series representations. Exploiting the fact that $Z_c^*(t)$ is a pure jump process, algorithms FK72 and WI98 are based on representing $Z_c^*(t)$ as the sum

$$Z_c^*(t) = \sum_i J_i I\{U_i \leq t\} \quad (15)$$

where, for $i = 1, 2, \dots$, J_i is a random jump level and U_i is a random location. This idea has been used to simulate a whole trajectory of the process by [12, 13 and 16]. See also, [17], who reviewed the different methods of representing the Poisson process of the jumps underlining the Lévy–Khinchine formula in equation (1). Since for $\nu_\infty(\mathbb{R}_+) = \infty$ the sum in equation (15) has infinitely many terms, in practice one has to truncate the series and approximate the process with a finite number of jumps. The error of approximation is determined by both the number of considered jumps and their sizes. Both algorithms aim at simulating $\{J_i\}$ and $\{U_i\}$ via inversion of the Lévy measure, but they differ on whether to draw first the jump sizes or the jump locations.

The FK72 algorithm is as follows. Define the jumps $\{J_i\}$ by

$$\text{Prob}(J_1 \leq z_1) = \exp(-\nu_\infty^*[z_1, \infty)) \quad (16)$$

$$\begin{aligned} \text{Prob}(J_i \leq z_i \mid J_{i-1} \leq z_{i-1}) \\ = \exp(-\nu_\infty^*[z_i, \infty) + \nu_\infty^*[z_{i-1}, \infty)) \end{aligned} \quad (17)$$

where $z_i \leq z_{i-1}$. This can be done by generating successive jumps $\tau_1, \tau_2, \dots$ from a Poisson process of unit rate (partial sums of independent standard exponential variates), then J_i is taken as the solution z of the equation: $\tau_i = \nu_\infty^*[z, \infty)$, that is via inversion of the Lévy measure $\nu_\infty^*[\cdot, \infty)$. Then the process $Z_c^*(t)$ is represented as the series:

$$Z_c^*(t) = \sum_i J_i I\{\omega_i \leq n_t(J_i)\} \quad (18)$$

where $\omega_1, \omega_2, \dots$ are i.i.d. random numbers from the uniform distribution on $[0, 1]$ and $n_t(z) = \int_0^t k^*(z, s) ds / \int_0^\infty k^*(z, s) ds$. Note that, by property (L.2), $n_t(z)$ is nondecreasing and, thus, the jumps are generated in decreasing order; see [16] for more details. For the special case of the beta-Stacy process, the algorithm can be detailed as follows:

FK72 Algorithm

- Write $M(z) = \nu_\infty^*[z, \infty)$ (see equation (7)) and note that

$$M(z) = \int_0^\infty B_{e^{-z}}(\beta(s) + Y(s), 0) \alpha(ds) \quad (19)$$

where $B_x(a, b) = \int_0^x s^{a-1} (1-s)^{b-1} ds$ denotes the incomplete beta-function.

- Generate m successive jump times $\{\tau_i\}$ of a Poisson process of unit rate.
- Perform a **Monte Carlo** integration of $M(z)$: generate K independent draws $\{s_j\}$ from a distribution function $\alpha(ds)/\alpha(\mathbb{R}_+)$, then set

$$M(z) \approx K^{-1} \sum_{j \leq K} \alpha(\mathbb{R}_+) B_{e^{-z}}(\beta(s_j) + Y(s_j), 0) \quad (20)$$

- For $i = 1, \dots, m$, generate J_i as the value z solution of $\tau_i = M(z)$.
- Generate m independent draws $\{\omega_i\}$ from the uniform distribution on $[0, 1]$ and set, for

$i = 1, \dots, m$, U_i as the solution s of the equation

$$\omega_i = \frac{\int_0^s e^{-z[\beta(u)+Y(u)]} \alpha(du)}{\int_0^\infty e^{-z[\beta(u)+Y(u)]} \alpha(du)} \quad (21)$$

- Set $Z_c^*(t) \approx \sum_{i=1}^m J_i I\{U_i \leq t\}$. $\square$

The WI98 algorithm aims at generating jump locations first. Assume that we may write the Lévy measure in the form

$$\nu_t^*(dz) = dz \int_0^t k^*(z, s) dz ds = dz \int_0^t \eta(z, s) \Pi(ds) \quad (22)$$

for $\Pi(ds)$ a probability measure on $\mathbb{R}_+$ from which samples may be drawn, and so $\eta(z, s) = ds k^*(z, s) / \Pi(ds)$. This form of $\nu_t^*(\cdot)$ actually covers all the Lévy processes appearing in the Bayesian literature. For example, for the posterior beta-Stacy process we may take $\Pi(ds) = \alpha(ds) / \alpha(\mathbb{R}_+)$ (see the Monte Carlo step above) and $\eta(z, s) = \alpha(\mathbb{R}_+) (1 - e^{-z})^{-1} \exp(-z[\beta(s) + Y(s)])$. The algorithm proceeds by generating m random locations $\{U_i\}$ from $\Pi(ds)$. Then, for $i = 1, \dots, m$, J_i is set as the solution z of the equation $\tau_i = \int_z^\infty \eta(x, U_i) dx$, where $\tau_1, \dots, \tau_m$ are successive jump times of a standard Poisson process at unit rate. The approximation error decreases with the number of jumps considered, but the jumps are not generated in decreasing order, unless one takes $\Pi(ds)$ constant. For more details, see [18], where the algorithm is adapted to sample from the beta-process, the extended gamma-process (see [19]), and the simple homogeneous process. See also [18] for a comparison of WI98 with DLS95, and [16] for a comparative discussion with FK72. The details for the WI98 algorithm in the beta-Stacy case are as follows:

WI98 Algorithm

- Use the incomplete beta-function to write

$$\int_\epsilon^\infty \eta(z, s) dz = \alpha(\mathbb{R}_+) B_{e^{-\epsilon}}(\beta(s) + Y(s), 0) \quad (23)$$

- Generate m independent draws $\{U_i\}$ from the distribution $\alpha(ds) / \alpha(\mathbb{R}_+)$.
- Generate m successive jump times $\{\tau_i\}$ of a Poisson process of unit rate.

- For $i = 1, \dots, m$, set J_i as the solution z of the equation

$$\tau_i = \alpha(\mathbb{R}_+) B_{e^{-\tau_i}}(\beta(S_i^c) + Y(S_i^c), 0) \quad (24)$$

- Set $Z_c(t) \approx \sum_{i=1}^m J_i^c I\{S_i^c \leq t\}$. $\square$

Simulation of the Jump Component

There exist a few methods for sampling from densities known up to a constant of proportionality like the density in equation (11), following the emergence of Markov chain Monte Carlo methods (see **Markov Chain Monte Carlo, Introduction**). Indeed, it is possible to use techniques for generating random variates as in [10, Appendix A], consisting in a Gibbs sampling with introduction of auxiliary variables, see [11, Section 3.1]. Note, however, that this is not required for the beta-Stacy process, since the jumps of $[F(t) | \text{data}]$ follow a beta-distribution of equation (6). In practice one has to generate beta-variates $\{e_i\}$, with $e_i \sim \text{beta}(N\{t_i\}, \beta(t_i) + Y(t_i) - N\{t_i\})$, for each noncensored observation and, then, set $J_{t_i}^* = 1 - \log(1 - e_i)$.

Conclusions

We have described four different algorithms for simulating from the beta-Stacy process. Note that such algorithms can be adapted to any NTR process and that the Lévy–Khinchine formula constitutes the theoretical background for these contributions. Another method for simulating the increment of a nondecreasing, independent-increment process is in [15], where a different characterization of infinitely divisible distributions *via* shot noise processes is exploited. See also [16] and [17] for series representations of Lévy processes based on this method, and [20] for an application to the extended gamma-process.

The Dirichlet Process and Mixtures

Bayesian nonparametric **prior distributions** have become a valuable tool within the context of hierarchical modeling (*see Survival Analysis, Nonparametric; Polya Trees and Their Use in Reliability and Survival Analysis*). In contrast to traditional empirical distribution- or rank-based methods, nonparametric modeling in the Bayesian paradigm consists of constructing prior distributions on the space of all possible distribution functions or some large subset of it. It entails putting a prior distribution on the *distribution* of data without use of a family indexed by a finite-dimensional parameter as in parametric Bayesian models. This difference allows the data distribution to escape unwanted constraints of parametric families, such as unimodality. The resulting flexibility is especially useful when modeling mixture distributions, because the composition of the mixture does not have to be specified deterministically.

The most popular nonparametric prior distribution, the Dirichlet process, was formally introduced in the work of Ferguson [1, 2]. If we consider an arbitrary distribution function, G , on the positive real numbers, and any finite partition of $(0, \infty)$ given by $0 < t_1 < t_2 < \dots < t_{k-1} < \infty$, then the Dirichlet process prior results in the representation of the uncertainty in G via the Dirichlet distribution as $Y = (Y_1, \dots, Y_k) \sim \mathcal{D}(\pi_1, \dots, \pi_k)$ where

$$Y_1 = G(t_1), Y_i = G(t_i) - G(t_{i-1}), \\ i = 2, \dots, k-1, Y_k = 1 - G(t_{k-1}) \quad (1)$$

$\pi_i = \alpha(G_0(t_i) - G_0(t_{i-1}))$, $\alpha > 0$, and G_0 is a distribution function on $(0, \infty)$. The development in [1] is much more general, defining the Dirichlet process for distributions on arbitrary probability spaces, thus including the usual multivariate case of finite-dimensional Euclidean space with the Borel σ algebra.

While Ferguson's work provided the theoretical foundation for modeling using the Dirichlet process, we will discuss a particular extension – the Dirichlet process mixture (DPM) – that has proved useful in

applications. The difference between the two can be seen readily within the context of a simple hierarchical model for data $\mathbf{Y} = (Y_1, \dots, Y_n)$, written as

$$Y_i | \theta_i \stackrel{\text{ind}}{\sim} L(Y_i | \theta_i) \\ \theta_i | G \stackrel{\text{ind}}{\sim} G \\ G | \alpha, G_0 \sim \mathcal{DP}(\alpha G_0) \quad (2)$$

Here $L(Y_i | \theta_i)$ represents the likelihood of an observed data point conditional on a parameter θ_i , with unknown distribution G , on which we place a Dirichlet process prior involving the two parameters α and G_0 . The latter is a centering distribution for the process, while α is a scalar variability parameter controlling how much one allows G to deviate from G_0 . The likelihood $L(Y_i | \theta_i)$ has a parametric form, for example $\text{Normal}(\mu, \sigma^2)$ where $\theta = (\mu, \sigma^2)$. In this case, G is a bivariate distribution on $(-\infty, \infty) \times (0, \infty)$. Thus, the model is a DPM of parametric distributions in the likelihood.^a While the DPM model is contained in the work of Lo [5], its computational feasibility and usefulness was initially demonstrated in a paper [6] by Escobar.

The DPM model has been extended in many ways, including the use of a prior distribution for α and taking G_0 to be a member of a parametric family, $G_0(\cdot | \kappa)$, with a random parameter κ . For the sake of simplicity, we will consider the case where α and κ are fixed. Incorporating prior distributions on these parameters is straightforward (for example, see [7] for placing a prior on α and [8] for placing one on κ).

To make inferences from data, we need to address the posterior distribution conditional on Y . The objects of inference here are $\theta_1, \dots, \theta_n$ as well as G , the distribution governing future values of θ . From a simulation perspective, inference for G can be obtained via samples from the conditional distribution of θ_{n+1} . In the next sections we therefore concentrate on sampling $\theta_1, \dots, \theta_n, \theta_{n+1} | \mathbf{Y}$.

When G_0 is a member of a parametric family that is conjugate to the likelihood in $L(Y_i | \theta_i)$, computation is simplified. In this case we refer to the DPM model as being *conjugate*. The complementary case is called a *nonconjugate DPM model*.

Simulation in Conjugate DPM Models

The first computational algorithm in DPM models originated in the work of Escobar[6], and Escobar

2 Dirichlet Process, Simulation of

and West [9], within the context of normal mixture models and density estimation. The basic theory behind the algorithm relates to the fact that the infinite-dimensional parameter G in equation (2) can be integrated out and the model written in terms of the marginal prior distribution for θ . Results in [10–12] imply that the distribution of θ is almost surely discrete and is given by

$$\theta_1 \sim G_0, \quad \theta_{k+1} | \theta_1, \dots, \theta_k \sim \frac{\alpha}{\alpha + k} G_0 + \frac{1}{\alpha + k} \sum_{i=1}^k \delta_{\theta_i}(\theta_{k+1}), \quad k = 1, \dots \quad (3)$$

where $\delta_{\theta_i}(\cdot)$ denotes a unit point mass at θ_i . This means that given $(\theta_1, \dots, \theta_k)$, θ_{k+1} is either a distinct value (with probability $\alpha/(\alpha + k)$) drawn from G_0 , or one randomly drawn from the existing θ_i ($i = 1, \dots, k$). This prior can then be applied to carry out posterior inference by iteratively sampling θ_i within a Gibbs loop (*see Markov Chain Monte Carlo, Introduction*) via the full conditionals

$$\theta_i | \theta_{-i}, \mathbf{Y} \sim q_0 G_i(\theta_i) + \sum_{j=1, j \neq i}^n q_j \delta_{\theta_j}(\theta_i) \quad (4)$$

where θ_{-i} is $(\theta_1, \dots, \theta_{i-1}, \theta_{i+1}, \dots, \theta_n)$, $q_j = L(y_j | \theta_j)$, $G_i(\theta_i)$ is the parametric posterior distribution conditional on the i th observation given by $dG_i(\theta_i) \propto L(y_i | \theta_i) dG_0(\theta_i)$, and $q_0 = \int L(Y_i | \theta_i) \times dG_0(\theta_i)$. If $L(Y_i | \theta_i)$ and G_0 are conjugate, the integral in q_0 can be derived explicitly.

Many of the other algorithms developed for conjugate DPM models are very similar in spirit to Escobar's initial contribution. The differences lie in exploiting the inherent structure of the θ_i 's due to the discrete nature of the Dirichlet process. Rather than dealing directly with each θ_i individually, the current state of the $\theta = (\theta_1, \dots, \theta_n)$ can be represented in terms of a *configuration* [13].

Definition Let $K \leq n$ denote the number of distinct values in θ . Denote by $\phi = (\phi_1, \dots, \phi_K)$ these distinct values in some arbitrary order. Groups of elements of θ made by the ϕ_j 's are called *clusters*. Then define a vector of cluster membership pointers $s = (s_1, \dots, s_n)$ by $s_i = j \Leftrightarrow \phi_j = \theta_i$. A configuration c of θ is the pair (ϕ, s) . In addition, let n_j equal the number of θ_i 's equal to ϕ_j . Since the indices in ϕ

are arbitrary, there are $k!$ configurations representing a given θ .

By separating distinct values and membership pointers, this definition allows one to implement the sampling in equation (4) more efficiently by using the conditionals $\phi | s, Y$ and $s | \phi, Y$ or by integrating out the ϕ . We note here that $\phi_j | s, Y$ are independent random variates, each respectively from the posterior distribution obtained under prior G_0 and likelihood terms $L(Y_i | \theta_i)$ contributed by i such that $s_i = j$. Such algorithms based on configurations were utilized by Neal [14], MacEachern [15], and Bush and MacEachern [16]. We describe in some detail a more general and recent version in the section titled “Nonconjugate DPM Model Simulation”.

Split–Merge MCMC Techniques

Although the above algorithms produce **Markov chain** Monte Carlo (MCMC) chains that converge to the correct posterior distribution, they can run into difficulties when the true mixture components are not well separated. An example would be a mixture of normal distributions where the differences in component means are small relative to each component's variance. In this situation, the above algorithms can mix poorly because they update the cluster membership pointers in s sequentially. In order to separate two close components, the algorithm would need to move single observations into a new cluster. However, these new clusters can represent intermediate states with low associated probability [17]. In response to this difficulty, Jain and Neal [18] and Green and Richardson [19] have developed split–merge techniques whereby groups of observations are allowed to be updated simultaneously, thereby skipping low-probability intermediate states.

Jain and Neal begin by selecting at random two elements of θ whose membership pointers we denote as s_i and s_j . If $s_i \neq s_j$ then propose merging the two clusters into one. If $s_i = s_j$, then propose splitting that cluster into two. (In actual implementation, Jain and Neal advocate using a restricted Gibbs sampling scan in order to propose more likely splits of the single component.) For either of these situations, the decision to update the configuration with either the merge or split proposal is then based on a Metropolis–Hastings update [20–22]. If we denote the current

configuration as $c = (\phi, s)$, and the proposed state as $c^* = (\phi^*, s^*)$, then the chain would move to s^* with probability,

$$\alpha(s^*, s) = \min \left[1, \frac{q(s|s^*) \pi(s^*) p(y|s^*)}{q(s^*|s) \pi(s) p(y|s)} \right] \quad (5)$$

where $q(s^*|s)$ denotes the proposal probability of moving from s to s^* and $\pi(s)$ represents the prior probability for the entire configuration s . Expressions for $\pi(\cdot)$ and $q(\cdot, \cdot)$ are available in [18, 23].

The split–merge algorithm has been implemented in the conjugate situation as well as in what Jain and Neal term as *conditionally conjugate* DPM models (see [23] for details). The primary difficulty lies in evaluating the likelihood in the Metropolis update, namely,

$$p(y|s) = \prod_{i=1}^n \int L(y_i|\theta) H_{i,s_i}(\theta) \quad (6)$$

Here H_{i,s_i} is the posterior distribution for theta under the prior G_0 and all observations y_k such that $k \in \{k : k < i, s_k = s_i\}$. If the last set is empty, H_{i,s_i} simply equals G_0 . Unless the above integral is analytically tractable, as in conjugate models, the likelihood evaluation can quickly become nontrivial.

The split–merge algorithm of Green and Richardson originates from a reversible jump framework. The general sampling scheme proceeds in the same manner as with Jain and Neal’s algorithm where split and merge proposals are proposed and accepted with appropriate probabilities in a Metropolis–Hastings update. However, Green and Richardson construct their proposals based on general reversible jump guidelines, which we outline below.

Consider the DPM model in equation (2) where θ_i is p dimensional. As before, let $\phi = (\phi_1, \dots, \phi_K)$ represent the collection of distinct values of θ . During a split proposal we need to assign elements of a randomly chosen cluster $g_j = \{i : s_i = j\}$ to two clusters generically denoted g_{j-} and g_{j+} as well as choose corresponding ϕ_{j-} and ϕ_{j+} . In a reverse manner, a merge move combines two randomly chosen clusters and their parameter values into $g\phi_j$.

The general reversible jump scheme calls for the following steps.

1. Methods for combining ϕ_{j-} and ϕ_{j+} into ϕ_j during a proposed merge and generating ϕ_{j-} and

ϕ_{j+} from ϕ_j during a split. This is accomplished via p conservation conditions

$$m_l(\phi_j) = w_- m_l(\phi_{j-}) + w_+ m_l(\phi_{j+}), \quad l = 1, \dots, p \quad (7)$$

where the vector function $m : \mathcal{R}^p \rightarrow \mathcal{R}^p$ is invertible and $w_- + w_+ = 1$. Typically, m_l are **moments** of the distribution $L(y|\phi)$. For the merge proposal the above definition suffices, taking $w \sim \beta(n_{j-} + \omega, n_{j+} + \omega)$, where ω represents a fixed tuning parameter. For splitting, one uses auxiliary variables $u = (u_1, \dots, u_p)$ and a bijection between (ϕ_j, u) and (ϕ_{j-}, ϕ_{j+}) to arrive at ϕ_{j-} and ϕ_{j+} , with $w_- \sim U(0, 1)$.

2. Selecting and constructing split/merge clusters. First draw two membership pointers, s_i and s_k at random.

(a) If $s_i = s_k = j$ propose a split by

$$P(s_i = j-) = \frac{w_- L(Y_i|\phi_{j-})}{w_- L(Y_i|\phi_{j-}) + w_+ L(Y_i|\phi_{j+})}, \quad \text{for each } i \ni s_i = j \quad (8)$$

- (b) If $s_i \neq s_k$, merge clusters g_{s_i} and g_{s_k} into one with an associated parameter obtained as in Step 1.

3. Calculate the Metropolis–Hastings acceptance probability for the proposed new configuration c^*
 - (a) For split proposals, $\alpha(c^*, c) = \min(1, A)$.
 - (b) For merge proposals, $\alpha(c^*, c) = \min(1, A^{-1})$.

Here A is problem specific and depends, for example, on $L(y|\phi)$ and the Jacobian of the bijection in Step 1. For the mixture of normal likelihoods, Green and Richardson [19] provide an expression for A .

The split–merge techniques of Jain and Neal and Green and Richardson should be viewed as enhancements rather than replacements for the sequential approaches. In fact, Jain and Neal advocate using a combination of both procedures, especially in the case of complicated mixtures. The split–merge algorithm enables large component movements, which can then be fine-tuned by following with a sequential update. This combination is straightforward (although potentially computationally demanding) within a Gibbs sampling scheme, as one can simply

iterate between split–merge and sequential updates, perhaps randomly with some predetermined probabilities.

Nonconjugate DPM Model Simulation

In the case of nonconjugate DPM models, MacEachern and Müller [13] propose an algorithm that avoids calculating q_0 , instead replacing it by likelihood evaluations. They begin by extending ϕ to n components $(\phi_1, \dots, \phi_n)$ and defining two distinct sets,

$$\begin{aligned}\phi &= \{\phi_F, \phi_E\}, & \phi_F &= \{\phi_1, \dots, \phi_K\}, \\ \phi_E &= \{\phi_{K+1}, \dots, \phi_n\}\end{aligned}\quad (9)$$

Here ϕ_F can be thought of as full clusters, meaning that each θ_i is currently equal to one of the ϕ_j for $j = 1, 2, \dots, K$ whereas ϕ_E represents empty clusters with no current members among the θ_i . For updating the configuration, while maintaining the above structure of $\phi = (\phi_F, \phi_E)$, the authors then introduce a *no-gaps* constraint on the labeling of clusters, meaning that for $j = 1, 2, \dots, K$, they require $n_j \geq 1$. Given this constraint, the algorithm involves the following steps.

1. For $i = 1, 2, \dots, n$, sample $(s_i | s_{-i}, \phi_F)$.
 - (a) Case 1: If $n_{s_i} = 1$, leave s_i unchanged with probability $(k-1)/k$. Otherwise, relabel the current cluster labeled s_i as cluster K . Then assign θ_i to one of the clusters $j = 1, 2, \dots, K$ via

$$\begin{aligned}P(s_i = j | s_{-i}, \phi_F, y_i) \\ = c_K^{-1} (n_j^-)^{\delta(1 \leq j < K)} \left(\frac{\alpha}{K}\right)^{\delta(j=K)} L(y_i | \phi_j)\end{aligned}\quad (10)$$

where n_j^- are cluster sizes without θ_i , i.e., $n_j - I(s_i = j)$, and $c_K = \sum_{j=1}^K P(s_i = j | s_{-i}, \phi_F, y_i)$. Note that unless s_i is placed in the K th cluster, the configuration loses a distinct value, meaning $K = K - 1$.

- (b) Case 2: If $n_{s_i} > 1$ then draw ϕ_{K+1} from G_0 and sample s_i with probabilities $(j = 1, 2, \dots, K + 1)$,

$$P(s_i = j | s_{-i}, \phi_F, y_i) = c_{K+1}^{-1} (n_j^-)^{\delta(1 \leq j \leq K)}$$

$$\times \left(\frac{\alpha}{K+1}\right)^{\delta(j=K+1)} L(y_i | \phi_j) \quad (11)$$

If s_i is put into cluster $K + 1$, this adds a component to the configuration, implying that $K = K + 1$.

2. Sample $(\phi | s)$. For $\phi_j \in \phi_F$, we now have K independent parametric models, $y_i | \phi \sim L(y_i | \phi_j) \forall i \ni s_i = j$ and $\phi_j \sim G_0$, $j = 1, \dots, K$, each with sample size n_j . Thus ϕ_j can be updated from the corresponding posteriors. However, when $L(y_i | \theta_i)$ and $G_0(\theta_i)$ are nonconjugate, this update could require sampling from non-standard densities, therefore necessitating general sampling approaches like adaptive-rejection Sampling [24, 25] or the Metropolis–Hastings algorithm (*see Hierarchical Markov Chain Monte Carlo (MCMC) for Bayesian System Reliability*).

Neal [26] proposed an alternative to the no-gaps algorithm that also avoids, in the cluster updating step, the need for integration in the nonconjugate setting. He uses the conditional prior for s_i as a proposal density in constructing a Metropolis–Hastings update for s_i . Conditional on the current configuration, a new cluster membership, s_i^* can be proposed as

$$P(s_i^* = j | s_{-i}) = \frac{n_j^-}{n - 1 + \alpha}, \quad \forall j \ni s_k = j \text{ for some } k = 1, \dots, n \quad (12)$$

$$P(s_i^* \neq s_k \forall k \neq i | s_{-i}) = \frac{\alpha}{n - 1 + \alpha} \quad (13)$$

Note that in the latter case, a new $\phi_{s_i^*}$ needs to be generated from G_0 . Given this proposal density, the acceptance probability reduces to a convenient ratio of likelihoods:

$$\alpha(s_i^*, s_i) = \min \left[1, \frac{L(Y_i | \phi_{s_i^*})}{L(Y_i | \phi_{s_i})} \right] \quad (14)$$

The final step in the algorithm is exactly Step 2 in the no-gaps algorithm.

Another interesting and simple algorithm for the nonconjugate setting, based on an entirely different approach that uses a latent variable formulation, is due to Walker and Damien [27]. They rewrite the

target conditional posterior distribution in equation (4) as

$$p(\theta_i | \phi^-, \mathbf{Y}) \propto L(Y_i | \theta_i) \left\{ \alpha G_0(\theta_i) + \sum_{j=1, j \neq i}^n \delta_{\theta_j}(\theta_i) \right\} \quad (15)$$

and then introduce latent variables u_i , which are conditionally distributed $\text{Uniform}(0, L(Y_i | \theta_i))$. With $u = (u_1, \dots, u_n)$ this leads to the joint conditional distribution

$$p(\theta, u | \mathbf{Y}) \propto \prod_{i=1}^n \left\{ \delta(u_i < L(Y_i | \theta_i)) \left(\alpha G_0(\theta_i) + \sum_{j < i} \delta_{\theta_j}(\theta_i) \right) \right\} \quad (16)$$

Clearly, the introduction of u still leads to the same conditional distribution as in equation (15). The update for θ involves the following two steps. First sample all $u_i | \theta_i$ independently from uniform densities on $(0, L(Y_i | \theta_i))$, and then sample from the conditional for each θ_i available in the convenient form

$$p(\theta_i | u_i, \mathbf{Y}) \propto \alpha G_0(\theta_i) \delta(L(Y_i | \theta_i) > u_i) + \sum_{L(Y_i | \theta_j) > u_i} \delta_{\theta_j}(\theta_i) \quad (17)$$

Walker and Damien [27] provide two examples of the method.

Extensions

The Dirichlet process has been generalized in many different directions. These include neutral-to-the-right processes [28], Polya trees [2, 4, 29], Lévy-driven **Markov processes** [30], and others. From the computational standpoint, generalizations that have more commonalities with the basic techniques developed for the Dirichlet process are stick-breaking priors [31], species sampling models [32], and use of the weighted Chinese restaurant process in [32]. Dirichlet process techniques have also been incorporated in and adapted to other classes of models, in particular, multiplicative intensity models [33]. The continued popularity of methods stemming from the Dirichlet

process appears to be driven by its flexibility and computational feasibility.

End Notes

^aDirichlet process mixtures (the focus of this chapter) are distinct from mixtures of Dirichlet processes (MDP), as introduced in the work of Antoniak [3]. MDPs begin with G as distribution for data, and express uncertainty in G by mixing Dirichlet processes with different centering measures, making G_0 itself random. Hanson and Johnson [4] elaborate the difference between MDP and DPM. Unfortunately, the terminology has not yet become standardized and often appears in the literature in conflicting ways.

Smoothed Function Estimation for Censored Data

Introduction

Consider a nonnegative random variable X with *distribution function* (d.f.) $F(\cdot)$ and *density function* $f(\cdot)$. In the context of reliability and survival analysis, among many associated functions of interest are the *survival function* (s.f.) $S(t) = 1 - F(t)$, the *hazard function* $h(t) = f(t)/S(t) = -(d/dt) \log S(t)$, the *cumulative hazard function* (chf)

$$H(t) = \int_0^t h(y) dy = -\log S(t), \quad t \geq 0 \quad (1)$$

and the *mean residual life*

$$m(t) = E(T - t | T > t) = \frac{\left(\int_t^\infty S(y) dy \right)}{S(t)} \quad (2)$$

Since the knowledge of the density function or the d.f. provides information about other functions, the basic strategy for finding their smooth estimators is to find a smooth estimator of the d.f. and use it to find smooth estimators of other derived functions. The setup considered here is that of right censoring in which instead of observing the random sample $X_1, \dots, X_n$, from the distribution F , we observe the censored lifetimes $Z_i = \min(X_i, Y_i)$ and the indicator variables $\delta_i = I(X_i \leq Y_i)$, where $Y_1, Y_2, \dots, Y_n$ represents a sequence of independent censoring times with d.f. G . In this case we have the nonparametric maximum-likelihood estimator of $S(t)$ as given by Kaplan and Meier [1], also known as the *product-limit* (PL) estimator. It may be written as (see Bhattacharjee and Sen [2])

$$\hat{S}_n(t) = \begin{cases} 1 & \text{for } 0 \leq t < Z_{1:n}^* \\ \prod_{i \leq j} \left(\frac{n - k_i}{n - k_i + 1} \right) & \text{for } Z_{j:n}^* \leq t < Z_{j+1:n}^*; 1 \leq j \leq M_n \end{cases} \quad (3)$$

where $Z_{i:n}^*$, $i = 1, 2, \dots, M_n$, denote the M_n ordered *failure points*, i.e., $Z_{j:n}^* = Z_{k_j:n}$ ($Z_{0:n}^* = 0$, $Z_{M_n+1:n}^* =$

∞), with $Z_{i:n}$, $i = 1, 2, \dots, n$ denoting the ordered statistics of the sample $Z_1, \dots, Z_n$. This estimator has jump discontinuities at the failure points and therefore is not suitable for producing estimates of $f(t)$ and $h(t)$, though estimators of $H(t)$ and $m(t)$ may be obtained by replacing $S(t)$ by $\hat{S}_n(t)$ in equations (1) and (2).

On the other hand, Aalen [3] exploited counting-process martingale theory to propose and study the following *unbiased* estimator of $H(t)$, called the *Nelson–Aalen estimator*:

$$\hat{H}_n(t) = \int_0^t \frac{dN_{1n}(s)}{R_n(s)} = \sum_{i: Z_{i:n} \leq t} \frac{\delta_{(i:n)}}{n - i + 1} \quad (4)$$

where $N_{1n}(t) = \sum_{i=1}^n \delta_i I(Z_i \leq t)$ and $R_n(t) = \sum_{i=1}^n I(Z_i \geq t)$ are the *failure* (i.e., uncensored) and the *number-at-risk* counting processes, respectively, and $\delta_{(i:n)}$ denotes the value of δ_i corresponding to the ordered statistic $Z_{i:n}$.

Notably, however, none of the above estimators produce *smooth* estimators of $H(t)$ and $m(t)$. Thus, the main emphasis in the literature on smooth function estimation so far has been on *density* or *hazard-rate* estimation, that is, on smoothing either $S_n(t)$ or $H_n(t)$. This has been influenced by advances and popularity of the *kernel density estimator* Rosenblatt [4] and Parzen [5] as discussed below for some of the procedures under each category. Recall that a kernel estimator for uncensored data is given by

$$\hat{f}_n(x) = (\omega_n)^{-1} \int_0^\infty k\left(\frac{x-s}{\omega_n}\right) d\hat{F}_n(s) \quad (5)$$

where $\hat{F}_n(\cdot)$ is the empirical distribution function (edf), $\omega_n(>0)$, known as the *bandwidth*, chosen so that $\omega_n \rightarrow 0$ but $n\omega_n \rightarrow \infty$, as $n \rightarrow \infty$; $k(\cdot)$ is termed the *kernel function* and is typically assumed to be a symmetric probability density function (pdf) with zero mean and unit variance.

Density Estimation: Smoothing of PL Estimator

Blum and Susarla [6] proposed and studied an adaptation of the kernel estimator to censored data, by considering an equivalent problem for the uncensored observations. Lo *et al.* [7] proved the consistency and asymptotic normality of the kernel density estimators using an improved version of an almost-sure representation of a *modified* $\hat{F}_n(x) = 1 - \hat{S}_n(x)$ originally

2 Smoothed Function Estimation for Censored Data

due to Lo and Singh [8], of the form

$$\hat{F}_n(x) = F(x) + n^{-1} \sum_{i=1}^n \xi_i(x) + O\left(\frac{\log n}{n}\right) \quad (6)$$

Here $\xi_i(x) = S(x)\zeta(X_i, \delta_i, x)$, where

$$\zeta(z, \delta, x) = -g(z \wedge x) + [\bar{L}(x)]^{-1} I\{z \leq x, \delta = 1\} \quad (7)$$

with $g(y)$, $\bar{L}(x)$, and $L_1(x)$ defined as

$$g(y) = \int_0^y [\bar{L}(s)]^{-2} dL_1(s) \quad (8)$$

$\bar{L}(x) = (1 - F(x))(1 - G(x))$ and $L_1(x) = P(X_i \leq x, \delta_i = 1)$. A smooth estimator of the hazard function is then given by $\hat{h}_n(x) = \hat{f}_n(x)/(1 - \hat{F}_n(x))$, consistency and other large sample properties of which also follow (see Lo *et al.* [7]).

Hazard Estimation: Smoothing of Nelson–Aalen Estimator

Ramlau-Hansen [9], Yandell [10], and Tanner and Wong [11] all considered kernel smoothing of the Nelson–Aalen estimator, providing a smooth estimator of $h(t)$ as given by

$$\begin{aligned} \hat{h}_n(t) &= (\omega_n)^{-1} \int_0^\infty k\left(\frac{t-s}{\omega_n}\right) d\hat{H}_n(s) \\ &= (\omega_n)^{-1} \sum_{i=1}^n \frac{\delta_{(i:n)}}{n-i+1} k\left(\frac{t-Z_{i:n}}{\omega_n}\right) \end{aligned} \quad (9)$$

While Ramlau-Hansen [9] used martingale methods to obtain pointwise asymptotic normality, and Yandell [10] obtained asymptotic distribution of *maximum absolute deviation* via a strong approximation, they restricted the observations to a compact set. Tanner and Wong [11], however, avoid this restriction in an interesting way – by tackling the estimator directly via *Hájék projection*.

A list of available results concerning the above smooth density estimator and other variants along with hazard rate is contained in the survey article by Padgett and McNichols [12].

Bandwidth Selection and Other Methods

Choice of the bandwidth, $\omega_n > 0$, is the most crucial issue in any kind of smoothing. Typically, ω_n has an

optimal rate of $O(n^{-1/5})$. Marron and Padgett [13] show that *least-squares cross-validation* produces asymptotically optimal bandwidths in the case of density estimation. Patil [14] proves the same for hazard-rate estimation. Further, Patil [15] obtains the convergence rate of these bandwidths, as well as that of the corresponding *integrated squared error*, in a unified framework that covers all the four cases: density or hazard rate, uncensored or censored data.

As for alternative estimation methods, Antoniadis *et al.* [16] study wavelet-based hazard estimators, which have more recently been generalized by Brunel and Comte [17], who consider general projection estimator methods that include trigonometric series, polynomials, and wavelets. These authors prove optimality of the estimators in an asymptotic minimax sense.

Kernel estimators suffer from the following two kinds of *boundary bias*. First, as observed by Silverman [18] and others, they may provide positive mass outside the support of the target function. Even otherwise, as remarked in Wand *et al.* [19], the estimator in equation (5) “works well for densities that are not far from Gaussian in shape”; however, “it can perform very poorly when the shape is far from Gaussian”, especially near the boundaries. Second, it may fail to estimate discontinuity at boundaries, such as in the case of exponential distribution.

Different approaches proposed to deal with these problems in the uncensored data case can also be adapted to the censored data case. Below we mention some of the prominent methods: the transformation methods of Wand *et al.* [19], Ruppert and Wand [20], and Marron and Ruppert [21]; the method of Bagai and Prakasa Rao [22] based on a kernel k with support $\mathbb{R}^+$, which, however, fails to use the whole data; the interesting, asymmetric-kernel estimators of Chen [23] using gamma kernels, and of Scaillet [24], using inverse Gaussian and reciprocal inverse Gaussian kernels, whose variances, however, blow up at $x = 0$. These last methods have been recently adapted by Bouezmarni and Rombouts [25] for density estimation in the censored-data case, but the problems mentioned above still persist in this case.

Chaubey and Sen [26], on the other hand, proposed a density estimator as the derivative of a smooth version of the edf, by adapting Hille’s smoothing lemma (see [27]) in a stochastic setup.

This, in contrast to the proposal of Bagai and Prakasa Rao [22], uses the whole data and easily generalizes to the censored-data case, as studied in Chaubey and Sen [28] for estimation of density, survival, hazard, and chfs, and in Chaubey and Sen [29] for mean residual life function. It does not suffer from the problems mentioned above. In the next section we demonstrate the use of Hille's lemma for obtaining smooth estimators.

The Chaubey–Sen Estimator

Here we shall consider, as in Chaubey and Sen [28], the following modification of $\hat{S}_n(t)$ as in Efron [30]:

$$S_n(t) = \begin{cases} \hat{S}_n(t) & \text{for } t < Z_{n:n} \\ 0 & \text{for } t \geq Z_{n:n} \end{cases} \quad (10)$$

Further, we state Hille's lemma which underlies the construction of all the estimators in this section:

Lemma (Feller [27, Lemma 1, Section VII.1]) *Let $u(t)$ be a bounded, continuous function on $\mathbf{R}^+$. Then*

$$e^{-\lambda t} \sum_{k \geq 0} u\left(\frac{k}{\lambda}\right) \frac{(\lambda t)^k}{k!} \rightarrow u(t), \text{ as } \lambda \rightarrow \infty \quad (11)$$

uniformly in any finite interval $\mathbf{J}$ contained in $\mathbf{R}^+$.

Substituting Efron's $S_n(t)$ [30] for $u(t)$ in the above lemma, Chaubey and Sen [28] obtained the following smooth survival function estimator:

$$\tilde{S}_n(t) = \sum_{k=0}^N S_n\left(\frac{k}{\lambda_n}\right) p_k(\lambda_n t) \quad (12)$$

where $p_k(\mu)$, $k = 0, 1, 2, \dots$ denote the Poisson probabilities, $p_k(\mu) = e^{-\mu} \mu^k / k!$, $k = 0, 1, 2, \dots$, $N = [\lambda_n Z_{n:n}]$, and λ_n is suitably chosen (see Chaubey and Sen [31] for a discussion on the choice of λ_n).

This is an extension of the idea of Chaubey and Sen [26, 32] to the case of randomly censored data. Chaubey and Sen [28] used truncated Poisson weights constructed in a suitable manner. It was later recognized for the uncensored case that (see Chaubey and Sen [33]) the truncated weights may not be suitable in forming the associated estimator of the *mean residual life* function. Moreover, the untruncated weights are asymptotically equivalent to truncated weights.

Hence, we exclude the discussion of the truncated weights here and present smooth estimators based on the untruncated weights. Chaubey and Sen [28] show that the absolute error between smooth and nonsmooth estimators of the s.f. over any compact set is of the order $O(n^{-3/4}(\log n)^{1+\delta})$, for some $\delta > 0$, under the existence of the first moment of F .

Noting that $\tilde{S}_n(t)$ defined above is smooth, bounded, and continuously differentiable with respect to $t \in \mathbf{R}^+$, we obtain the following estimators of the associated functionals:

$$\begin{aligned} \tilde{F}_n(t) &= 1 - \tilde{S}_n(t), \quad \tilde{f}_n(t) = \lambda_n \sum_{k=0}^N p_k(\lambda_n t) \\ &\times \left[S_n\left(\frac{k}{\lambda_n}\right) - S_n\left(\frac{k+1}{\lambda_n}\right) \right] \end{aligned} \quad (13)$$

$$\tilde{h}_n(t) = \frac{\tilde{f}_n(t)}{\tilde{S}_n(t)}, \quad \tilde{m}_n(t) = \frac{1}{\tilde{S}_n(t)} \int_t^\infty \tilde{S}_n(y) dy \quad (14)$$

Further, an alternative hazard-rate estimator is obtained by smoothing the Nelson–Aalen estimator:

$$\tilde{H}_n(t) = \sum_{k=0}^N H_n\left(\frac{k}{\lambda_n}\right) p_k(\lambda_n t) \quad (15)$$

$$\begin{aligned} \tilde{h}_n^{\text{NA}}(t) &= \left(\frac{d}{dt}\right) \tilde{H}_n(t) = \lambda_n \sum_{k=0}^N p_k(\lambda_n t) \\ &\times \left[H_n\left(\frac{k+1}{\lambda_n}\right) - H_n\left(\frac{k}{\lambda_n}\right) \right] \end{aligned} \quad (16)$$

where $H_n(\cdot)$ is as in Equation (4). The computational form of the smooth mean residual life estimator is provided below (see Chaubey and Sen [28]):

$$\tilde{m}_n(t) = \frac{\sum_{k=0}^N P_k(\lambda_n t) S_n\left(\frac{k}{\lambda_n}\right)}{\lambda_n \sum_{k=0}^N p_k(t \lambda_n) S_n\left(\frac{k}{\lambda_n}\right)} \quad (17)$$

where $N = [\lambda_n Z_{n:n}]$ and, $P_k(\mu)$ denotes the cumulative probability for the Poisson distribution with mean μ , namely, $P_k(\mu) = \sum_{r=0}^k p_r(\mu) = \sum_{r=0}^k e^{-\mu} \times$

4 Smoothed Function Estimation for Censored Data

Figure 1 Kaplan–Meier survival function estimates and the corresponding Chaubey–Sen smooth estimates for survival, density, hazard, and mean residual life for remission duration data

$(\mu^r/r!)$. The asymptotics of $\tilde{m}_n(t)$ are obtained in Chaubey and Sen [29]. The smoothing procedure discussed here is also found useful in smooth isotonic estimation of density, hazard, and mean residual life functions by Chaubey and Sen [34].

The choice of λ_n is important in the study of the asymptotic properties of the estimators $\tilde{S}_n$, $\tilde{f}_n$, $\tilde{h}_n$, and $\tilde{H}_n$. Chaubey and Sen [28] recommend the choice $\lambda_n = n/Z_{n:n}$, for a practical purpose, which is appropriate for the censoring and lifetimes having infinite support and finite first **moments** (in this case $N = n$). However, through further numerical investigations (see Chaubey and Sen [31]), the choice $\lambda_n = (n - 1)/Z_{n:n}$ is found more suitable. This is the choice used in the numerical illustration below.

A Numerical Example

Here we illustrate the smooth estimators using the data in Gehan [35], in which the drug 6-mercaptopurine (6-MP) was compared to a placebo with respect to the ability to maintain remission in acute leukemia patients. We have only considered the

data for the 6-MP drug where 21 subjects were used and the maximum censored time was 35 weeks. The remission times (in weeks) and the corresponding PL survival probabilities are given in Table 1.

The value of λ_n chosen is $20/35 = 0.5714$. The plots of the smooth survival function, the density function, the hazard function, and the mean residual life function are presented in Figure 1. We see that, whereas the smooth survival curve stays very close to the Kaplan–Meier survival curve for the whole observed range, the smoothed mean residual life values seem to stay above the empirical mean residual life values, especially near the largest observation. The reason for this may lie in the fact that the empirical mean residual life estimator may not be defined beyond the largest failure.

Table 1 Remission times and Kaplan–Meier (KM) survival estimates for 6-MP study

Remission time(t_j)	6	7	10	13	16	22	23
$\hat{S}_n(t_j)$	0.857	0.807	0.753	0.690	0.627	0.538	0.448

Convergence and Mixing in Markov Chain Monte Carlo

Convergence and Mixing of Markov Chain Monte Carlo

The aim of Markov chain **Monte Carlo** (MCMC) simulation is to sample a target distribution of interest, π , or to summarize it, e.g., compute mean, variances, or probabilities with respect to π . A Markov chain having π as its unique invariant and limiting distribution is constructed and simulated until convergence to π . For a detailed description of various algorithms available to construct such Markov chains (Metropolis–Hastings, **Gibbs sampler**, etc.) and for conditions that guarantee uniqueness of the stationary distribution and convergence to it, see **Markov Chain Monte Carlo, Introduction**, whose notation is adopted here as much as possible. In the sequel, finite state spaces are referred to, to keep things simple, but the considerations made here extend to general state spaces. A Markov chain will be identified with the corresponding transition matrix (in finite state spaces) or kernel (in general state spaces). Given that the time available for simulation is limited, researchers search for strategies to improve the performance of the MCMC sampler they implement. Performance can be enhanced in two main ways: either by increasing the speed of convergence to stationarity or by reducing the asymptotic variance of the resulting MCMC estimators of, say, $\mu_\pi(f) = \int f(x)\pi(dx) = E_\pi f(X)$. The latter is often referred to as *improved mixing* (clever exploration of the state space) or *efficiency* (since asymptotically, MCMC estimators are unbiased, the **mean squared error** coincides with the variance). By asymptotic variance, we mean the limit as n (the simulation time) tends to infinity, of n times the variance of the MCMC estimator, $\hat{\mu}_n(f) = \frac{1}{n} \sum_{i=1}^n f(X_i)$, computed on a π -stationary chain updated using the transition matrix Q :

$$\begin{aligned} v(f, Q) &= \lim_{n \rightarrow \infty} n \text{Var}_\pi(\hat{\mu}_n) \\ &= \text{Var}_\pi f(X) \left[1 + 2 \sum_{j=1}^{\infty} \rho_j \right] \end{aligned} \quad (1)$$

where $\rho_j = \text{Cor}_\pi[f(X_0), f(X_j)]$ is the lag- j **autocorrelation** along the simulated π -stationary chain. The quantity $\tau = 1 + 2 \sum_{j=1}^{\infty} \rho_j$ is known as the *integrated autocorrelation time* and can be interpreted as the number of correlated samples with the same variance-reducing power as one independent sample. The integrated autocorrelation time can be estimated from the sample path, using Sokal's adaptive truncated periodogram estimator, $\hat{\tau}$ [1].

Speed of convergence is a decreasing function of the eigenvalues in absolute value of the Markov chain transition matrix (in particular what matters the most is the rate of convergence of the Markov chain, which coincides with the second largest eigenvalue in absolute value, the smaller the better), while efficiency is a function, again decreasing, of the plain eigenvalues. The two goals of speeding up convergence and reducing variance, can thus become conflicting and a good practice would be to use a transition matrix having good properties in terms of convergence for the first part of the simulation, i.e. during the burn-in phase and then switching to a Markov chain with good mixing properties. Still, the two goals are strictly connected in that pushing the spectrum of the transition matrix (which, we recall, is always between -1 and $+1$) toward the negative side, which can be achieved by inducing negative **correlation** along the Markov chain sample path, is a hard task. Thus, asymptotic variance reduction is, most of the time, in real applications, achieved by trying to reduce the autocorrelation along the sample path to zero.

In the sequel, we will review some of the current most popular practices to improve the performance of MCMC samplers giving the relevant references to the literature or pointing the reader to web sites with annotated bibliography of the relevant topics covered. One of the reference web sites for MCMC purposes is <http://www.statslab.cam.ac.uk/~MCMC> where preprints of many papers related to MCMC, referring to both theoretical and applied aspects, are posted.

Proper Scaling of the Proposal

For an **independence Metropolis–Hastings** algorithm, the closer the proposal is to the target, the faster is convergence to stationarity. In the limit, if the proposal coincides with the target, then MCMC

becomes **Monte Carlo simulation** and convergence happens in a single time step. In this case, the asymptotic variance of the (MC)MC estimator reduces to: $v(f, Q) = \text{Var}_\pi f(X)$. Unfortunately, in complicated realistic settings, it is quite unlikely that independent and identically distributed (i.i.d.) samples from the target can be obtained (*see Monte Carlo Methods, Univariate and Multivariate* for cases where direct Monte Carlo is available for multivariate distributions).

For a **random-walk Metropolis–Hastings** algorithm, guidelines to properly scale the target are given in [2, 3] for continuous state spaces. If the target is univariate normal, a random-walk Metropolis algorithm with proposal $x' = x_t + u$, where $u \sim N(0, \sigma^2)$, is optimally scaled when $\sigma = 2.38$, which corresponds to an acceptance rate of 44%. In general, if the scale parameter of the proposal is too small, nearly all proposals will be accepted, but the Markov chain will move around the state space very slowly. On the other hand, a scale parameter that is too large will result in an extremely poor acceptance rate and therefore in a highly inefficient algorithm. The authors in [2] suggest that the acceptance rate is a useful reference to be monitored when tuning the proposal in more general settings also. When the dimension of the target, d , increases, the optimal tuning parameter in a random-walk Metropolis–Hastings algorithm, becomes $\sigma = 2.4^2/d$, and the authors in [3] recommend calibrating the acceptance rate to about 25% to minimize the sample path autocorrelation. This golden rule seems to hold in a large variety of settings.

Metropolized Gibbs and Peskun Ordering

One of the advantages of the Gibbs sampler over Metropolis–Hastings type algorithms is that no tuning is needed since the proposal distribution coincides with the full-conditional. The difficulty with the Gibbs sampler arises when, in the target distribution, some of the coordinates are highly correlated. In these cases, a Gibbs sampler where each coordinate is updated separately (which is what is typically done in practice), results in very slow mixing in that the Markov chain takes a long time to traverse the state space. Unfortunately, not knowing much about the target, it is hard to guess which are the correlated coordinates that should be updated jointly

to improve efficiency; thus, a good practice is to monitor the estimated correlation as the simulation proceeds and change the sampling updating scheme if a problem is recognized. Having to sample from a highly correlated target creates mixing problems for the general Metropolis–Hastings algorithm also and the suggestion above would work here as well. As an alternative, one could try to reparameterize the target by transforming the original variables into less correlated ones. Having run the sampler on the transformed space, the original variables can be recovered simply by transforming back (assuming a unique inverse transformation exists). Examples of reparameterizations for a variety of linear and nonlinear models can be found in [4].

One interesting variation of the Gibbs sampler is the “Metropolized Gibbs sampler” [5]. The idea is to exclude, when updating each coordinate X_i , an immediate draw of X_i itself, thus ensuring that the Markov chain does not preserve the same position over successive points in time. The proposal distribution is not the full-conditional, $\pi(X_i|X_{-i})$ anymore, where $X_{-i} = (X_j, j \neq i)$, but a value Y_i , different from X_i is drawn with probability $\pi(Y_i|X_{-i})/[1 - \pi(X_i|X_{-i})]$. By doing so, one needs to insert a reject–accept step to correct for the possible bias induced by not using the full-conditional distribution as the proposal. The proper acceptance probability is given in [5]. The Metropolized Gibbs sampler is better than the regular Gibbs sampler on discrete state spaces (or when at least one of the components in the target is discrete) in terms of efficiency, i.e. better in the Peskun sense [6]. The intuition behind Peskun (partial) ordering is that whenever the same position is retained over time, the sampler becomes less efficient in that the state space is not explored. In general state spaces, the same position is retained over time whenever a proposal is rejected. Thus, in principle, we could improve the Metropolis–Hastings and the **Reversible jump** [7] algorithms in the Peskun efficiency ordering by decreasing the rejection frequency of the proposed moves. An application of this intuition appears in [8] and [9] where a delaying rejection mechanism is introduced to improve the Metropolis–Hastings and the Reversible jumps algorithms (respectively) on a sweep-by-sweep basis. The delaying rejection strategy is illustrated in more detail in the section titled “Adaptive MCMC and Particle Filters”.

Auxiliary Variables

For better mixing or faster convergence to stationarity, auxiliary or latent variables can be introduced in an MCMC simulation.

The idea of introducing auxiliary variables in MCMC sampling arose in statistical physics [10, 11], and was brought into the mainstream statistical literature by Besag and Green in [12].

Auxiliary variable techniques exploit the general principle that a complicated posterior distribution may become more tractable if it is embedded in a higher-dimensional state space. This is the same principle that drives data augmentation and expectation maximization (EM) algorithms (see **Expectation Maximization Algorithm** and [13]). Just to give an example of this principle at work, consider a Bayesian missing data problem. In this setting the “complete data” model (obtained by augmenting the observed data model with the missing data), typically has a nice analytical form and all the posterior computations can be carried out in closed form.

Once the higher-dimensional sample is obtained either by MCMC, importance sampling, or other simulation technique, a projection back on the original state space is obtained simply by discarding the auxiliary variables.

The simple *slice sampler* is probably the most popular auxiliary variable MCMC method, where a single auxiliary variable, γ , is introduced, and the joint distribution of the original variable of interest of interest, X and γ is specified by taking the marginal distribution of X to be the target and specifying the distribution of $\gamma|X$ to be uniform on the interval $[0, \pi(X)]$:

$$\begin{aligned}\pi(\gamma, X) &= \pi(X)\pi(\gamma|X) \\ &= \pi(X) \frac{1}{\pi(X)} \mathbf{1}_{\{0 \leq \gamma \leq \pi(X)\}}(\gamma)\end{aligned}\quad (2)$$

where $\mathbf{1}_A(\gamma)$ is the indicator function of the set A . The joint distribution over the enlarged state space is then explored *via* Gibbs sampler. This amounts to updating $\gamma|X$ by generating a uniform random variable over the interval specified above and then sampling $X|\gamma$ from a uniform distribution over the set $\{X : \pi(X) > \gamma\}$. While the first updating step is straightforward, the second one might be difficult since it requires the identification of the level sets of the target distribution. For a clever way to perform

this second update see [14], where an adaptive rejection mechanism is proposed for this aim.

Easy-to-check conditions for uniform and geometric ergodicity of the slice sampler are given in [15] and [16], respectively.

The simple slice sampler can be extended by introducing more than one auxiliary variable and this is of particular interest in a Bayesian context. The clever introduction of multiple auxiliary variables in a variety of Bayesian nonconjugate and hierarchical models is illustrated in [17].

In [15] it is proved that an independence Metropolis–Hastings algorithm can be turned into a corresponding slice sampler that produces MCMC estimators with a smaller asymptotic variance. In other words, the independence Metropolis–Hastings is dominated in the Peskun ordering [6] by the corresponding slice sampler. One can also easily devise over relaxed versions of slice sampling [14], which sometimes greatly improve the speed of convergence to stationarity by suppressing random-walk behavior.

Furthermore, in [18], the slice sampler is proved to be stochastically monotone with respect to the ordering given on the state space by the target: $X \prec Y$ if $\pi(X) \leq \pi(Y)$. This is the condition that is needed to turn the slice sampler into a perfect simulation algorithm (see **Perfect Sampling**). Another version of perfect slice sampler for mixture models is given in [19].

A different, interesting way of enlarging the state space by introducing auxiliary variables is given by *hybrid Monte Carlo* algorithms [20, 21], where a momentum vector (with the same dimension as the original variable of interest, X) is sampled from a Gaussian distribution and then a deterministic time-reversible and volume-preserving algorithm is run on the enlarged state space for some steps to obtain the proposed move, which is then either retained or rejected, based on some acceptance probability that preserves reversibility over the enlarged state space.

A final example of an auxiliary variable introduced for better mixing is the temperature parameter in the *simulated tempering* strategy [22]. The idea is to run, in series, m MCMC samplers with different stationary distributions and occasionally interchange the position of two of the chains. The m stationary distributions are obtained from the original target *via* incremental heating. Higher temperatures will lead to flatter stationary distributions that are thus easier to explore. A sampler converging to a heated target will

4 Convergence and Mixing in MCMC

be fast mixing and, *via* swap moves among adjacent chains, colder samplers will take advantage of this and inherit the good mixing property.

Langevin Diffusion MCMC Algorithms

If the gradient of the posterior distribution is available, it can be used to set up a Langevin algorithm. The simplest form of this type of algorithms uses as proposal density:

$$q(X, X') = \frac{1}{(2\pi\sigma^2)^{d/2}} \exp \left\{ -\frac{\|X' - X - \sigma^2 \nabla \log \pi(x)/2\|^2}{2\sigma^2} \right\} \quad (3)$$

for some suitable scaling parameter σ . Roberts and Rosenthal in [23] show that the choice of the scaling parameter should lead to an acceptance rate of 0.574 to achieve optimal convergence rates in a special case where the components of the target are uncorrelated. The only difference between a Langevin diffusion MCMC and a regular Metropolis–Hastings algorithm is that the additional information contained in the gradient (which, in difficult settings, could be replaced by numerical derivatives) is used to push the mean of the proposal toward high posterior regions. The caveat is that care should be taken in avoiding overshooting that causes the Markov chain to jump from one tail region of the posterior to another. Theoretical study of convergence properties of Langevin algorithm is given in [24–26].

Adaptive MCMC and Particle Filters

Recent research lines in MCMC aim at finding almost automatic algorithms that need little off-line pilot tuning of the proposal. To this scope, a few adaptive MCMC strategies have been recently proposed in the MCMC literature. There are mainly two ways of learning from the past history of the simulation to better design and calibrate the proposal. One can either preserve the Markovian structure of the sampler and this is obtained by performing only partial adaptation as in the delayed rejection strategy [9, 27], or by adapting at regeneration times as in [28]. Alternatively, one can adapt to the whole

history, thus obtaining a non-Markovian sampler, but then one has to prove the ergodicity of the resulting algorithm from first principles as in [29–31].

In the sequel, we will focus on two adaptive strategies, namely, a local and a global one. The intuition behind the *delayed rejection strategy* is that, upon rejection of a candidate move, instead of advancing simulation time and retaining the same position, a second-stage proposal distribution can be used to generate a new candidate move. The acceptance probability of this second-stage move is computed to preserve reversibility with respect to the target [32]. The rationale of this second-stage proposal is twofold: by trying harder to move away from the current position, better exploration of the state space is achieved. This improves the mixing properties of the sampler as can be formally proved by showing that the resulting algorithm dominates, in terms of Peskun ordering [6], the basic Metropolis–Hastings sampler. The other reason that makes the delayed rejection strategy interesting is that the second-stage proposal can be different from the first-stage one and can depend, not only on the current position of the Markov chain, but also on the first-stage proposal. This allows partial adaptation and local calibration of the proposal.

In the *adaptive Metropolis* algorithm, a Gaussian proposal distribution is centered at the current position and its **covariance** matrix is calibrated using the whole sample path of the Markov chain. After an initial nonadaptation period of length t_0 , the proposal covariance matrix is obtained as

$$C_t = s_d \text{Cov}(X_0, \dots, X_{t-1}) + s_d \varepsilon I_d, \quad t > t_0 \quad (4)$$

where s_d is a parameter that depends only on the dimension d of the state space where π is defined, $\varepsilon > 0$ is a constant that we may choose to be very small and I_d denotes the d -dimensional identity matrix. In [30] ergodicity of the resulting algorithm is proved if the target is bounded and supported on a bounded set. The adaptive Metropolis and other more flexible adaptive strategies are proved to be ergodic under less stringent hypothesis in [33]. A very powerful adaptive strategy that combines global and local adaptation is the DRAM algorithm (Delayed Rejection in Adaptive Metropolis). See [31], where the idea is tested on high-dimensional real applications.

Many important applications involve real-time data that are collected in a sequential manner. Examples include signal processing problems, target tracking, on-line medical monitoring, computer vision, financial applications, speech recognition, and communications, among others. When new data become available, the likelihood and therefore also the posterior distribution are updated and thus the target distribution of the MCMC simulation evolves as we analyze it.

In this setting, there is little time to run, until convergence, a new simulation between two successive data inputs. Still we can rely on the fact that the target distribution should not change much between two successive time intervals and thus, instead of running a totally new MCMC sampler, one could reweight the current, realized Markov chain path. Furthermore, instead of running a single chain, we can work with a set of “particles” that approximate the target at any given point in time. Particle filter algorithms are constructed by combining steps that involve updating the weights, resampling with probabilities proportional to the weights to eliminate unrepresentative particles, and changing the particle position by MCMC moves, among others.

Interested researchers can refer to the web site of sequential Monte Carlo methods and particle filtering: <http://www.sigproc.eng.cam.ac.uk/smc/> and to the book by Doucet *et al.* [34], for further reading on the topic.

To conclude, it is emphasized that particle filters can be helpful also in static contexts where standard MCMC algorithms show poor mixing. For example, given static target distribution can be turned into a dynamic one, as suggested in [35], by splitting the available data into batches that are used to recursively update the target that thus artificially evolves in time.

Importance Sampling and Population Monte Carlo

A direct competitor of MCMC is importance sampling. An importance distribution is selected, say g , and samples are generated from it. Since the quantity $\mu_\pi(f)$ can be rewritten as

$$\mu_\pi(f) = \int f(x) \frac{\pi(x)}{g(x)} g(x) dx \quad (5)$$

an asymptotically unbiased estimator of μ is

$$\hat{\mu}_n^{(2)}(f) = \frac{1}{n} \sum_{i=1}^n f(X_i) \frac{\pi(X_i)}{g(X_i)}, \quad (6)$$

where X_i are i.i.d. from g . The quantities $w_i = \frac{\pi(X_i)}{g(X_i)}$ are the importance weights. The importance distribution, g , plays the same role as the proposal distribution, q , in the Metropolis–Hastings sampler and the weights, w , play a role similar to the one of the acceptance probabilities. The importance sampling estimator has finite variance only if

$$E_\pi \left[f^2(X) \frac{\pi(X)}{g(X)} \right] < \infty \quad (7)$$

For further details on the implementation and the performance of importance sampling, *see Monte Carlo Methods, Univariate and Multivariate*.

An interesting combination of importance sampling techniques, adaptive Metropolis–Hastings algorithms, and particle filter ideas gives rise to the so-called population Monte Carlo methodology, the name being inspired from a survey by Iba [36]. The idea is to produce a population of points (or particles) of size N , say, associated with importance weights, and to update both the position and the weight of those points repeatedly over iterations. More precisely, at any iteration t of the population Monte Carlo algorithm, N particles are generated from an importance distribution that is determined based on the behavior of the $N \times (t-1)$ previous particles with respect to the target distribution. (The iterations are completely artificial in that their number can be chosen beforehand or during the simulation experiment and that stopping the experiment at any iteration does not modify the validity of the algorithm.) The new particles thus generated are then reweighted and possibly resampled by multinomial sampling or more clever schemes ([37, 38]). The major appeal of population Monte Carlo is that the importance distribution can be constructed in a completely open way based on all particles at any time in the past while preserving the fundamental importance sampling property. This idea sounds very similar to what is done in the adaptive MCMC strategies but with much more **degrees of freedom** because there is no need to worry about ergodicity and burn-in issues. As a result, importance sampling is much more amenable to adaptivity than MCMC because its asymptotics are only in N (as regular importance sampling schemes), not in t (as

MCMC methods). While the first paper on population Monte Carlo is [39], more details and updates are provided in both [40] and [41], the latter establishing improvement over the iterations.

Conclusions

Despite the fact that properly scaling the proposal distribution in a Metropolis–Hastings type algorithm is a hard task, guidelines exist in the literature, and adaptive MCMC strategies can be quite helpful as they permit almost automatic on-line tuning. Another difficult task in MCMC simulation is the definition of the length of the burn-in phase. Fortunately, free software for convergence diagnostics can, at least, tell us when convergence is not achieved. Also, when available, perfect simulation avoids the burn-in issues. For a detailed description of perfect simulation see **Perfect Sampling**, here we recall that both the independence sampler [42] and the slice sampler [18, 19], can be turned into perfect samplers under some regularity conditions, which are the same conditions that guarantee their uniform ergodicity. Another way to avoid the burn-in issue and, at the same time, to take advantage of adaptation in designing the instrumental distribution is *via* population Monte Carlo.

One of the main advantages of MCMC over other deterministic approximation methods is that it does not suffer the curse of dimensionality.

It is commonly agreed that “finding the ideal proposal chain is an art” [43] and this chapter gives some guidelines on where to look for it and what it looks like. Finally, techniques to reduce the amount of computation per iteration are also important in reducing run times and thus improving efficiency.

Also, even if a nonoptimal sampler has been run, the obtained samples could still be used in a more efficient way than simply taking the ergodic average. In particular, it is recalled that postprocessing the chain, by subsampling or Rao–Blackwellization can be quite useful.

When subsampling, typically every $\hat{\tau}$ observation is retained, thus reducing the covariance term in the expression of the asymptotic variance and building the MCMC estimators on almost-independent samples.

Rao–Blackwellization relies on the well-known principle that conditioning reduces the variance. The

idea is to replace $f(X_i)$ in $\hat{\mu}_n(f)$ by a conditional expectation, $E_\pi[f(X_i)|h(X_i)]$, for some function h , or to condition on the previous value of the chain thus using $E[f(X_i)|X_{i-1} = x]$ instead [44–47].

To conclude, we point out that there remains much to be done toward automation of MCMC simulations. Still there is a caveat to the blind use of MCMC without first trying to analytically integrate out some of the parameters, whenever possible, or checking that the distribution of interest is proper.

ANTONIETTA MIRA

Optimal Reliability Design-Modeling

Introduction

Reliability has become an even greater concern in recent years because high-tech industrial processes, with increasing levels of sophistication, comprise most engineering systems today. Based on enhancing **component reliability** and providing **redundancy**, while considering the trade-off between system performance and resources, optimal reliability design that aims to determine an optimal system-level configuration has long been an important topic in reliability engineering (*see Reliability Optimization*). Since 1960, many publications have addressed this problem using different system structures, performance measures, optimization techniques, and options for reliability improvement.

References 1, 2 and 3 provide good overview of the early work in system reliability optimization. Tillman *et al.* [3] were the first to classify articles by system structure, problem type, and solution methods. Also described and analyzed in [4] are the advantages and shortcomings of various optimization techniques. It was during the 1970s that various heuristics were developed to solve complex system reliability problems in cases where the traditional parametric optimization techniques were insufficient. In their 2000 report, Kuo and Prasad [1] summarize the developments in optimization techniques, along with recent optimization methods such as metaheuristics. This chapter discusses the contributions made to the literature since the publication of [1]. Most of the recent work in this area is devoted to:

- multistate system (MSS) optimization;
- percentile life as a system performance measure;
- multiobjective optimization;
- active and cold-standby redundancy;
- optimization techniques.

Based on their system performance, reliability systems can be classified as binary-state systems and MSS. A binary-state system and its components may exist in only two possible states—either working or failed. Binary-state system reliability models have played very important roles in practical

reliability engineering. To satisfactorily describe the performance of a complex system we may need more than two levels of satisfaction, for example, excellent, average, and poor [5]. For this reason, MSS reliability models were proposed in the 1970s and since 1998 a large part of the work devoted to MSS optimal design has emerged (*see Multistate Reliability Theory*). The primary task of MSS optimization is to define the relationship between component states and system states.

Measures of system performance are basically of four kinds: reliability, availability, mean time-to-failure (TTF), and percentile life (*see System Availability*). Reliability has been widely used and thoroughly studied as the primary performance measure for nonmaintained systems. For a maintained system, however, availability, which describes the percentage of time the system really functions, should be considered instead of reliability. Availability is most commonly employed as the performance measure for renewable MSS. Meanwhile, percentile life is preferred to reliability and mean TTF when the system mission time is indeterminate, as in most practical cases.

Some important design principles for improving system performance are summarized in [1]. This chapter primarily reviews articles that address either the provision of redundant components in parallel or the combination of structural redundancy with the enhancement of component reliability (*see Reliability of Redundant Systems; Reliability Allocation*). These are called *redundancy allocation problems* and *reliability-redundancy allocation problems*, respectively. Redundancy allocation problems are well documented in [1] and [5], which employ a special case of reliability-redundancy allocation problems without exploring the alternatives of component-combined improvement. Recently, a lot of the effort in optimal reliability design has been placed on general reliability-redundancy allocation problems, rather than on redundancy allocation problems.

In practice, two redundancy schemes are available: active and cold-standby. Cold-standby redundancy provides higher reliability, but it is hard to implement because of the difficulty of failure detection. Reliability design problems have generally been formulated considering active redundancy; however, an actual optimal design may include active redundancy or cold-standby redundancy or both.

2 Optimal Reliability Design-Modeling

However, any effort for improvement usually requires resources. Quite often it is hard for a single-objective system to adequately describe a real optimal design problem. For this reason, multiobjective system design problem always deserves a lot of attention.

This chapter describes the state-of-the-art of optimal reliability design. Emphasizing the foci mentioned above, it includes four main problem formulations in optimal **reliability allocation**; describes advances related to those four types of optimization problems; and also provides conclusions and a discussion of future challenges related to reliability optimization problems.

Problem Formulations

Among the diversified problems in optimal reliability design, the following four basic formulations are widely covered.

Problem 1 (P_1):

$$\begin{aligned} & \max R_S = f(x) \\ & \text{s.t.} \\ & g_i(x) \leq b_i, \quad \text{for } i = 1, \dots, m \\ & x \in X \\ & \text{or} \\ & \min C_S = f(x) \\ & \text{s.t.} \\ & R_S \geq R_0 \\ & g_i(x) \leq b_i, \quad \text{for } i = 1, \dots, m \\ & x \in X \end{aligned}$$

Problem 1 formulates the traditional reliability-redundancy allocation problem with either reliability or cost as the objective function. Its solution includes two parts: the component choices and their corresponding optimal redundancy levels.

Problem 2 (P_2):

$$\begin{aligned} & \max t_{\alpha, x} \\ & \text{s.t.} \\ & g_i(t_{\alpha, x}; x) \leq b_i, \quad \text{for } i = 1, \dots, m \\ & x \in X \end{aligned}$$

Problem 2 uses percentile life as the system performance measure instead of reliability. Percentile life is preferred especially when the system mission time is indeterminate. However, it is hard to find a closed analytical form of percentile life in decision variables.

Problem 3 (P_3):

$$\begin{aligned} & \max E(x, T, W^*) \\ & \text{s.t.} \\ & g_i(x) \leq b_i, \quad \text{for } i = 1, \dots, m \\ & x \in X \\ & \text{or} \\ & \min C_s(x) \\ & \text{s.t.} \\ & E(x, T, W^*) \geq E_0 \\ & g_i(x) \leq b_i, \quad \text{for } i = 1, \dots, m \\ & x \in X \end{aligned}$$

Problem 3 represents MSS optimization problems. Here, E is used as a measure of the entire **system availability** to satisfy the custom demand represented by a cumulative demand curve with a known T and W^* .

Problem 4 (P_4):

$$\begin{aligned} & \max z = [f_1(x), f_2(x), \dots, f_S(x)] \\ & \text{s.t.} \\ & g_i(x) \leq b_i, \quad \text{for } i = 1, \dots, m \\ & x \in X \end{aligned}$$

For multiobjective optimization, as formulated by Problem 4, a Pareto optimal set, which includes

Table 1 Reference classification by problem formulations

P_1	[6], [7], [8], [9], [10], [11], [12], [13], [14], [15], [16], [17], [18], [19], [20], [21], [22], [23], [24], [25], [26], [27], [28], [29], [30], [31], [32], [33], [4], [34], [35], [36], [37], [38]

P_4	[65], [66], [67], [68], [69], [70], [71], [72], [73], [37], [38]

all of the best possible trade-offs between given objectives, rather than a single optimal solution, is usually identified.

In the above formulations, the resource constraints may be linear or nonlinear or both.

The articles, classified by problem formulations, is summarized in Table 1.

Brief Reviews of Advances in P_1 – P_4

Active and Cold-Standby Redundancy (P_1)

P_1 is generally limited to active redundancy. A new optimal system configuration is obtained when active and cold-standby redundancies are both involved in the design. A cold-standby redundant component does not fail before it is put into operation by the action of switching, whereas the failure pattern of an active redundant component does not depend on whether the component is idle or in operation. Cold-standby redundancy can provide higher reliability, but it is hard to implement because of the difficulties involved in failure detection and switching.

In reference 10, optimal solutions to reliability-redundancy allocation problems are determined for nonrepairable systems designed with multiple **k -out-of- n** subsystems in series. The individual subsystems may use either active or cold-standby redundancy, or they may require no redundancy. Assuming an exponentially distributed component TTF with rate λ_{ij} , the failure process of subsystem i with cold-standby redundancy can be described by a **Poisson process** with rate $\lambda_{ij}k_i$, while the subsystem reliability with active redundancy is computed by standard binomial techniques. For series-**parallel systems** with only cold-standby redundancy, reference 11 employs the more flexible and realistic Erlang distributed component TTF and $\rho_i(t)$ is introduced to describe the reliability of the imperfect detection/switching mechanism for each subsystem. Reference 12 directly extends this earlier work by introducing the choice of redundancy strategies as an additional decision variable. For each of these methods, however, no mixture of component types or redundancy strategies is allowed within any of the subsystems.

In addition, reference 74 investigates the problem of where to allocate a spare in a k -out-of- n : F system of dependent components through minimal standby redundancy; and reference 75 studies the allocation

of one active redundancy when it differs based on the component with which it is to be allocated. Reference 28 considers the problem of optimally allocating a fixed number of s -identical multifunctional spares for a deterministic or stochastic mission time. In spite of some sufficiency conditions for optimality, the proposed algorithm can be easily implemented even for large systems.

Percentile Life Optimization (P_2)

Many diversified models and solution methods, where reliability is used as the system performance measure, have been proposed and developed since the 1960s. However, this is not an appropriate choice when mission time cannot be clearly specified or a system is intended for use as long as it functions. Average life is also not reliable, especially when the implications of failure are critical or the variance in the system life is high. Percentile life is considered to be a more appropriate measure, since it incorporates system designer and user risk. When using percentile life as the objective function, the main difficulty is its mathematical inconvenience, because it is hard to find a closed analytical form of percentile life in the decision variables.

Reference 39 solves redundancy allocation problems for series-parallel systems where the objective is to maximize a lower percentile of the system TTF distribution. Component TTF has a Weibull distribution with known deterministic parameters. Later in the literature, reference 40 addresses similar problems where Weibull shape parameters are accurately estimated but scale parameters are random variables following a uniform distribution.

Reference 42 develops a lexicographic search methodology that is, the first to provide exact optimal redundancy allocations for percentile life optimization problems. This algorithm is general for any continuous increasing lifetime distribution.

Three important results are presented in [41], which describe the general relationships between reliability and percentile life maximizing problems.

- S_2 equals S_1 given $\alpha_t = 1 - R_s(t, x_t^*)$, where $x_t^* \in S_1$;
- S_1 equals S_2 given t_{α, x_{α}^*} , where $x_{\alpha}^* \in S_2$;
- let $\psi(t)$ be the optimal objective value of P_1 . For a fixed α , $t_{\alpha} = \inf\{t \geq 0 : \Psi(t) \leq 1 - \alpha\}$ is the optimal objective value of P_2 .

MSS Optimization (P_3)

MSS is defined as a system that can unambiguously perform its task at different performance levels, depending on the state of its components, which can be characterized by nominal performance rate, availability and cost. Based on their physical nature, MSS can be classified into two important types: Type I MSS (e.g., power systems) and Type II MSS (e.g., computer systems), which use capacity and operation time as their performance measures, respectively.

In the article, an important optimization strategy, combining universal generating function (UGF) and genetic algorithm (GA), has been well developed and widely applied to reliability optimization problems of renewable MSS. In this strategy, there are two main tasks:

- According to the system structure and the system physical nature, obtain the system UGF from the component UGFs.
- Find an effective decoding and encoding technique to improve the efficiency of the GA.

Reference 43 first uses a UGF approach to evaluate the availability of a series-parallel MSS with relatively small computational resources. The essential property of the U -transform enables the total U -function for a MSS to be obtained by simple algebraic operations involving individual component U -functions. Later, reference 76 combines importance and sensitivity analysis and reference 77 extends this UGF approach to MSS with dependent elements. Table 2 summarizes the application of UGF to some typical MSS structures in optimal reliability design.

Table 2 Application of UGF approach

Series-parallel system	[43], [45], [76], [49], [51], [54], [57] [58], [59], [62]
Bridge system	[44], [46], [78], [61]
LMSSWS	[53], [79], [60]
WVS	[48], [80]
ATN	[52], [81]
LMCCS	[55], [56]
ACCN	[82]

LMSSWS: linear multi-state sliding-window system; WVS: weighted voting system; ATN: acyclic transmission network; LMCCS: linear multi-state consecutively connected system; ACCN: acyclic consecutively connected network

With this UGF and GA strategy, reference 61 solves the structure optimization of a MSS with time redundancy; reference 47 considers a MSS consisting of two parts: RGS including a number of resource generating subsystems and MPS including elements that consume a fixed amount of resources to perform their tasks; references 49, 54, 78 considers multistate series-parallel systems with two failure modes – open mode and closed mode, and references 46, 50, 55, 57–59 use survivability, instead of reliability to describe the ability of a MSS to tolerate both internal failures and external attacks.

In addition to a GA, reference 62 presents an ant colony method that combines with a UGF technique to find an optimal series-parallel power-structure configuration.

Besides this primary UGF approach, a few other methods have been proposed for MSS reliability optimization problems. Reference 64 develops a heuristic algorithm RAMC for a Type I multistate series-parallel system, while reference 83 presents a novel continuous-state system mode approximating the objective reliability function by a **neural network** approach.

Multiobjective Optimization (P_4)

In the previous discussion, all problems were single-objective problems. Rarely does a single-objective problem with several hard constraints adequately represent a real problem for which an optimal design is required. When designing a reliable system, as formulated by P_4 , it is always desirable to simultaneously optimize several opposing design objectives such as reliability, cost, even volume, and weight. For this reason, a recently proposed multiobjective system design problem deserves a lot of attention. The objectives of this problem are to maximize the system reliability estimates and minimize their associated variance while considering the uncertainty of the component reliability estimations. A Pareto optimal set, which includes all of the best possible trade-offs between the given objectives, rather than a single optimal solution, is usually identified for multiobjective optimization problems.

When considering complex systems, the reliability optimization problem has been modeled as a fuzzy multiobjective optimization problem in reference 69, considering the influence of various kinds of aggregators.

With a weighting technique, references 70, 71 solve multiobjective reliability-redundancy allocation problems using similar linear membership functions for both objectives and constraints; reference 67 transfers P_4 into a single-objective optimization problem and proposes a GA-based approach whose parameters can be adjusted with the experimental plan technique; and reference 65 develops a multiobjective GA to obtain an optimal system configuration and **inspection policy** by considering every target as a separate objective.

P_4 is considered for series-parallel systems, $RB/1/1$, and bridge systems in [66] with multiple objectives to maximize the system reliability while minimizing its associated variance when the component reliability estimates are treated as random variables. For series-parallel systems, component reliabilities of the same type are considered to be dependent since they usually share the same reliability estimate from a pooled data set. The system variance is straightforwardly expressed as a function in the higher **moments** of the component unreliability estimates [84]. For $RB/1/1$, the hardware components are considered identical and statistically independent, while even independently developed software versions are found to have related faults as presented by the parameters Prv and $Pall$. Pareto optimal solutions are found by solving a series of weighted objective problems with incrementally varied weights. It is worth noting that significantly different designs are obtained when the formulation incorporates estimation uncertainty or when the component reliability estimates are treated as statistically dependent. Similarly, [68] uses a multiobjective GA to select an optimal network design that balances the dual objectives of high reliability and low uncertainty in its estimation. But the latter exploits **Monte Carlo simulation** as the objective function evaluation engine (see also **Monte Carlo Methods, Univariate and Multivariate**).

Besides GA, reference 72 illustrates the application of the ant colony optimization algorithm to solve both continuous function and combinatorial optimization problems, while reference 73 tests five simulated annealing-based multiobjective algorithms—suppapitnarm multi-objective simulated annealing (SMOSA), ulungu multi-objective simulated annealing (UMOSA), pareto simulated annealing (PSA), pareto domination based multi-objective

simulated annealing (PDMOSA) and weight based multi-objective simulated annealing (WMOSA).

Conclusions and Discussions

We have reviewed the recent research on optimal reliability design. Many publications have addressed this problem using different system structures, performance measures, problem formulations and optimization techniques.

The systems considered here mainly include series-parallel systems, k -out-of- n ; G systems, bridge networks, n -version programming architecture, recovery block architecture and other unspecified coherent systems (see **Coherent Systems; Parallel, Series, and Series-Parallel Systems; k -out-of- n Systems**). The recently introduced N -version programming (NVP) and recovery block (RB) belong to the category of fault tolerant architecture, which usually considers both software and hardware.

Reliability is still employed as a system performance measure in most cases, but percentile life does provide a new perspective on optimal design without the requirement of a specified mission time. Availability is primarily used as the performance measure of renewable MSS whose optimal design has been emphasized and well developed in the past 10 years. Optimal design problems are generally formulated to maximize an appropriate system performance measure under resource constraints, and more realistic problems involving multiobjective programming are also being considered.

Optimal reliability design has attracted many researchers, who have produced hundreds of publications since 1960. Because of the increasing complexity of practical engineering systems and the critical importance of reliability in these complex systems, this still seems to be a very fruitful area for future research.

Compared to traditional binary-state systems, there are still many unsolved topics in MSS optimal design, which include the following:

- using percentile life as a system performance measure;
- involving cold-standby redundancy;
- nonrenewable MSS optimal design.

The research dealing with the understanding and application of reliability at the nano-level has also

demonstrated its attraction and vitality in recent years. Optimal system design that considers reliability within the uniqueness of nano-systems has seldom been reported in the literature. It deserves a lot more attention in the future. In addition, uncertainty and component dependency will be critical areas to consider in future research on optimal reliability design.

Notations

x_j	number of components at subsystem j
r_j	component reliability at subsystem j
n	number of subsystems in the system
m	number of resources
x	$(x_1, \dots, x_n, r_1, \dots, r_n)$
$g_i(x)$	total amount of resource i required for x
R_S	system reliability
C_S	total system cost
R_0	a specified minimum R_S
C_0	a specified minimum C_S
α	system user's risk level, $0 < \alpha < 1$
$t_{\alpha,x}$	system percentile life, $t_{\alpha,x} = \inf\{t \geq 0 : R_S \leq 1 - \alpha\}$
E_S	generalized MSS availability index
E_0	a specified minimum E_S

WAY KUO AND RUI WAN

Expectation Maximization Algorithm

Introduction

Dempster *et al.* [1] introduce the expectation maximization (EM) algorithm as a technique to produce maximum-likelihood estimates (MLEs) in problems where the data are incomplete. Latent variables or missing data points can be an intrinsic feature of the problem or they can be artificially imputed to ease computation.

The EM algorithm appeared in various guises before the paper by Dempster *et al.* [1], but this paper provided a unifying framework for the algorithm. Newcomb [2] is one of the earliest known works using the EM algorithm in which it is used for fitting a mixture of normal distributions. Blight [3] finds the MLE of an exponential family for censored data using an EM algorithm.

In principle, the EM process is straightforward to implement and has broad applicability. It is a two-step iterative algorithm consisting of an expectation step (E-step) followed by a maximization step (M-step). During the E-step, the expected value of the log-likelihood of the complete data (i.e., the observed and unobserved data) is computed. In the M-step, the expected complete data log-likelihood is maximized producing an MLE of the model parameters. The parameter estimates produced during the M-step are then used in a new E-step and the cycle continues until convergence.

While the EM algorithm will not decrease the observed data likelihood function (see Dempster *et al.* [1]), there is no guarantee that the resulting sequence of parameter estimates will converge to the global maximum of the likelihood. Multiple runs of the algorithm from different parameter starting values should help avoid local maxima.

McLachlan and Krishnan [4] provide an excellent review of the EM algorithm and its extensions. Other good resources include Pawitan [5, Chapter 12] and Tanner [6, Chapter 4].

A summary of the EM algorithm is provided in the next section including methods for determining convergence (Convergence Diagnostics). Many generalizations of the EM algorithm have been developed; a selection are introduced in the section

titled “Generalizations”. The section titled “Implementation of the EM Algorithm” illustrates implementation within the context of a finite mixture model. In conclusion, some properties of the EM algorithm are discussed.

EM Algorithm

Let $\mathbf{x} = (x_1, x_2, \dots, x_M)$ denote the observed data and $\mathbf{z} = (z_1, z_2, \dots, z_M)$ denote the unobserved (or latent) data. The likelihood function is $L(\phi) = p(\mathbf{x}|\phi)$ and a MLE $\hat{\phi}$ satisfies $L(\hat{\phi}) \geq L(\phi)$ for all ϕ . The complete data likelihood is of the form $L_c(\phi) = p(\mathbf{x}, \mathbf{z}|\phi)$.

The EM algorithm involves the following steps.

1. Let $\phi^{(0)}$ be an initial estimate of the unknown parameter. Let $t = 0$.
2. E-step: Compute

$$Q(\phi, \phi^{(t)}) = \int_{\mathbf{z}} p(\mathbf{z}|\mathbf{x}, \phi^{(t)}) \log p(\mathbf{x}, \mathbf{z}|\phi) d\mathbf{z} \quad (1)$$

3. M-step: Maximize $Q(\phi, \phi^{(t)})$ with respect to ϕ and let $\phi^{(t+1)}$ be the maximizing value.
4. Check for convergence. If converged, stop. Otherwise, increment t and return to Step 2.

The EM algorithm is guaranteed to give a sequence of estimates that have monotonically non-decreasing likelihood values, that is $L(\phi^{(t+1)}) \geq L(\phi^{(t)})$. The algorithm can converge to local maxima of the likelihood function. Wu [7] and McLachlan and Krishnan [4, Chapter 3] provide a detailed overview of the convergence properties and stationary points of the EM algorithm.

Convergence Diagnostics

Convergence is a feature of any iterative algorithm which must be considered. Aitken’s acceleration criterion [8–10] is often used as a convergence diagnostic for the EM algorithm.

Denote by $\{l^{(t)} = \log L(\phi^{(t)})\}$ the sequence of log-likelihood values that emerge from the EM algorithm. Assuming l^* is the limiting value of these log-likelihoods for iteration $(t + 1)$ of the EM algorithm, it follows that

$$l^{(t+1)} - l^* \approx a(l^{(t)} - l^*) \quad \text{for } 0 \leq a \leq 1 \quad (2)$$

2 Expectation Maximization Algorithm

$$\Rightarrow l^{(t+1)} - l^{(t)} \approx (1 - a)(l^* - l^{(t)}) \quad (3)$$

Thus, if $a \approx 1$, a small increase in the log-likelihood value does not necessarily imply that the EM algorithm is close to convergence. It can be shown that estimating a by the ratio of successive increments leads to the Aitken acceleration estimate of the limiting log-likelihood value

$$l^* \approx l^{(t)} - \frac{\{l^{(t+1)} - l^{(t-1)}\}}{\{l^{(t)} - l^{(t-1)}\}} \{l^{(t+1)} - l^{(t)}\} \quad (4)$$

The EM algorithm should be stopped if $|l^{(t+1)} - l^*| < \epsilon$, where ϵ is a prespecified tolerance level. Since this criterion is not an exact indicator of convergence, multiple runs of the algorithm with random starts must be employed.

Generalizations

Many extensions of the EM algorithm have also been developed. Dempster *et al.* [1] define the generalized expectation maximization (GEM) algorithm which increases the value of the likelihood at the M-step without actually completing a full maximization. The GEM algorithm weakens the requirement of maximizing $Q(\phi, \phi^{(t)})$ with respect to ϕ to a requirement of finding $\phi^{(t+1)}$ such that $Q(\phi^{(t+1)}, \phi^{(t)}) \geq Q(\phi^{(t)}, \phi^{(t)})$.

The expectation conditional maximization (ECM) algorithm [11] is a GEM algorithm for multivariate parameter problems which replaces the maximization of $Q(\phi, \phi^{(t)})$ with respect to ϕ with a series of conditional maximizations with respect to components of the ϕ vector. The multicycle ECM algorithm [11] is a variant of the ECM algorithm that maximizes only with respect to a subset of the components of the ϕ vector between E-steps; the multicycle ECM algorithm can converge faster or slower than the ECM algorithm.

The **Monte Carlo** expectation maximization (MCEM) algorithm [12, 13] approximates the expectation calculation in the E-step with a Monte Carlo estimate of

$$Q(\phi, \phi^{(t)}) \approx \frac{1}{S} \sum_{s=1}^S \log p(\mathbf{x}, \mathbf{z}^{(s)} | \phi) \quad (5)$$

where $\mathbf{z}^{(s)}$ are samples from $p(\mathbf{z} | \mathbf{x}, \phi^{(t)})$.

The stochastic expectation maximization (SEM) algorithm [14] for mixture models can be viewed as a special case of the MCEM algorithm with $S = 1$.

The alternating expectation conditional maximization (AECM) algorithm [15] is an extension of the ECM algorithm that allows for different definitions of the complete data at some of the conditional M-steps; this approach is advantageous in many latent variable modeling situations.

McLachlan and Krishnan [4] provide extensive details of further extensions of the EM algorithm, with an emphasis on algorithms that accelerate the EM convergence. Lange *et al.* [16] and Hunter and Lange [17] show that the EM algorithm fits into a larger class of optimization algorithms which use majorization techniques.

Implementation of the EM Algorithm

Finite mixture models provide an example of a framework in which the use of the EM algorithm is particularly advantageous. Mixture models arise in reliability analysis where failures occur due to multiple causes (e.g., [18, 19]). Extensive reviews of mixture models and their applications are given by Everitt and Hand [20], Titterton *et al.* [21], McLachlan and Basford [22], and McLachlan and Peel [10].

A finite mixture model uses a finite collection of K components to construct a model; in reliability analysis, these could be K different modes of failure. It is assumed that the probability of mixture component k is π_k – these values are called *mixing proportions*. In addition, an observation x_i from mixture component k has a probability density $p(x_i | \theta_k)$, where θ_k denotes unknown model parameters. Hence, the resulting model with parameter $\phi = (\underline{\pi}, \underline{\theta})$ for a single observation x_i is

$$p(x_i | \phi) = p(x_i | \underline{\theta}, \underline{\pi}) = \sum_{k=1}^K \pi_k p(x_i | \theta_k) \quad (6)$$

that is, a K -component mixture model.

Directly finding MLEs of the parameters in the mixture model is complicated because the likelihood function involves a product of terms of the form equation (6). However, the use of the EM algorithm allows for relatively straightforward model fitting for many component models, $p(x_i | \theta_k)$.

Finite mixture models can be formulated as having the component membership labels for each observation as missing data. Maximization of the likelihood function is simplified by augmenting the data to include the missing membership labels for each observation. Furthermore, the EM algorithm provides estimates not only of the model parameters but also of the unknown component memberships of the observations.

Suppose we have observed data $\mathbf{x} = (x_1, x_2, \dots, x_M)$ that have arisen from a K -component mixture model. The term *complete* data refers to the combination of both the observed data and the missing membership variables. The complete data is denoted by $(\mathbf{x}, \mathbf{z}) = \{(x_1, z_1), (x_2, z_2), \dots, (x_M, z_M)\}$, where

$$z_i = (z_{i1}, z_{i2}, \dots, z_{iK}) \quad \forall i = 1, \dots, M \quad (7)$$

with

$$z_{ik} = \begin{cases} 1 & \text{if observation } x_i \text{ belongs to component } k \\ 0 & \text{otherwise} \end{cases}$$

That is, the missing data z_i is an indicator of the component membership of observation x_i . On convergence of the EM algorithm, the estimated values of z_{ik} are the estimated conditional probabilities of observation x_i belonging to component k .

Under a finite mixture model, the complete data log-likelihood is formulated as follows. The density of the observed data is

$$p(\mathbf{x}|\underline{\theta}, \underline{\pi}) = \prod_{i=1}^M \sum_{k=1}^K \pi_k p(x_i|\theta_k) \quad (8)$$

Accounting for the missing component membership labels $\mathbf{z}$, it follows that the complete data likelihood is

$$p(\mathbf{x}, \mathbf{z}|\underline{\theta}, \underline{\pi}) = \prod_{i=1}^M \prod_{k=1}^K \{\pi_k p(x_i|\theta_k)\}^{z_{ik}} \quad (9)$$

The EM algorithm involves two steps, an E-step followed by an M-step. The E-step involves calculating the expectation of the complete data log-likelihood. Since the complete data log-likelihood is linear in the missing variables, the E-step simply replaces each z_{ik} by its expected value. The M-step then proceeds to maximize the expected complete data log-likelihood to estimate the model parameters.

Specifically, the EM algorithm proceeds as follows:

1. Initialize: Choose starting values for $\underline{\pi}^{(0)}$ and $\underline{\theta}^{(0)}$. Let $t = 0$.
2. E-step: Compute

$$\hat{z}_{ik}^{(t)} = \frac{\pi_k^{(t)} p(x_i|\theta_k^{(t)})}{\sum_{k'=1}^K \pi_{k'}^{(t)} p(x_i|\theta_{k'}^{(t)})} \quad (10)$$

for $i = 1, \dots, M$ and $k = 1, \dots, K$ where $\hat{z}_{ik}^{(t)}$ is the estimated posterior probability of observation x_i belonging to component k .

3. M-step: Maximize the complete data log-likelihood function

$$\sum_{i=1}^M \sum_{k=1}^K \hat{z}_{ik}^{(t)} \{\log \pi_k + \log p(x_i|\theta_k)\}$$

to yield new parameter estimates $\underline{\pi}^{(t+1)}$ and $\underline{\theta}^{(t+1)}$. Increment t by 1.

4. Convergence: Repeat the E-step and M-step until convergence (see the section titled ‘‘Convergence Diagnostics’’). The final parameter values are the MLEs $\hat{\underline{\pi}}$ and $\hat{\underline{\theta}}$.

Finite Mixture of Exponentials

The finite mixture of exponential distributions can be used to model data that has multiple modes of failure [18]. Suppose that there are K modes of failure which occur with probabilities $\pi_1, \pi_2, \dots, \pi_K$. In addition, suppose that lifetimes of components within each mode of failure are modeled using an exponential distribution with mean θ_k . Hence, the data are modeled using a finite mixture of exponentials, that is,

$$p(x_i) = \sum_{k=1}^K \pi_k p(x_i|\theta_k) = \sum_{k=1}^K \frac{\pi_k}{\theta_k} \exp\left(-\frac{x_i}{\theta_k}\right) \quad (11)$$

Let z_{ik} be an indicator for the unknown mode of failure of item i . The joint density of the complete data (x_i, z_i) is

$$p(x_i, z_i) = \prod_{k=1}^K \left\{ \frac{\pi_k}{\theta_k} \exp\left(-\frac{x_i}{\theta_k}\right) \right\}^{z_{ik}} \quad (12)$$

The EM algorithm proceeds as follows:

1. Initialize: Choose starting values for $\underline{\pi}^{(0)}$ and $\underline{\theta}^{(0)}$. Let $t = 0$.

4 Expectation Maximization Algorithm

2. E-step: Compute

$$\hat{z}_{ik}^{(t)} = \frac{(\pi_k^{(t)} / \theta_k^{(t)}) \exp(-x_i / \theta_k^{(t)})}{\sum_{k'=1}^K (\pi_{k'}^{(t)} / \theta_{k'}^{(t)}) \exp(-x_i / \theta_{k'}^{(t)})} \quad (13)$$

for $i = 1, \dots, M$ and $k = 1, \dots, K$.

The current value of the log-likelihood can be calculated as

$$l^{(t)} = \sum_{i=1}^M \log \left\{ \sum_{k=1}^K \frac{\pi_k^{(t)}}{\theta_k^{(t)}} \exp \left(-\frac{x_i}{\theta_k^{(t)}} \right) \right\} \quad (14)$$

which only uses terms required for computing $\hat{z}_{ik}^{(t)}$.

3. M-step: Maximize the complete data log-likelihood function

$$\sum_{i=1}^M \sum_{k=1}^K \hat{z}_{ik}^{(t)} \left\{ \log \pi_k - \log \theta_k - \frac{x_i}{\theta_k} \right\}$$

to yield new parameter estimates

$$\pi_k^{(t+1)} = \frac{\sum_{i=1}^M \hat{z}_{ik}^{(t)}}{M} \text{ and } \theta_k^{(t+1)} = \frac{\sum_{i=1}^M \hat{z}_{ik}^{(t)} x_i}{\sum_{i=1}^M \hat{z}_{ik}^{(t)}} \quad (15)$$

Increment t by 1.

4. Convergence: Repeat the E-step and M-step until convergence. The final parameter values are MLEs $\hat{\pi}$ and $\hat{\theta}$.

Properties

Convergence

The EM algorithm is a linearly convergent algorithm in the neighborhood of the MLE, that is,

$$\|\phi^{(t+1)} - \hat{\phi}\| < a \|\phi^{(t)} - \hat{\phi}\| \quad (16)$$

for some value $a < 1$. Other iterative optimization methods (e.g., Newton–Raphson) have quadratic convergence, that is,

$$\|\phi^{(t+1)} - \hat{\phi}\| < a \|\phi^{(t)} - \hat{\phi}\|^2 \quad (17)$$

for some $a < 1$. Hence, one criticism of the EM algorithm is its slow convergence rate. However, the EM algorithm is very stable and for many problems it involves simple calculations; for many problems it does not involve computing and inverting a Hessian matrix (in contrast to Newton–Raphson). Hence, the EM algorithm is still used for a wide variety of problems where faster alternatives exist.

Standard Errors

Early criticisms of the EM algorithm focused on the fact that the algorithm does not automatically produce standard errors (or an approximate **covariance** matrix of the MLEs). However, McLachlan and Krishnan [4] and McLachlan and Peel [10] detail methodologies that provide approximate standard errors of parameter estimates derived during an EM algorithm. In particular, they demonstrate ways in which the observed information matrix may be calculated within the EM framework.

The observed information matrix could be directly estimated after convergence of the EM algorithm, but in general evaluation of the second-order derivatives of the log-likelihood is cumbersome. However, the observed information matrix can be expressed in terms of derivatives of the complete data log-likelihood which are introduced within the EM algorithm.

McLachlan and Krishnan [4] deal with the particular case of independent data where standard errors can be produced without additional work beyond the necessary EM algorithm calculations. Meilijson [23] defines the *empirical* observed information matrix which can be expressed in terms of the score functions of the complete data log-likelihood. Thus the empirical observed information matrix can be constructed from the final estimates produced by the EM algorithm. Computation of second-order partial derivatives is therefore avoided. The covariance matrix of $\hat{\phi}$ is then approximated by the inverse of the empirical observed information matrix.

Dynamic Programming Methods in Repair and Replacement

Introduction

In this article, we focus on the usefulness of dynamic programming (DP) ideas and methods in the study of repairable systems with a specific emphasis on replacement and other repair strategies. After an overview of early work in this area, which concentrated on optimal planned replacement of stochastically failing equipment, we briefly survey later development on different formulations of more pragmatic repair schemes that have been proposed over the years, as a prelude to demonstrating how different notions of imperfect repair can be encompassed in a unified stochastic DP setting.

The name *dynamic programming* was coined by Richard Bellman as a shorthand description of a body of theory and methods for solving optimization problems in multistage decision processes, illustrated in his now classic book [1]. Such problems are typically characterized by a system described *via* proxy variables (*system states*) that change (undergo deterministic or, stochastic *transitions*) as a result of decisions (*actions*) chosen from a set of available options. Corresponding to each transition is a reward or, penalty (negative reward) which depends on the chosen action associated with the transition as well as the system state before and/or after the transition. This describes a typical stage of the multistage process, which is then repeated in the next stage. The planning horizon of a DP problem is the finite or infinite number of stages for which decisions on the choice of actions have to be made. A policy, or, strategy is any well-defined rule to determine the choice of actions based possibly on the system's past history to date. The goal is to maximize the value (expected value, under stochastic regimes) of the stream of rewards over the entire planning horizon, and identify strategies which achieve, or nearly achieve the optimum value function. The "value" of a reward stream is usually defined as the total cumulative reward with or without discounting. In some problems, the average reward per unit time is considered as an alternative value function.

Such optimization problems over a finite, or infinite horizon is conceptually equivalent to finding the global maximum of an objective function with respect to a large number of variables – a task that is often fraught with analytical as well as computational difficulties, referred to collectively as the *curse of dimensionality*. Bellman's basic simplifying idea, embodied in his celebrated "principle of optimality" was to break down the problem into one of sequential choices, which together with backward induction can routinely solve the optimization problem when the planning horizon and the set of available actions are both finite. Over the years, these methods have correspondingly found extensive use in many application areas in engineering and operations research. Subsequently, in a series of papers, Blackwell [2, 3] and Strauch [4] set the original ideas of Bellman on a firm theoretical foundation, including a general (and not problem specific) proof of Bellman's principle of optimality, that covers both finite and infinite horizon problems. It is this conceptual framework on which rests much of our following discussions on DP formulations of repairable systems. It is important to remark at this point that a DP formulation to describe the temporal evolution of a system can be a useful vehicle for its modeling and analysis even when there is no choice of actions to be made; i.e., when there is no explicit optimization task at hand, as our discussions in the section titled "Illustrative Applications" will illustrate.

The basic premise of the importance of repairs, apart from generally lesser costs compared to replacement, is that it allows the reuse of equipment, even though such repaired equipment will typically have altered reliability characteristics compared to the original as a result of repair – as reflected in the distribution of postrepair survival times. Contemporary concerns about finite environmental resources further underscores the importance of such "recycling" of equipment and systems. Additionally, there may be economic incentives for considering replacement or, less than perfect repair options, since such repairs are typically less costlier than replacement. The impact of a repair strategy to maintain an equipment is reflected in the point process of failures as it evolves over time. In applications, the effectiveness of a repair strategy is determined by appropriate objective functions that are statistical functionals of the underlying failure process. Examples of such objective functions are (a) the expected number of failures/repairs over a given

time interval, (b) the total expected costs/benefits of a repair scheme, and so on. It is here in the modeling and analysis of the effectiveness of such repairs that DP ideas and methods can be fruitfully exploited.

To the best of our knowledge, as of today, there is no standard commercial or, open-source general-purpose DP software that would allow users to conveniently specify and solve arbitrary DP problems. Instead, the most common and fruitful approach to the computational implementation of DP solutions to real-world problems appears to be developing application-specific DP software. In our search for DP software on repair and replacement, we came across only one such modular software “CompEcon (toolbox for MATLAB)” which includes solvers for discrete-time/discrete, or continuous variable DP problems, and was developed to accompany a book by Miranda and Feckler [5]. The “CompEcon Toolbox” can be found at <http://www4.ncsu.edu/~pfackler/compecon/toolbox.html>. A similar search for a general purpose DP software, led us to “dProg”, a software package for specifying DP algorithms that – given a recursive definition of the problem – generates codes for solving the problem using DP. The “dProg” package, developed by Thomas Mailund, is available as a freeware at <http://www.daimi.au.dk/~mailund/dprog.html>, although it may be of relatively limited use in our context of repairable systems.

The section titled “Early Work, Minimal Repairs, and Other Imperfect Repair Schemes” describes some early work exploiting DP ideas to investigate problems in reliability, followed by a summary of relevant modeling approaches adopted by different authors to address possible notions of imperfect repairs (IRs). It is then shown that these different formulations can be synthesized in a common setting. A general DP formulation for the analysis of a repairable system is then described. Various IR schemes proposed by different authors are then seen to be special cases. The section titled “Illustrative Applications” shows the usefulness of a DP formulation to study repair and replacement problems drawing on some recent work in the literature.

Early Work, Minimal Repairs, and Other Imperfect Repair Schemes

Early Work and Repair-Replacement

The early literature on the system maintenance aspect of reliability naturally focused on replacements as

the analytically tractable option for modeling system repair, since the tools of renewal theory, a well-developed theme in probability, are then immediately applicable. By contrast, attention to modeling other relatively more pragmatic notions of repair had to wait until the 1970s and 1980s. Although not directly related to the theme of repair and replacement, a work by Bellman and Dryfus [6] appears to be the earliest reference we can find of the use of DP methods for maximizing system reliability under given constraints. Another example of such use of DP, unrelated to replacements and repair, is a work by Kettelle [7] on optimum allocation of **redundancy**.

Among the early classic illustrations of the application of DP methods for the analysis of optimal replacement policies are the works by Jorgenson and Radner [8] and Radner and Jorgenson [9]. They consider a series system of $(M + 1)$ independent components, $M \geq 1$, when components $i = 1, 2, \dots, M$ have exponential lifetimes that can be continuously monitored. The remaining other component (component $i = 0$) is assumed only to have a positive density with infinite support, and cannot be inspected except at replacement times. Using a DP formulation, the authors construct an optimal replacement policy, called the (n_i, N) policy, that maximizes the total expected discounted value of time that the system is in good operational state, less costs, and can be described as follows. For $i = 1, 2, \dots, M$, (a) replace component i alone when it fails, if the corresponding age of component 0 is between 0 and n_i , (b) replace components i and 0 together, when component i fails and component 0 has age between n_i and N at that time, and (c) replace component 0 alone, if all components $1, 2, \dots, M$ have survived until component 0 has reached age N . The same policy remains optimal for other alternative criteria such as expected total discounted time in good state, and the ratio of expected total discounted good time to expected total discounted costs.

Work on **replacement strategies** have continued over the years, with researchers addressing different variations on the assumptions regarding failure and repair time distributions, rewards and costs with or without discounting, finite or infinite planning horizon, and the objective function (suitably defined total or long-run average net reward). Chen and Feldman [10] consider optimal replacement policies with **minimal repair** (MR) and age-dependent costs. Also notable among works on the optimal

repair–replacement theme are Lam Yeh [11, 12], Stadjé and Zuckerman [13], and Boshuizen [14]. In particular, Boshuizen’s [14] analysis derives the optimal rules without imposing some reliability theoretic and monotonicity conditions, as employed in Lam Yeh [11, 12] and Stadjé and Zuckerman [13], by solving an optimal stopping problem first in a finite horizon setting, and then extending it to the infinite horizon case.

Barlow and Proschan [15] investigated sequential replacement policies for finite-time horizons in which the next scheduled replacement age depends on the time remaining. They prove that without loss of generality, it is enough to restrict attention to nonrandomized replacement policies, prove the existence of a least-cost sequential policy and demonstrate how to construct them. Although there is no direct reference to DP methods in their arguments, since a formal theory of stochastic DP [2, 3, 4, 16] was still in its relative infancy, such ideas are clearly recognizable from a careful reading of their arguments for optimality.

Minimal Repairs and Other Imperfect Repair Schemes

A repair mode is defined by its effect on the equipment as described by the distribution of its postrepair life. If X is the lifelength of a new unit and L_x denotes the lifelength of an instantaneously repaired unit that failed at age x , then setting $L_x \stackrel{d}{=} X$ defines a *replacement* by a statistically identical copy ($\stackrel{d}{=}$ denoting equality in distribution), whereas $L_x \stackrel{d}{=} X - x | X > x$, the *residual life* at the age x at failure, defines the so-called MR option. A *perfect repair* (PR), by contrast, is defined as a repair that restores an equipment to its original condition, as parameterized by its *age* when it started working prior to the most recent failure. Thus, for a currently failed equipment with failure having occurred at age x (which implies that it last started functioning at some age t satisfying $0 \leq t < x$), a PR is defined by setting $L_x \stackrel{d}{=} X - x | X > x$. Note, a renewal (or replacement) is equivalent to PR only if the currently failed unit was new when it started working.

For most equipments that exhibit some form of aging over time, replacement and MR conceptually represent two extreme positions in terms of the extent to which a failed equipment’s **degradation** is arrested and restored by repairs. The need for considering

more realistic notions of repair, which are in a broad sense intermediate between MR and PR, was mainly voiced by the engineering community, which then led to efforts to formulate alternative notions of IRs. The notions of IR, refer to those repair assumptions that are, in a broad sense, more realistic than the traditional renewal (replacement) hypothesis.

The first IR model was proposed by Brown and Proschan [17]. It underwent a significant and nontrivial extension by Block *et al.* [18]. The Block–Borges–Savits (BBS) model randomizes the choice of repair between a replacement/PR or MR with a probability that is age dependent (choosing a replacement/PR or MR with probabilities $p(x)$ ($1 - p(x)$, respectively), if failure occurred at age x). The Brown–Proschan (BP) model is covered by the BBS model as a special case when $p(x)$ is a constant. Bhattacharjee [19] provided an alternative shock model argument for the distribution of the sojourn time between consecutive PRs, possibly interspersed with a random number of MRs.

Kijima [20] proposed and investigated two models of IR, based on the idea that if an equipment failed at a certain age, after repair, its age is not necessarily restored to the age when it failed (as is the case with MR), but may be different depending on how good or bad the repair is. This effective postrepair age is referred to as the *virtual age*. In Kijima’s models, the virtual age process V_k after the k th failure is linear in V_{k-1} and the lifetime X_k after the $(k - 1)$ st failure (the k th functioning lifetime) such that the slope of V_k depends on the “degree of repair” a assuming values in $[0, 1]$ with $a = 0, 1$ implying PRs and MRs, respectively, whereas intermediate values of $a \in (0, 1)$ reflect varying degrees of repair effectiveness.

Several other virtual age type models, which are basically extensions of Kijima’s models, have been considered by Finkelstein [21], Makis and Jardine [22], and Dagpunar [23]. Virtual age models capture the idea of arresting degradation in performance by system age recovery as a result of repairs. Stadjé and Zuckerman [24, 25] investigate analytical and numerical methods to determine least expected discounted cost age-dependent repair strategies that allow for varying degrees of repair over an infinite planning horizon. Guo *et al.* [26], in a review article, provide a summary of various virtual age models and provide references to work on optimal repair and replacement policies based on such models.

4 Dynamic Programming Methods in Repair and Replacement

A Unified Setting for Imperfect Repair (IR) Models

Bhattacharjee [27] argued that a reasonable way to conceptualize the effect of a given repair mode or action a is to make the repaired unit have an effective *virtual age* Y after repair, whose distribution A_z^a depends on the repair mode a and the age z at failure. Thus, if $L_{z,a}$ denotes the postrepair life after instantaneous repair using repair mode a on failure at age z , the effect of repair is defined by the postrepair survival probability,

$$P\{L_{z,a} > t\} := E\bar{F}_Y(t) = \int_0^\infty \bar{F}_y(t) A_z^a(dy) \quad (1)$$

where $\bar{F}_y$ is the tail of the distribution of the *residual life* at age y , given by $\bar{F}_y(x) = \bar{F}(x+y)/\bar{F}(y)$. Two repair modes a, a' such that $L_{z,a} \stackrel{d}{=} L_{z,a'}$, all $z \geq 0$, are equivalent ($a \sim a'$), as their effects on equipment degradation cannot be distinguished.

The *virtual age* idea was also considered by Baxter *et al.* [28] to study the interfailure time distribution

$$B(t) = \int_0^\infty F_Y(t) P(dy) = E_P F_Y(t) \quad (2)$$

with P governing the distribution of the virtual age after repairs. Bhattacharjee's [27] formulation in equation (1) corresponds to parameterizing the virtual age distribution as $P \equiv A_z^a$, leading to the distribution of postrepair life. If $P(Y = z) = A_z^a\{z\} < 1$, we may interpret the value of effective postrepair virtual age Y of the unit which failed at age z , as the difference between the degree of effort needed for a PR *versus* the actual repair effort measured in units of operating time.

Starting with a unit (of age $x \geq 0$), which then fails at age $z(\geq x)$, it follows that the distribution of the postrepair survival times under PR, MR, BP, and BBS repair modes are given by,

$$P\{L_{z,a} > t\} = \begin{cases} \bar{F}_x(t), & a := \text{PR} \\ \bar{F}_z(t), & a := \text{MR} \\ p\bar{F}_x(t) + q\bar{F}_z(t), & a := \text{BP} \\ p(z)\bar{F}_x(t) + q(z)\bar{F}_z(t), & a := \text{BBS} \end{cases} \quad (3)$$

where F_x denotes the *residual life* distribution at age x , with $F_0 \equiv F$. When the MR option is chosen in the BP and BBS models, note that the additional age accumulated at the most recent failure is $z - x \geq$

0; setting $S := F_x$, it follows that the postrepair life distribution, conditional on the choice of MR, is

$$\begin{aligned} \bar{S}_{z-x}(t) &= \frac{\bar{S}(z-x+t)}{\bar{S}(z-x)} \equiv \frac{\bar{F}_x(z-x+t)}{\bar{F}_x(z-x)} \\ &= \frac{\bar{F}(z+t)}{\bar{F}(z)} = \bar{F}_z(t) \end{aligned} \quad (4)$$

justifying equation (3). Note also that, if the currently failed unit began working as a new equipment ($x = 0$), then a PR in equation (3) corresponds to a replacement. As a general formulation of the notion of *IR*, equation (1) is sufficiently flexible to allow different variations by suitably choosing the virtual age distribution A_z^a . Such choices can include nonparametric constraints on the postrepair life distribution, such as specifying (a) *maximum allowable improvement in virtual age*: $0 \leq A_z\{0\} < 1$ and/or, $A_z(0, \epsilon) = 0$, for some $\epsilon > 0$, (b) *a limit on maximum possible degradation*: $A_z(z+L, \infty) = 0$, $L > 0$; i.e., virtual age after repair is at most an additional L over the age at failure, or (c) *specify a best/worst case scenario for the mean virtual age*: the expected virtual age after repair is no more than (at least, respectively), the age at failure $\int_0^\infty y A_z(dy) \leq (\geq) z$.

A Dynamic Programming Framework for Repairable Systems

The DP model described below is based on Bhattacharjee [27], drawing on the foundations of a theory of stochastic DP developed by Blackwell [2, 3] and Strauch [4]. The *states* s of the system are defined by a pair $s = (t, x)$, where

t = remaining clock-time, for a given time horizon,

x = *virtual age* of the unit, which starts functioning at t

The set $S = \{(t, x) : x \geq 0\}$ is the state space and the states of the system correspond to those time epochs, when a unit starts working, possibly after a repair. The subset $S^* = \{(t, x) : x \geq 0, t \leq 0\}$ is the set of *trap states* in the sense that the process ends on entering S^* . (For an infinite time horizon, it is simpler to define the system's state s as the virtual age x of the unit at those time epochs when the unit starts working.) A repair *action* is a repair mode

that one can implement with its effect on postrepair life described by equation (1). The set of available choices of repair actions a is $A = \{a : a \in A\}$.

Let $T_x \stackrel{d}{=} X - x \mid X > x \sim F_x$ denote the residual life at age x ($T_0 \stackrel{d}{=} X \sim F$). Note also that if we start with an unit of age x (i.e., at a state $(\cdot, x)$), its time to next failure is T_x with distribution function (d.f.) F_x , and *not* F . When we choose a repair action $a \in A$ at a state $s = (t, x) \notin S^*$, our system moves to a new state s' , possibly depending on $(s \equiv (t, x), a)$, according to the transition scheme:

$$s = (t, x) \xrightarrow{a} s' = (t - T_x, V_{x,a}) \quad (5)$$

where the repaired unit's virtual age $V_{x,a}$ depends on its age x when it last began functioning and the repair mode a executed when it subsequently failed. Thus, the conditional probability distribution $q(ds' \mid (s, a))$, governing the transition in equation (5) is determined by the joint distribution of $(T_x, V_{x,a})$. The particular form of the virtual age $V_{x,a}$ in turn depends on the chosen repair action a ; e.g.,

$$V_{x,a} = \begin{cases} 0, & \text{for } a = \text{Replacement} \\ x, & \text{for } a = \text{PR} \\ x + T_x, & \text{for } a = \text{MR} \\ x + aT_x, & \text{Model I (Kijima), } 0 \leq a \leq 1 \\ a(x + T_x), & \text{Model II (Kijima), } 0 \leq a \leq 1 \end{cases} \quad (6)$$

where $a \in A = [0, 1]$ reflects the “degree of repair” in Kijima’s models [20]. Here, increasing values of a represent progressively worse quality of repair. When $a = 1$, both models of Kijima reduce to MR. By contrast, $a = 0$ represents a PR in Model I, but a replacement in Model II.

A *repair strategy* is a sequence $\pi = \{\pi_1, \pi_2, \dots\}$ that spells out a sequential plan of repair actions to choose after each failure, possibly based on the past history. Formally, the choice of repair after the n th failure is governed by π_n , a conditional distribution on the available set A of repair actions, given the past history $(s_1, a_1 \dots s_{n-1}, a_{n-1}, s_n)$ of failures and repairs. Note that, based on our formulation of the state space, a repair strategy need only specify each π_n when the most recent state $s_n \notin S^*$.

Among the simpler strategies, which are intuitively appealing, are Markovian and/or stationary ones. A strategy $\pi = \{\pi_n, n \geq 1\}$ is Markovian if each π_n is a regular conditional distribution on the

set of repair actions A , given the state at the most recent failure. If each π_n is degenerate, i.e., if $\pi_n \equiv f_n : S \mapsto A$; then $\pi = \{f_n, n \geq 1\}$ is a *nonrandomized Markov* repair strategy. If $f_n \equiv f : S \mapsto A$ is time-homogeneous, then $\pi := f^\infty \equiv \{f, f, \dots\}$ is a *nonrandomized stationary* strategy of repairs.

To illustrate some of the IR repair modes and the corresponding repair schemes considered in the literature, described in the section titled “Early Work, Minimal Repairs, and Other Imperfect Repair Schemes”, as repair strategies in a DP framework; let 0 and 1 denote a PR and an MR mode, respectively. If $A = \{1\}$, then the only available strategy is “forever minimal repairs” (FMR): $\pi = 1^\infty$. Similarly, if $\{0, 1\} \subset A$, then available choices include the age-dependent BBS repairs, as the randomized stationary strategy $\pi := \pi_1^\infty$, where

$$\begin{aligned} \pi_1(\{0\} \mid (t, x)) &= p(T_x), \\ \pi_1(\{1\} \mid (t, x)) &= 1 - p(T_x); \quad (t, x) \notin S^* \end{aligned} \quad (7)$$

noting that the age of the currently failed unit, which started working as a possibly old unit of age x , is $T_x \stackrel{d}{=} X - x \mid X > x$. The Brown–Proschan (BP) repair scheme corresponds to the special case of the BBS strategy when $p(\cdot) \equiv p$ with $0 < p \leq 1$. The case $p \equiv 1$ is the strategy of “forever perfect repairs” (FPR), which is equivalent to a strategy of replacements when the process starts with a new equipment. This equivalence is clear by noting that while replacement by a new copy of the failed equipment is technically an option that is distinct from PR; setting $x = 0$ in the stochastic transition for a PR option:

$$s = (t, x) \xrightarrow{\text{PR}} s' = (t - T_x, x) \quad (8)$$

the transition corresponding to $x = 0$ (new equipment) is $s = (0, x) \xrightarrow{\text{PR}} s' = (t - X, 0)$, and thus equivalent to a replacement.

Similarly, for various “degree of repair” models considered by Kijima [20] and others; $A = [0, 1]$ parameterizes the degree of repair efforts, as described in equation (6); any repair strategy is a sequence of distributions on the unit interval, given the past.

For a given initial state $s = (t, x)$, a repair strategy π determines a probability P_π on $H := ASAS\dots$, the set of future histories of the system. Rewards between transitions are defined by a

bounded real-valued function r on SAS such that $r(s, a, s')$ is the reward for choosing repair action a , at state s , used to repair the equipment when it fails. The choice of r is determined by our objective. For example, to compute the expected number of failures (repairs) in a time interval $(0, t)$, take $r(s, a, s') = 1$, for all a , if s and $s' \notin S^*$, and $= 0$ otherwise. A history $h = (s \equiv s_1, a_1, s_2, a_2, \dots)$, starting at s , generates a sequential stream of random rewards $r_n := r(s_n, a_n, s_{n+1})$ resulting in a total reward $R := \sum_{n=1}^{\infty} \beta^n r_n$ defined on SH , with a discount factor $\beta \in (0, 1]$ (in the undiscounted case $\beta = 1$). The *return* (total expected reward) of a repair strategy π is

$$I_\pi(s) := E_{P_\pi} R = \int_H R(s, h) P_\pi(dh), \quad s \in S \quad (9)$$

I_π is finite under discounting, or other suitable conditions on r . The *optimal return* is $I^*(s) := \sup_\pi I_\pi(s)$, $s \in S$. An optimal repair strategy π^* , if it exists, is one for which $I_{\pi^*} = I^*$, all $s \in S$.

Illustrative Applications

We give two examples of how the preceding ideas can be employed to investigate repair and replacement problems. It should be emphasized that even if our interest is confined to the analysis of performance of a specific repair strategy, such as the Brown–Proschan (BP) repair scheme, and not in pursuing possible optimality, ideas from DP can often allow us an elegant way to analyze specific repair schemes.

Computing the Sojourn Time to the Next Perfect Repair

In the Brown–Proschan (BP) repair scheme, which defines a stationary randomized repair strategy with constant probabilities p and $(1 - p)$, respectively, of choosing a PR or an MR repair option; suppose that there is a *terminal payoff* $= 1$ on entering the trap states S^* , and that all other payoffs are zero. Beginning with a unit of age x , let T_x^* be the *sojourn time to the next* PR. If $X_1, X_2, \dots$ are the postrepair lives under successive MRs, and the next PR occurs at the τ -th failure ($\tau < \infty$, w.p. 1, if $p > 0$), then the *expected total return* of the BP-repair strategy is clearly,

$$E_{BP} \{1_{\{t - X_1 - X_2 - \dots - X_\tau < 0\}}\} = P_{BP}(T_x^* > t) \quad (10)$$

the tail of the sojourn time distribution to the next PR. To compute the sojourn time tail (equation 10) by using DP ideas, consider an operator L mapping nonnegative bounded functions into itself, such that for $(t, x) \notin S^*$,

$$\begin{aligned} Lu(t, x) &:= pE1_{T_x > t} + qE\{1_{T_x > t} + 1_{T_x \leq t} u(t - T_x, x + T_x)\} \\ &= \bar{F}_x(t) + q \int_0^t u(t - y, x + y) F_x(dy) \end{aligned} \quad (11)$$

and $Lu(t, x) = 1$, if $(t, x) \in S^*$. Then $Lu(t, x)$ is our expected reward if we use the BP repair mode at the first failure after (t, x) and then stop with our terminal payoff $u(\cdot, \cdot)$ at next state. Let $\mathbf{0}$ denote the function which identically vanishes on S . Then, it can be shown that,

Theorem 1 Bhattacharjee [27]

1. L is a contraction.
2. $L^n \mathbf{0}(t, x) \rightarrow P_{BP}(T_x^* > t)$, as $n \rightarrow \infty$.
3. $u^*(t, x) := 1_{(t, x) \in S^*} + 1_{(t, x) \notin S^*} [\bar{F}_x(t)]^p$, is the unique fixed point of L .
4. $P_{BP}(T_x^* > t) = [\bar{F}_x(t)]^p$, for $(t, x) \notin S^*$.

Brown and Proschan's [17] result on the sojourn time distribution follows as a special case of claim 4, with $x = 0$.

Bounding the Renewal Function via Dynamic Programming

Blackwell [29] first pointed out the utility of exploiting DP ideas to derive sharp probability bounds. Renewal functions, which represent the expected number of failures (repairs) under a replacements-only strategy, can be explored using such ideas, to provide sharp bounds on renewal functions under various nonparametric constraints on the failure distribution generating the renewal process.

The renewal function can be viewed as the total expected payoff, in a game against a passive nature, in which the states are points $t \geq 0$ on the half-line, and stochastic transitions are defined by $t \longrightarrow \max(t - X, 0)$, where $X \geq 0$ with df F . The game stops on hitting the origin. Corresponding to this transition, we earn a "reward" $1_{\{X < t\}}$. Corresponding to successive moves dictated by an independent and

identically distributed sequence $X_1, X_2, \dots$ with df F , the total expected payoff is clearly,

$$\begin{aligned} E \left(\sum_{n=1}^{\infty} 1_{\{\sum_{j=1}^n X_j \leq t\}} \right) \\ = E \max \left\{ n : \sum_{j=1}^n X_j \leq t \right\} := M(t) \end{aligned} \quad (12)$$

the renewal function. In the spirit of the section titled “A Dynamic Programming Framework for Repairable Systems”, and the work of Blackwell [29], a method to construct sharp upper bounds to the renewal function was developed by Bhattacharjee [30], by considering an operator U mapping the set of real-valued, nonnegative nondecreasing functions Q , such that $Q(0) = 0$, $Q(\infty) = \infty$, into itself, defined by

$$UQ(t) := F(t) + \int_0^t Q(t-x)F(dx), \quad t \geq 0 \quad (13)$$

to show that,

1. $U^n \mathbf{0}(t) \rightarrow M(t)$ as $n \rightarrow \infty$,
2. U is monotone, and $UQ \leq Q$ implies $M \leq Q$ pointwise,
3. $M(t)$ is the minimal fixed point of U .

The well-known upper bound $M(t) \leq (t/\mu)$ for NBUE (new better than used in expectation) life distributions with a mean μ can be derived as an application of this result, by choosing $Q(t) := t/\mu$. When F has the stronger NBU (new better than used) property, the same method is used by Bhattacharjee [30] to show that

$$F \text{ is NBU implies } M(t) \leq -\ln\{1 - F(t)\}, \quad t \geq 0$$

i.e., the “hazard function” is an improved sharp upper bound for the renewal function under the NBU hypothesis.

One can thus explore the performance of repair strategies for appropriate payoff functions corresponding to state transitions that capture a desired objective function, such as the total expected number of failures (repairs) in a time interval $(0, t)$, starting with a unit of age $x \geq 0$. The corresponding technical issues that must be addressed in such analysis often reduce to finding the minimal solution or, tight bounds to the solution, of an integral equation. Such

an approach can also be used to explore optimal or near-optimal repair strategies. When we superimpose suitable costs (of repair) and rewards between transitions (incomes generated during equipment functioning cycles), and possibly an infinite-time horizon with or without discounting, we then have a corresponding economic optimization problem, for which DP methods are eminently suitable.

Splines and other Metamodels in Reliability Analysis

Introduction

In structural reliability, the limit state function (LSF) defines some measure of performance of a system, by means of a reliability index or probability of failure, to a vector of observed properties of the system. This function might be of very complex form, leading to the use of various approximations to both evaluate it and to fit it to data. In this contribution, the metamodel approach is looked at, in which the use of a relatively simple function to approximate the state function. Four possible examples are looked at and compared: response surfaces (RSs), splines (SPs), **neural networks** (NN), and ordinary kriging (OK). In addition, an optimization procedure for the calculation of the reliability index is presented.

Expressing the LSF in a closed form is often not possible in the reliability analysis of complex systems. In principle, any algorithm used for structural reliability evaluation may be adapted to handle implicit LSFs. However, when the gradients of the LSF are required, which is the case for first-order reliability methods (FORM) and second-order reliability methods (SORM), the performance is affected when direct or analytical differentiation are not available [1–3]. In the latter, system behavior is not included either.

The use of an RS in combination with a simulation method to increase the efficiency is widely spread [3–5]. The main idea is that the response consisting of a complex function of input variables is approximated by a simple function of the input variables. If the RS is capable of handling the system behavior, the reliability analysis can be performed on the RS, instead of using the original problem [2]. Complex system behavior might however not be captured accurately by a low-order polynomial. Ideally, no functional form is preset and a “universal estimator” is used. Therefore, other extensions are proposed, in general called *metamodels* [6, 7].

Techniques employing simulation procedures such as **Monte Carlo** and directional sampling (DS) inherently account for the system behavior. The disadvantage of these techniques is the number of samples – and thus calls to the implicit LSF – to come up with a sufficiently accurate value of the system failure probability. Importance sampling reduces the number of samples to a certain extent, but the overall performance remains far below the performance of FORM or SORM methods.

In the next section possible metamodels are reviewed. In the section titled “Reliability Analysis Framework”, the accompanying reliability analysis framework is presented. In the section titled “Example: A Series System with Four Branches”, an example application is worked out. The conclusions of this contribution are covered in the final section.

Possible Metamodels

Response Surface (RS) – Low-Order Polynomial

In its most general form, the RS consists of a constant, linear, mixed, and quadratic terms [1–5]:

$$g_{MM}(\mathbf{x}) = a_0 + \sum_{i=1}^n a_i x_i + \sum_{i=1}^n \sum_{j \geq i}^n a_{ij} x_i x_j \quad (1)$$

where $g_{MM}(\mathbf{x})$ is the metamodel of the LSF $g(\mathbf{x})$ in which $\mathbf{x}$ is a vector with size $1 \times n$; n the number of random variables defining the problem at hand; and a_0, a_i, a_{ij} the least-square regression coefficients.

Splines (SP)

The piecewise continuous polynomials are based on the thin-plate smoothing SP concept, that is able to deal with multivariate input and a single output – outcome of the LSF [7, 8]. Because of its simple form, evaluation afterward is straightforward. The LSF can be written as follows:

$$g_{MM}(\mathbf{x}) = \sum_{j=1}^{n_{LSFE}} a_j \psi(\mathbf{x} - \mathbf{x}_{c_j}) \quad (2)$$

where a_j : the smoothing SP coefficients ($1 \times n_{LSFE}$); $\mathbf{x}_{c_j}$: the coordinates at which the limit state function evaluation (LSFE) is available ($1 \times n_{LSFE}$); and $\psi(\mathbf{x})$: the thin-plate SP basis function, that equals

$$\psi(\mathbf{x}) = \|\mathbf{x}\|^2 \log(\|\mathbf{x}\|^2) \quad (3)$$

2 Splines and other Metamodels in Reliability Analysis

This thin-plate smoothing SP $g_{\text{MM}}(\mathbf{x})$ is the unique minimizer of the weighted sum

$$sE(g_{\text{MM}}(\mathbf{x})) + (1-s)R(g_{\text{MM}}(\mathbf{x})) \quad (4)$$

with $E(g_{\text{MM}}(\mathbf{x}))$ an error measure and $R(g_{\text{MM}}(\mathbf{x}))$ a roughness measure.

Neural Networks

NN reply to the criteria of a “universal estimator” and therefore offer an interesting perspective [7, 9]. The weighting functions that are the basis of the network are very flexible and adapt to virtually any kind of functional behavior. Therefore, there are no limits as to shape, dimension, singularity, or type of function.

A single neuron k is not capable of describing an arbitrarily relationship in an accurate way. The output of neuron k as a function of the input signals x_i is described as follows:

$$y_k = \varphi \left(\sum_{i=1}^{n_{\text{LSFE}}} w_{k,i} x_i + \theta_k \right) \quad (5)$$

where $x_i (i = 1, \dots, n_{\text{LSFE}})$ are the input signals; $w_{k,i}$: weights; θ_k : bias term; and φ : activating function (often sigmoidal). Multilayer networks are quite powerful. A network of two layers, where the first layer is sigmoid and the second layer is linear, can be trained to approximate any function (with a finite number of discontinuities) arbitrarily well. Different learning rules exist as a procedure for modifying the weights ($w_{k,i}$) and biases (θ_k) of a network [9]. These algorithms use the gradient of the performance function – direction of the steepest descent – to determine how to adjust the weights to minimize the average error between the network outputs and the target outputs. To further increase the convergence speed, quasi-Newton learning rules are applied, such as the Levenberg–Marquardt learning rule. The Hessian – a matrix of second-order derivatives of the performance function – is calculated numerically based on the gradient.

Ordinary Kriging

Preferably an error measure should be linked to the availability of information in the surrounding region. When more information is available in the sample region, the quality of the metamodel will probably be better, compared to other directions or points in which the availability of information is limited. OK provides

an answer to that requirement. OK is widely used to estimate a value at a point ($\mathbf{x}_0$) of a region for which a variogram is known, using data in the neighborhood ($\mathbf{x}_i; i = 1, \dots, n$) of the estimation location [7, 10]:

$$g_{\text{MM}}(\mathbf{x}_0) = \sum_{i=1}^{n_{\text{LSFE}}} w_i g_{\text{LSF}}(\mathbf{x}_i) \quad (6)$$

where $g_{\text{LSF}}(\mathbf{x}_i)$ is the known outcome of the LSF in point $\mathbf{x}_i$; $g_{\text{MM}}(\mathbf{x}_0)$ the estimated outcome in point $\mathbf{x}_0$; and w_i are the OK unit sum weights warranting the unbiasedness. Kriging is the best linear unbiased estimator. The estimation variance equals:

$$\begin{aligned} \sigma_{\varepsilon_0}^2 &= E[(g_{\text{MM}}(\mathbf{x}_0) - g_{\text{LSF}}(\mathbf{x}_0))^2] \\ &= - \sum_{i=1}^{n_{\text{LSFE}}} \sum_{j=1}^{n_{\text{LSFE}}} w_i w_j \gamma(\mathbf{x}_j - \mathbf{x}_i) + 2 \sum_{i=1}^{n_{\text{LSFE}}} w_i \gamma(\mathbf{x}_0 - \mathbf{x}_i) \end{aligned} \quad (7)$$

where $\gamma(\mathbf{h})$ is the semivariogram [10]. To minimize the estimation variance with the constraint of the weights, a Lagrange multiplier (λ) is introduced. The minimized mean-squared prediction error or kriging (or prediction) variance can be rewritten into:

$$\sigma_{\varepsilon_0}^2 = \lambda + \sum_{i=1}^{n_{\text{LSFE}}} w_i \gamma(\mathbf{x}_0 - \mathbf{x}_i) - \gamma(\mathbf{x}_0 - \mathbf{x}_0) \quad (8)$$

OK also is an exact interpolator. In the case in which $\mathbf{x}_0$ corresponds to one of the data points $\mathbf{x}_i$ in which the outcome is known, the estimated outcome will be identical to the outcome of the LSF. In all other cases a direct measure of the prediction error is obtained. The semivariogram $\gamma(\mathbf{h})$ represents the spatial correlation between the available data points. The success of the kriging procedure very much depends on the knowledge of the semivariogram. Furthermore, to be able to solve the set of equations, the semivariogram has to be positive definite.

Reliability Analysis Framework

The goal of this section is to calculate the reliability index or failure probability in an optimal way, in combination with the building of the metamodel. Therefore, this is performed, parallel with the construction of the metamodel. Therefore, in Step 1, a limited number of experiments are performed, for

which the outcome is calculated based on the real LSF. In Step 2, the initial metamodel is estimated. In Step 3, which is an iterative step, the procedure is repeated until a sufficiently accurate result is obtained.

Building a metamodel and performing the reliability analysis on the metamodel instead of the real LSF, might be a shift of effort. The number of LSFs required to build an accurate metamodel might be equally large. Therefore, an adaptive scheme is applied, that has three main steps that are described below ([11, 12], Figure 1):

- **Step 1**

The value of each random variable is increased individually until the root ($\lambda_{LSF,i}$) of the limit state

is found in the standard normal space, u -space (uncorrelated multivariate space, in which all random variables have zero mean and standard deviation equal to one). First a linear estimate is calculated, based on the outcome in the origin of the u -space (standard normal space) $(0, 0, 0, \dots, 0)$ and the point $(0, 0, \dots, \pm \beta_0, \dots, 0)$. When known, the start value β_0 is set equal to the expected reliability index β . Experience shows that $\beta_0 = 3$ performs well too. Further approximations are based on a piecewise continuous polynomial fit of second-order through the outcome of the different iteration points. Generally after three to four iterations the root is found. As a result an initial set of data is available linking the input variables with the corresponding output using the initial LSF. This initial dataset is used in Step 2.

Figure 1 Different steps in the reliability framework

• Step 2

An initial metamodel (RS, SP, NN, OK) is fit through the data. Depending on the type of metamodel, different techniques are used to fit the metamodels: **least squares** in the case of RS; minimizing a weighted function with an error measure and roughness measure in the case of SP [8]; through the estimated semivariogram in the case of OK minimizing the estimation variance introducing a Lagrange multiplier; and one of the several learning rules available in case of NN, such as the quasi-Newton learning rule called *Levenberg–Marquardt*.

• Step 3

The metamodel is adapted and the reliability index is updated in an iterative procedure until the required accuracy is reached. Therefore, coarse DS or importance sampling Monte Carlo (ISMC) is performed on the metamodel. If the sample or its outcome is judged to be outside the important region, then the outcome based on the metamodel is used. If, on the other hand, the sample or its outcome is in the important region, a new LSFE is performed. The metamodel is updated as soon as new data are available.

Directional Sampling – Distinction between Important and Unimportant Regions

In the iterative procedure, Step 3, crude DS is performed on the metamodel. It is proved that the expected value $E(\hat{p}_f)$ of all contributions ($\hat{p}_i$) is an

unbiased estimate of the global failure probability (p_f) [13]:

$$p_f = E(\hat{p}_f) = \frac{1}{N} \sum_{i=1}^N \hat{p}_i \text{ with } \hat{p}_i = \chi_n^2(\lambda_{MM,i} \text{ or } \lambda_{LSF,i}) \quad (9)$$

For each sample, a first estimate of the distance $\lambda_{MM,i}$ to the origin in the standard normal space, u -space, is made based on the metamodel. An additional distance λ_{add} is used to make distinction between important and less important directions: $\lambda_{MM,i} < \lambda_{min} + \lambda_{add}$, in which λ_{min} is the minimum distance found so far, Figure 2(a). In case of a low-order RS, SP, or NN, a global error measure is used. The additional distance (λ_{add}) is based on the difference between the root of the real LSFE ($\lambda_{LSF,i}$) and the root of the metamodel ($\lambda_{MM,i}$) in the sample direction. A 99% **confidence interval** is taken as measure for λ_{add} :

$$\lambda_{add} = \max\{\text{abs}(\mu(\varepsilon_{rt}) \pm t_{0.01, n_{rt}-1} \times \sigma(\varepsilon_{rt}))\} \text{ with} \\ \varepsilon_{rt,i} = \lambda_{LSF,i} - \lambda_{MM,i} \quad (10)$$

When a good agreement is found between the roots of the real LSF and the metamodel, a low value of the additional distance (λ_{add}) is obtained; in other cases the distance will be larger.

In the case of OK, a local error measure is used. The kriging variance can be calculated for the point $\mathbf{x}_0$ in which the outcome is estimated, equation (11).

Figure 2 Additional distance (a) in the input space (λ_{add}) and (b) in the outcome space ($\Delta_{g,add}$)

Again a 99% confidence interval is taken as measure for λ_{add} :

$$\lambda_{\text{add}} = t_{0.01, n_{\text{LSFE}}-1} \times \sigma_{\varepsilon_i} \quad (11)$$

When data points are available in the neighborhood, the prediction error (σ_{ε}) and additional distance (λ_{add}) will be small. When the region is lacking information, the prediction error (σ_{ε}) and thus additional distance (λ_{add}) will be large. The higher the additional distance, the more LSFEs are performed. In case the obtained root ($\lambda_{\text{MM},i}$) has a relatively high contribution – $\lambda_{\text{MM},i} < \lambda_{\text{min}} + \lambda_{\text{add}}$ – to the estimated global failure probability (p_f), the root of the real response is used instead of the RS: $\lambda_{\text{LSF},i}$. The metamodel and the additional distance (λ_{add}) are updated with these new data. In case the contribution is less important – $\lambda_{\text{MM},i} > \lambda_{\text{min}} + \lambda_{\text{add}}$ – the contribution based on the root of the metamodel ($\lambda_{\text{MM},i}$) is used, avoiding time-consuming LSFEs.

Importance Sampling Monte Carlo – Distinction between Important and Unimportant Regions

Step 3 in the analysis can be performed using ISMC on the metamodel as well [11, 12]. Again, the expected value $E(\hat{p}_f)$ of all contributions ($\hat{p}_i$) is an unbiased estimate of the global failure probability (p_f) [13]:

$$p_f = E(\hat{p}_f) = \frac{1}{N} \sum_{i=1}^N \left\{ I[g(\mathbf{v}_i) < 0] \frac{f_{\mathbf{x}}(\hat{\mathbf{v}}_i)}{h_{\mathbf{v}}(\hat{\mathbf{v}}_i)} \right\} \quad (12)$$

The efficiency is believed to be comparable. To distinguish the important from the nonimportant region, the magnitude of the outcome values is checked. When the values are small, $g_{\text{MM},i} < \Delta_{g,\text{add}}$, the sample is believed to be near the limit between safe and unsafe, Figure 2(b). In that case the outcome is recalculated on the basis of the LSF. This only requires a single LSFE. The data are used to update the metamodel, the sampling function (variance) and the additional distance in the outcome space ($\Delta_{g,\text{add}}$).

Again, in the case of a low-order RS, SP, or NN, a global error estimate is used. The additional distance in the outcome space is related to the error between the metamodel and the LSFE. A 99% confidence interval is preset:

$$\Delta_{g,\text{add}} = \max\{\text{abs}(\mu(\varepsilon_g) \pm t_{0.01, n_{\text{LSFE}}-1} \times \sigma(\varepsilon_g))\} \text{ with} \\ \varepsilon_{g,i} = g_{\text{LSF},i} - g_{\text{MM},i} \quad (13)$$

In the case of OK, a local error measure is used, based on the kriging variance that can be calculated for the point $\mathbf{x}_i$ in which the outcome is estimated, equation (11). Again a 99% confidence interval could be chosen as measure for the additional distance in the outcome space $\Delta_{g,\text{add}}$:

$$\Delta_{g,\text{add}} = t_{0.01, n_{\text{LSFE}}-1} \times \sigma_{\varepsilon_i} \quad (14)$$

Example: A Series System with Four Branches

The LSF, often treated as a benchmark example in literature [11, 12] reads as follows (see also Figure 1):

$$g = \min \begin{cases} 3.0 + 0.1(u_1 - u_2)^2 - (u_1 + u_2)\sqrt{2} \\ 3.0 + 0.1(u_1 - u_2)^2 + (u_1 + u_2)\sqrt{2} \\ (u_1 - u_2) + 3.5\sqrt{2} \\ (u_2 - u_1) + 3.5\sqrt{2} \end{cases} \quad (15)$$

Both random variables (u_1, u_2) are standard normal distributed random variables. The different branches have comparable contribution to the system failure probability. The results of the reliability analysis are summarized in Table 1. For comparison, the random sampling is started from the same seed in each analysis. The following information is given in the subsequent rows: the used simulation procedure (DS or ISMC), the metamodel used (none, RS, SP, NN, OK), the resulting system reliability index (β) and corresponding failure probability (p_f), the required number of sample directions or points (N), n_{LSFE} and the additional distance in the standard normal space or outcome space λ_{add} (for DS) or $\Delta_{g,\text{add}}$ (for ISMC) respectively at the end of the analysis.

The different techniques all result in a good estimate of the system reliability index. Some differences in efficiency are apparent:

- (Crude) DS offers an optimal solution method because of the nearly radial shape of the LSF at hand. This results in a lower number of samples (N) as well as the number of LSFE (n_{LSFE}) compared to procedures using Monte Carlo with importance sampling.
- The low-order polynomial RS is not capable of estimating the real LSF behavior accurately. This can be seen from the relatively high values for λ_{add} (DS) or $\Delta_{g,\text{add}}$ (ISMC), respectively. Of

^(c) SP: splines.

^(d) NN: feed-forward neural network ($2 - n_n - 1$: with n_n the number of neurons in the hidden layer – $n_n = n + n_{\text{LSFE}}/4$; training function: scaled conjugate gradient).

^(e) OK: ordinary kriging.

course, SPs have to work well for this particular example, because the LSF is a kind of piecewise continuous low-order polynomial.

- With respect to OK it is clear that the overall efficiency is similar to SPs and NNs. The number of LSFEs is similar. Both additional distances (λ_{add} and $\Delta_{g,\text{add}}$) did become variable distances (var). For each estimation point, the value is a function of the available information in the neighborhood. Figure 3 illustrates the prediction error in the standard normal space, dependent on the estimation point. Areas in which more information is available will have a small prediction error. In other regions, the prediction error will be higher. In case of RS, SP, or NN, the additional distances are a global error measure of the quality of the metamodel accounting for all

information available at that moment. A linear semivariogram is used to represent the spatial correlation. Although the number of data is insufficient to obtain an accurate fit of the real correlation, the applied semivariogram results in an acceptable efficiency.

Conclusions

This contribution describes a methodology to calculate the reliability of structural systems. The focus is on a methodology that results in an accurate value of the system reliability index, within a limited number of calls to the original LSF. It covers the problem that is often encountered in practice, where the LSF is only specified implicitly. On top of that, several failure modes contribute to the global failure probability.

Therefore, use is made of a procedure based on DS or Monte Carlo with importance sampling and an adaptive metamodel. Using an adaptive metamodel, the LSF is only evaluated if needed. Besides low-order polynomial RSs, the use of SPs, NNs, or OK is incorporated.

On the basis of a benchmark example, their mutual efficiency is discussed. From this example it is evidenced that RSs work well for problems that can be easily described by a low-order polynomial. In case the LSF is more complex, the use of SPs, NNs, and OK is demonstrated to be beneficial. The latter enables local error estimation.

Data Mining, Evaluation Techniques in

Introduction

We use data mining techniques to identify models that facilitate accurate descriptions and predictions of real life processes. We are also typically interested in gaining insights into the underlying process that generates the data. To give an example, banks using data mining techniques to identify fraudulent use of credit cards are not only interested in identifying fraud before authorizing the transaction, but are also interested in being able to communicate to the irate customer why the transaction was declined. Furthermore, they are interested in being able to understand fraud patterns in order to design prevention measures.

Data mining techniques, unlike hypothesis driven approaches, do not justify the model with theorems about the processes that produce the data – such as consumer behavior models or market equilibrium models. Rather, data mining techniques, such as **neural networks**, decision trees, support vector machines, and their bagged or boosted versions, search through the immense space of possible functional forms and parameter values to identify a model that represents the data well; and is useful for the business/science task at hand (*see Data Mining in Quality and Reliability*). Some of these representations are simpler, and thus faster to process, easier to communicate and understand than others.

Therefore, our evaluation criteria for data mining techniques, roughly speaking are (a) the accuracy of the model – which could be tied to cost/benefit implications, and (b) ease of understanding, communicating and processing, which are all correlated with the complexity of the model – where, other things being equal, simpler models are preferred.

For supervised data mining tasks, such as classification and regression, the simplest evaluation method of accuracy is a comparison of the actual values to those predicted by the model. A more accurate model is the one whose predicted results are closer to the actual values. There are however four complicating issues. The first issue is *overfitting*. Models that *memorize* the pattern for each instance in the data will be very accurate for the data sample that was used to build the model, i.e., *the training data*;

but they will not be as accurate when new instances are seen, especially if there is noise or irrelevant features. The sensible remedy is to evaluate the model on data that has not been “seen” by the method; i.e., the *test data*. This brings us to the second issue of typical *scarcity of relevant data*; i.e., data that duly represents all segments, e.g., fraudulent transactions of different types. The third issue is that the *consequences of an inaccuracy* may not be the same. Going back to the fraud detection example, the cost of a fraudulent transaction being honored is arguably higher than a legitimate transaction being denied; further the cost of the fraudulent transaction will depend on its amount. The fourth and final issue is that the process that is generating the data may *evolve over time*. In the case of fraud detection, as old tricks are discovered new ones are developed by the fraudsters.

In this article, we focus on evaluating data mining models after feature selection and parameter **estimation** have already been performed. While evaluation techniques are typically independent of the data mining task, the goodness measures are task specific. For example, misclassification rate is a common goodness measure for classification tasks, but it is not meaningful for regression, clustering, or market basket analysis.

This article is organized as follows. In the next section we introduce the common goodness measures by data mining task along with illustrative examples. In the following section we introduce evaluation techniques. Finally, we provide conclusions and pointers for further reading.

Goodness Measures by Data Mining Task

We consider the following data mining tasks: classification, regression, clustering, associations, and rank prediction.

Classification

For classification tasks, the *misclassification rate*, also called the *error rate*, is the basic measure of goodness of the classification task. It is defined as follows:

$$\text{Misclassification rate} = \frac{\text{Number of misclassified instances}}{\text{Number of all classified instances}} \quad (1)$$

2 Data Mining, Evaluation Techniques in

Table 1 Example dataset with the actual class and predictions by two alternative algorithms

Instance number	Actual class	Prediction by Algorithm 1	Prediction by Algorithm 2
1	A	A	A
2	A	A	B
3	B	B	B
4	B	A	B
5	B	A	B
6	A	A	B
7	B	B	B
8	A	A	A
9	B	B	A
10	A	A	A

The smaller the misclassification rate the better. For example, in Table 1, the misclassification rate is 20% for Algorithm 1 and 30% for Algorithm 2.

The classification is summarized in a *confusion matrix*, to help assess the accuracy for particular classes. The *misclassification cost* is a useful measure when the cost of misclassifying an instance depends on the class the instance belongs. The misclassification cost is calculated by weighing each misclassified instance by the respective misclassification cost. Continuing with the earlier example, Table 2 displays the confusion matrix for Algorithms 1 and 2, as well as the unit misclassification costs: classifying a *B* as *A* is three times as costly as misclassifying an *A* as *B*. Consequently, the misclassification costs are 6 and 5 for Algorithms 1 and 2, respectively. Even though the first algorithm is preferred on the basis of misclassification rate, the second one is more attractive when the misclassification costs are considered.

If the model produces probability estimates for an instance to belong to each class and these estimates are used as an input to a secondary decision mechanism to classify the particular instance, then it makes sense to evaluate how close these estimates are to the actual probabilities. *Quadratic loss* and *informational loss* functions are used for this purpose.

Quadratic loss has well-studied properties in statistics (also known as *mean squared error*), and it is defined as follows:

$$MSE = \sum_i \sum_j (p_{ij} - I_{ij})^2 \quad (2)$$

Here, p_{ij} is the predicted probability that the instance i belongs to class j and I_{ij} takes value 1 if instance i belongs to class j , and 0 otherwise. The square root of *mean squared error* (MSE) is called *root mean squared error* (RMSE).

Informational loss measure has its origins in computer science and is defined as

$$Informational\ Loss = -2 \sum_i \sum_j I_{ij} \log(p_{ij}) \quad (3)$$

Both of these loss measures are minimized for the model that estimates the true probabilities. In fact the informational loss becomes the entropy measure, and the quadratic loss becomes the variance of the underlying data when the model estimates the true probabilities. On the other hand, when the model does not exactly estimate the true probabilities, these two measures may prefer different models. The entropy measure prohibitively penalizes the model that assigns zero probability to the actual class even for a single observation, as it becomes infinity, while the quadratic error has a cap on the loss from a particular observation. Another difference is that under the multinomial case, while the informational loss measure is only affected by the probability assigned to the actual class, the quadratic loss measure is influenced by how the rest of the probabilities are assigned. The quadratic loss measure prefers those models that do not have another strong candidate, i.e., equally distribute the probabilities amongst the nonselected classes.

The *receiver operating characteristic (ROC) curve* is a convenient way of depicting the trade-off between only using the model where it can predict the outcome with a high confidence and thus have a low false positive rate; and using the model to find

Table 2 The confusion matrices for the two algorithms and the misclassification costs

**Figure 1** ROC curve for the example

as many cases of the target class as possible, and but having a higher false positive rate. The former situation corresponds to the bank calling only the most suspicious cases (i.e., those assigned a high probability) a fraud and thus avoids annoyance problems but ending up allowing quite a few fraudulent transactions go undetected. In the latter,

the bank disrupts transactions at the slightest hint of fraud and manages to catch a high proportion of fraudulent transactions, but incurs a high annoyance cost. The illustrative example in Table 3 has 25 instances that are sorted in decreasing order of predicted probability to belong to class A. Figure 1 depicts the associated ROC curve, assuming that the target class is A. The y axis is the true positive percentage (cumulative true positives/total positives) and the x axis is the false positive percentage (cumulative false positives/total negatives). The diagonal corresponds to the performance of the random targeting, i.e., the naïve performance. In general, the larger the area under the curve the better model accuracy.

A close relative of the ROC curve that is used predominantly in targeting applications in marketing is the *lift chart*. The idea is that acting on, e.g., 10% of the cases, we should be catching more than 10% of the positive cases, for the algorithm to be beneficial. Lift is defined as the ratio of the probability of the target class in sample (that we

4 Data Mining, Evaluation Techniques in

act on) to the probability of the target class in the population [1].

$$\text{Lift} = \frac{\text{Cumulative percentage of true positives acted on}}{\text{Cumulative percentage of all cases acted on}} \quad (4)$$

The higher the lift, the better the model performance. We produce the lift chart for the previous example in Figure 2, where the last two columns in Table 3 form the axes. In general, the lift starts high and decreases with larger targeted sample.

Both the lift chart and ROC curve can be used (a) to select a model and (b) to select a cutoff probability to act on an instance; however, they stop short of pointing the optimal model and target sample. The missing piece is the cost of misclassification and the benefit from correct classification, which can be incorporated to these calculations to estimate the expected profit.

Regression

For *regression tasks*, the basic idea of goodness measures is that the actual and the predicted values should be as close to each other as possible. Therefore, low *RMSE* and *mean absolute deviation (MAD)* and *mean absolute percentage error (MAPE)* values are desired. While they all prefer more accurate models, *RMSE* is more sensitive to large errors, and *MAPE* considers the error relative to the size of the prediction. The R^2 which is based on the squared error,

expresses the percentage of the variability explained by the model in a scale of 0–100%.

$$RMSE = \sqrt{\sum_i (e_i)^2 n^{-1}}; MAD = \sum_i |e_i| n^{-1};$$

$$MAPE = \sum_i |e_i| |x_i|^{-1} n^{-1} \quad (5)$$

$$R^2 = 1 - \frac{\sum_i (e_i)^2}{\sum_i (x_i - \bar{x})^2} \quad (6)$$

Here, e_i stands for the error, i.e., the difference between the actual and predicted value, for instance i , x_i is the actual observation value, for instance i , $\bar{x}$ is the average of the actual observation values, and n is the number of observations.

Other measures, such as an information criterion (AIC) proposed by Akaike [2], and Bayesian information criterion (BIC) – also called *Schwarz information criterion (SIC)* [3], measure model accuracy while penalizing models that are more complicated.

$$AIC = -2 \log L + 2k \quad (7)$$

$$BIC = -2 \log L + k \log(n) \quad (8)$$

Here, k is the number of free parameters in the model, and L is the likelihood of the observed data given the model, while n is the number of observations.

Minimum description length (MDL) principle developed by Rissanen [4] seeks to combine measures of model accuracy and model simplicity, and suggests that the best model is the one that provides the shortest description of the data, where the description length resembles the number of digits in a binary string used to code the transmissions [5].

Rank prediction

While *rank prediction tasks* are frequently handled as a scoring task, the implied assumption of equal (or when logs are taken uniformly decreasing) distance between the subsequent instances may be misleading. Other more suitable measures include nonparametric correlation coefficients commonly used in statistics such as the *Spearman's ρ* and *Kendall's τ* [6]. Spearman's ρ is basically the Pearson correlation coefficient applied on the rankings. Kendall's τ represents the difference between the probability

Figure 2 Lift chart for the example

that the observations have the same order and the probability that they are ordered differently, based on the concordant and discordant pairs of predicted and actual values.

Clustering

For *clustering tasks*, the goodness measures used are (a) *within cluster distance* (or variability) and (b) *between cluster distance* (or variability). The R^2 measure defined as the ratio of within cluster variability to between cluster variability combines the two measures. As expected, this measure improves as the number of clusters increases. *MDL* has been suggested as a natural fit for clustering evaluation.

Market Basket Analysis

For *market basket analysis*, or *association tasks*, the evaluation issue is not accuracy, since the result from all algorithms is the same. The relevant goodness measure is processing speed [7].

Evaluation Techniques

To summarize our discussion in the introduction section, evaluation techniques should be able to answer the following questions: how accurate is the model? Does it have repeatable performance over different data sets and over time as the underlying process evolves? Is it just memorizing the data? Is it accurate in situations that are of high importance?

Estimating Performance of Algorithms

The *resubstitution estimate* refers to the evaluation of the model on the training data set. For example, in the earlier example of Table 1, the resubstitution misclassification rate of Algorithm 1 was 20%. The resubstitution estimate, of course, overestimates the true accuracy of the model, since the model's parameters have been optimized to yield minimum misclassification rate on this very sample. In other words, we are not able to evaluate whether and to what extent the model is memorizing the dataset down to the irrelevant facts, i.e., noise, and will misclassify when it is presented a different random sample from the same underlying data generation process.

An unbiased accuracy estimate can be obtained by evaluating the accuracy of the model on a *holdout dataset*, i.e., a representative dataset that was not used for training the model, which includes feature and technique selection and parameter estimation steps. (Especially in **time series** analyzes, models trained on a particular time period are tested on holdout data that is from a more recent time period to evaluate whether the model is still valid.) As the overall dataset is partitioned into training and test data, stratified sampling can be used to ensure representativeness. For classification tasks stratification can be performed in terms of the proportion of classes, while for regression tasks proportion of high/medium/low actual values can be taken as basis.

Representativeness, of course, goes beyond just the response variable, the relationship between the x 's are also of high importance for training the model and for evaluating its accuracy. However, the single holdout dataset approach does not provide a variability estimate for the accuracy. It would be nice to be able to repeatedly train the algorithm on a representative set and test on a different dataset, and see how robust the accuracy is. The problem is that relevant and clean data representative of the underlying process is a scarce resource.

The *v-fold cross-validation* addresses most of these concerns. The idea is to partition the available dataset to v (typically 10) pieces randomly, repeatedly leaving out one piece of the data for testing, while training the algorithm on the remaining data. Accuracy is then calculated for each test set. The average becomes the point estimate, and the standard deviation becomes the variability estimate of the algorithm's accuracy on random samples coming from the same underlying data generation process. For added assurance on representativeness of the samples resulting from the folds, this technique can be used with stratification.

A common extension is the *10-by-10-fold cross-validation* in which case the 10-fold cross-validation is repeated 10 times to get a better estimate of the standard deviation.

A special case of the v -fold cross-validation is the *leave-one-out cross-validation*, also called the *jack-knife estimate* [8]. Here, for a dataset with n observations, we perform n -fold cross-validation. Notice that the average and standard deviation of the accuracy will not vary with the sequence of the points left out. While this technique eliminates the sampling issues,

the computational effort is substantially higher, especially for large datasets.

We can use statistical theory to provide a $(1-\alpha)\%$ **confidence interval** for the true accuracy as follows:

$$\bar{a} \pm t_{v-1, \alpha/2} \text{std}(a) v^{-0.5}$$

where $\bar{a}$ is the average accuracy, and $\text{std}(a)$ is the standard deviation of accuracy calculated from the samples. $P(t > t_{v-1, \alpha/2}) = \alpha/2$, where t has the t distribution with $v - 1$ **degrees of freedom**. For example, constructing the 95% confidence interval for 10-fold cross-validation, v is 10, $t_{9, 0.025}$ is 2.26 as can be read from tables available in any elementary statistics book, or retrieved with the *tin* function in Excel. We can make these intervals tighter if we are happy to accept a lower confidence level such as 90%, whereas higher confidence levels imply a larger interval.

A related sampling scheme to the v -fold cross-validation is the **bootstrap** [8], where the training data is sampled from the original data with replacement, and those observations that are not picked for training form the test dataset. This process is repeated many times and results are averaged. While the bootstrap provides a good method of evaluation for very small datasets, it is not commonly used for large datasets.

Comparing Performance of Algorithms

Frequently, we are concerned with comparing the accuracy of two algorithms operating on the same data. Considering the uncertainty in the accuracy estimates, comparing the point estimates; i.e., the average accuracy of each algorithm is misleading. Even if two algorithms have the same true accuracy, the probability that their accuracy on a sample will be the same is very low, and it is zero for regression tasks. What should be compared are the confidence intervals of the accuracy, if these are overlapping, then there is not sufficient evidence to conclude that these two algorithms perform differently in terms of accuracy on the data coming from the same underlying data generation process.

There are three ways in which we can be more decisive about the relative accuracy of algorithms. The first involves decreasing confidence levels, say from 95 to 90%. The second involves increasing the number of partitions for the v -fold cross-validation, thus reducing the t -statistic and the $v^{-0.5}$ term. Notice

that the effect of adding more folds decreases as the number of folds increases, for example, the decrease in the multiplier of the $\text{std}(a)$; i.e., $t_{v-1, \alpha/2} v^{-0.5}$, from $v = 10$ to $v = 20$ is only 0.27 while the decrease from $v = 10$ to $v = 5$ is 0.63, as can be seen from Table 4.

The third way to be more decisive about the relative accuracy of algorithms is to construct the test statistic of the paired difference: the difference of the accuracy measures for the two algorithms is calculated at each step of the v -fold cross-validation, thus ensuring that the differences observed in the algorithm's accuracy are not stemming from being exposed to different data samples. The average of the differences provides a point estimate for the difference in accuracy between the two algorithms. The standard deviation of the v differences is used to test the hypothesis that the difference in accuracy between the two algorithms is zero. The test statistic $\bar{d} v^{0.5} / \text{std}(d)$ is compared against the t distribution with $v - 1$ degrees of freedom. Typically, a p value less than 5% indicates reasonable evidence that the accuracy of the two algorithms is not the same. Taking the alternative hypothesis, as any of the two could be more accurate, the t -statistic with 9 degrees of freedom and $\alpha = 0.025$ can be used as a reference value (2.262). Hence, if the absolute value of the test statistic exceeds this reference value, we can conclude that the true accuracy of the algorithms is different.

While we have focused on accuracy evaluation in this section, the above evaluation techniques can be used with other goodness measures as well, such as processing speed.

Conclusion and Further Reading

The knowledge discovery in databases (KDD) and data mining movement initially emphasized finding

Table 4 The multiplier of $\text{std}(a)$ in the confidence interval of accuracy

		v in v -fold cross-validation		
		5	10	20
Confidence level	90%		0.611	
	95%	1.388	0.754	0.480
	99%		1.083	

actionable/interesting knowledge in the data. “Interestingness” was defined as a somewhat subjective concept containing validity, novelty, usefulness, and simplicity [9]. For further references on developments on interestingness measures for data mining we refer the reader to the survey by Geng and Hamilton [7].

In conclusion, the two main criteria that are used in the evaluation of data mining algorithms are accuracy and simplicity. While the MDL principle suggested by Rissanen [4] is generating a lot of interest [5], and while there are some measures related to the MDL such as AIC and BIC, due to practical considerations, accuracy and simplicity are typically evaluated separately. Tenfold cross-validation is the standard method [10].

Applications of Extreme Statistics in Science and Engineering

Generalities

Applications of **risk analysis** in science and engineering abound. For some theoretical background and the resulting statistical issue, we refer to **Risk Analysis, Extremes in**. Before we illustrate this use of extreme value theory we should mention that real life applications have been responsible for major developments of the theory. It is actually remarkable that historically the basic Fisher–Tippett result was proved long before the appearance of Cramér’s treaty of the central limit problem in Cramér [1]. In spite of some earlier attempts like in Gumbel [2], the genuine development of statistics of extremes only took off in the last two decades of the twentieth century. The appearance of theoretical texts like de Haan [3] and Leadbetter *et al.* [4] have instigated this development.

Nevertheless, many problems related to extremal thinking already appeared in specific applications. Large claims have been modeled by **Pareto**-type distributions already in Jung [5] in 1964. In the 1970s, wind speed data with their extremes have been investigated and modeled using extreme value procedures, see Simiu *et al.* [6].

Moreover, applications have been responsible for a change in statistical thinking in that the usual central limit paradigms had to be replaced by intrinsic extreme value thinking. The fact that investigators were forced to draw statistical conclusions from a meager set of rare events is one of the reasons for this approach. Moreover, extreme values are often only rough guesses like in the case of casualties from major natural catastrophes. Perhaps in some cases one might be able to expand the meager data set by proper inclusion of calibrated data that refer to other timescales and/or geographical areas.

In the examples below we will avoid to emphasize again and again the important role played by the extremes. The latter should be clear from the specific context. In an attempt not to overload the list of references we only refer to the main historical contributions and/or to recent publications where more information and references can be found. For

an early publication with a variety of applications of extreme value theory, see Galambos *et al.* [7]. For a recent textbook treatment of *operational risk*, see Panjer [8].

Operations Research

Network Models

Owing to the extreme heterogeneity in machines, subnetworks, and administrative organizations over which networks are laid, customers must be aware that certain constituent components can cause problems with the performance and/or reliability of the network.

Van Uitert and Borst [9] investigate the quality of service in integrated-services networks. The overall workload may be influenced if not controlled by one particular flow that has long-tailed traffic characteristics. As studied in Resnick [10] heavy-tailed **time series** result from the increasing availability of large data sets from communication networks in which heavy-tailed distributions are ubiquitous and long-range dependence may be present. For an application of bivariate extreme value theory to Internet traffic data, see Heffernan and Resnick [11].

Reliability

Structural systems are often subject to severe forms of risk. Load combinations for bridges, corrosion, metal fatigue are but a few key words that come to mind when dealing with such risks. For a compilation of contributions in this area, see Maes and Huyse [12]. Structural systems are subject to deterioration over time due to a variety of reasons: improper use, exposure to aggressive environment, wear, extreme accidents, and so on. Usually, these reasons can be subdivided into two not necessarily disjoint categories; the first being aging that affects the lifetime of the structure on a continuous basis, the second being shocks that act on a discrete timescale. Stochastic modeling of such events suggests the use of a combination of stochastic differential equations coping with the continuous scale and a superimposed discrete-time process dealing with the shocks. See Crowder *et al.* [13] for a textbook treatment and Ciampoli [14] for an example of a reinforced concrete shear wall in a nuclear power plant, subject to deterioration.

2 Applications of Extreme Statistics

Many forms of structure fail due to combinations of extremal processes. In Coles and Tawn [15], multivariate extremes are introduced as elements in the design process.

- Heffernan and Tawn [16] studied data on *wave impacts on ships*. The data were obtained from physical model studies for different models of bulk carriers and a broad range of sea and ship conditions. The generalized Pareto distribution is used to describe the distribution of wave impact pressures exceeding some threshold and a **Poisson process** for the number of such impacts.
- **Software reliability** has been treated in Tsokos and Nadarajah [17] where the reliability of a new software package is determined prior to being marketed.
- In **genetic algorithms** one only seems to use random variables with normal-like behavior. Nevertheless the performance of these algorithms often proves to be controlled by extremal rather than central values, see Adler *et al.* [18].
- *Corrosion* of pipelines is the subject of Isogai *et al.* [19] where the pit depth of metal oxide films is modeled while the stress is modeled by a compound process.
- Probably one of the most important applications of extreme value thinking concerns metal *fatigue strength* where the largest inclusions are at the origin of this phenomenon. The mathematical treatment of this problem is made complicated by the fact that inference on three-dimensional inclusions has to be based on two-dimensional cross sections, see Murikami and Beretta [20] and Beretta and Anderson [21].

Geophysics

The whole area of geophysics offers vast possibilities to apply extreme value theory. For a general text, see Smith [22].

Hydrology

- *River floods and droughts* are the extremes when considering river levels. An overshoot of a certain safety threshold causes floods, but droughts are caused when the level gets below a lower safety margin. There already exists a wide

variety in treated problems and corresponding methodologies. Let us first look at the river levels at a single point. As is illustrated in the section on genetic algorithms, hydrologists can draw statistical conclusions on the basis either of one or more annual maxima or of floods above a given threshold, see Li *et al.* [23] for this approach. Engeland *et al.* [24], apply different extremal models and estimation procedures to fit flood extremes and droughts durations.

Multivariate procedures have also found applications in hydrology. Shiau [25] combines flood volume and flood peak in a bivariate extreme value model. Nagaraja *et al.* [26] look at extreme river levels of the same river but at different sites. Extreme floods are modeled by fractal theory in Turcotte [27]. See Hutson [28] for the construction of a **confidence interval** for the **quantiles** in a hydrological data set.

- *Rainfall* data add a spatial component to extreme value theory. Cowpertwait [29] models rain storms by a Poisson process while the storms themselves generate a cluster of heavy and light cells. For a time series approach, see Coles and Tawn [30]. For a Bayesian approach, see Coles and Tawn [31]. Joe *et al.* [32] treat bivariate data on sulfate and nitrate levels taken from a major study of acid rain.

Oceanography

It goes without saying that extreme sea levels are among the most dangerous natural events. The number of human casualties at recent coastal floods can hardly be estimated. As explained in Dixon and Tawn [33], the sea level is the composition of meteorological surge and astronomical tidal processes. It exhibits temporal nonstationarity due to a combination of long-term trends in the mean level, the deterministic tidal component, surge seasonality, and interactions between tide and surge. Ignoring nonstationarity usually leads to an underestimation of extreme sea levels.

Ocean waves are described by crest height, trough height, and their interrelationship. Return periods of sea storms in which either the maximum crest or trough height exceeds a fixed threshold are discussed in Arena [34]. Extreme-event analysis is applied to the time series of sea data in specific locations by Tirozzi *et al.* [35]. For a trivariate model for extremal sea-level data, see Tawn [36]. For one based on

the Gumbel distribution, see Escalante-Sandoval and Raynal-Villasenor [37]. For a bivariate extremal treatment of wind velocities and wave heights, see Liu *et al.* [38].

de Haan and Rootzén [39] have investigated height requirements for *sea dikes*. Bruun and Tawn [40] study the combination of extreme water levels and wave heights. For a generalization to Gaussian fields and seas, see Podgórski *et al.* [41].

Meteorology, Climatology

Risks in climatology offer a wealth of applications of extreme value theory. The assumptions of independence and/or of stationarity in the data are mostly violated. Fortunately as shown *inter alia* in Leadbetter *et al.* [4] and subsequent research, the extreme value distributions remain useful candidates to describe yearly maxima. Estimations are often improved by relying on more of the largest data values. For an early attempt in this direction, see Buishand [42].

- *Meteorological data* generally have no alarming effect as long as they are situated in a fixed band around the average. Once the boundaries of this safe region are crossed, extreme value theory comes into action. Let us mention a couple of examples, first of all, extreme *temperatures*. Davison and Ramesh [43], offer a semiparametric approach to sample extremes. Beirlant *et al.* [44] treat a case study of temperature data using a Markov model. Hall and Tajvidi [45] use a non-parametric approach to estimate temporal trends in a weakly dependent time series of maximal temperatures.
- *Wind* encompasses a number of meteorologically different subjects like storms, tornadoes, hurricanes, typhoons, and so on. Kestens and Teugels [46] survey some of the modeling problems. See also Simiu *et al.* [6] and Beirlant *et al.* [44] for large-scale investigations of wind speed data. Since data on hurricane wind speed are often unreliable, Casson and Coles [47] have developed a two-stage approach starting from a spatial pressure model and the resulting associated wind speeds. In Teugels and Vandewalle [48], it is shown that casualty data from hurricanes are well modeled by a Pareto distribution with an extreme value index (EVI) $\gamma > 1$, indicating that the data do not support the finiteness of the variance, even of the mean.

- Other delicate risk-oriented topics within climatology are *global warming* and *ozone depletion*. For attempts to model the latter using extreme value theory, see Smith [49] and Dasgupta and Bhaumik [50]. Both subjects are commonly discussed within the realm of *environmetrics*, a scientific area where the role of extremes can hardly be overestimated. Pollution levels for rivers do not give rise to specific actions as long as they are considered to be about average. Extreme value theory comes into play as soon as the pollution level hits a value that is too high. Many similar examples can be found when one is interested in the values of environmental indicators.

Seismology

Earthquakes form another major area of application of extreme value analysis. Pisarenko and Sornette [51] analyzed shallow earthquakes over the period 1977–2000. Also in Beirlant *et al.* [44] the same data have been subjected to further extremal analysis.

Economics

Also in **finance** and insurance, heavy-tailed models have been popular. See for example the survey by Zinchenko [52] and the textbook by Embrechts *et al.* [53].

Finance

One of the key Black–Scholes assumptions is that price movements in financial markets (assets, credit, etc.) follow the lognormal distribution. In practice, however this is not always the case. Empirical distributions exhibit far more frequent extreme outcomes of *heavy tails*. This observation has forced financial mathematics to introduce concepts like heavy-tailed distributions, long-range dependency, and extreme value behavior. For a recent comprehensive treatment, see the textbook by Malevergne and Sornette [54].

- A first area of interest is the construction and estimation of *risk measures*, especially for heavy-tailed distributions. The most popular such measure is the *value at risk* but there are many alternatives, see, for example, Suárez and Carrillo [55] and Cai and Li [56].

- Another area is the modeling of one-dimensional *asset returns* with heavy tails. Like in most applications, extreme value statistics can only offer partial answers since such large returns are rare. Underestimation usually results from ignoring the potential heaviness of the tail of the distribution; but then again overestimation is a consequence of taking this tail as too heavy. A first form of dependence can be found within the same financial environment when successive returns are no longer assumed to be independent. See Deo [57] and Schmidbauer and Rösch [58] for models that incorporate this dependence for stock returns.
- Another is the detection and modeling of *dependency* among heavy-tailed assets. It turns out that large risks are not solely due to the heavy tails of the asset returns but also to their collective behavior. This observation lies at the introduction of measures of dependence, often expressible in terms of copulas. Dependence can be measured by the *coefficient of tail dependence* that quantifies the probability for an asset to lose a large amount knowing that another asset (or the market) has dropped significantly, see also Cizek *et al.* [59]. In Schmidbauer and Rösch [58] an attempt is made to compare this dependence between the assets in periods of low and intense market activity. For a case study, see Poon *et al.* [60]. Another illustration of such dependence is offered by the interaction between portfolio quality and credit losses, see Lucas *et al.* [61]. For an application of Markov chain modeling, see Bortot and Coles [62].

Insurance

Historically actuarial science has been one of the first areas in which extremes have played a vital role. For a general introduction, see the article on extremes by Beirlant [63]. In *nonlife insurance*, certain portfolios have a tendency to occasionally include a large claim that jeopardizes the solvency of a portfolio. Apart from major accidents as earthquakes, hurricanes, airplane crashes, and so on, there are a vast number of occasions where large claims occur. Many illustrations from general insurance can be given.

- The distribution of the *total claim amount* in such a portfolio is very sensitive to the inclusion of

heavy-tailed distributions. Mikosch and Nagaev [64] give a treatment that puts the theories of extremes and large deviations in insurance in perspective.

- Morales [65] constructs a simulation scheme to estimate *ultimate ruin probabilities* for the classical surplus model in the presence of heavy- and medium-tailed severity distributions.
- See Beirlant *et al.* [66, 44] for treatments of *car accident* data.
- Rootzén and Tajvidi [67] look for statistical connections between large insurance claims from *windstorm losses* and wind speeds.
- *Fire portfolios* sometimes encounter large claims. Industrial fires, especially, cause a lot of side effects in loss of property, temporary unemployment, and lost contracts.
- Still other areas of nonlife insurance can give raise to large claims. We mention accidents with oil tankers and platforms, environmental spills, explosions at nuclear power stations, and so on. A special mention should be given to lawsuits resulting from medical malpractice that often lead to excessive claims from the insured.

Let us mention that *reinsurance* is a branch of actuarial practice that studies risk sharing by passing on part of the risk to one or more other insurance companies. Also the calculation of *insurance premiums* forces both the insurer and the reinsurer to be aware of potential extremes in the data. For such an example, see Jang and Krvavych [68].

Polya Trees and Their Use in Reliability and Survival Analysis

A Polya Tree Prior Centered at the Weibull Family

Polya trees generalize and add flexibility to standard parametric models such normal, Weibull, lognormal, Pareto, log-logistic, gamma, and others used for the statistical analysis of time to event data. A simple Weibull model for survival times $\mathbf{T} = (T_1, \dots, T_n)'$ assumes a distribution function G with a particular form, i.e.

$$T_1, \dots, T_n | G \stackrel{\text{i.i.d.}}{\sim} G, G(t|\alpha, \lambda) = 1 - \exp(-t^\alpha/\lambda) \quad \text{for } t \geq 0 \quad (1)$$

This type of model is referred to as *parametric* because the class of possible density shapes is indexed by a small number of parameters, here $\theta = (\alpha, \lambda)$. Parametric survival models are straightforward to fit and draw inferences from, but the trade-off for this ease of implementation is lack of flexibility to capture more complex features (e.g., multimodality, **skewness**, and clustering) that may be present in time to event data. This motivates expanding the class of distributions to include not only the Weibull family (or more generally any parametric family) but also deviations from it supported by the data. A Bayesian nonparametric Polya tree prior for G achieves this flexibility. Other approaches include the Dirichlet process [1], Dirichlet process mixtures, beta, and gamma processes (*see Dirichlet Process, Simulation of; Survival Analysis, Nonparametric; Lévy Processes, Simulation of*).

A Polya tree adds $2^{J+1} - 2$ additional parameters, $\mathcal{X}_J$, to equation (1) that collectively “adjust” the overall shape of G to add more probability mass where data are clumped and remove mass where data are sparse relative to the Weibull distribution $G(t|\alpha, \lambda) = 1 - \exp(-t^\alpha/\lambda)$. The parameters $\theta = (\alpha, \lambda)$ serve to fix the overall shape, location, and spread of the distribution G ; the parameters $\mathcal{X}_J$ refine its shape to match the observed data more closely. In fact, the parameters $\mathcal{X}_J$ adjust G on intervals derived from **quantiles** of the Weibull(α, λ)

distribution, obtained from the quantile function $G^{-1}(p|\theta) = (-\lambda \log(1 - p))^{1/\alpha}$. These intervals partition the sample space and are constructed as follows.

Initially, $(0, \infty)$ is split into two pieces, $B_\theta(0) = [0, G^{-1}(0.5|\theta))$ and $B_\theta(1) = [G^{-1}(0.5|\theta), \infty)$. These two sets partition $[0, \infty)$ and have equal probability, 0.5, under the parametric Weibull(α, λ) model. The set $B_\theta(0)$ is further split into two subsets $B_\theta(00) = [0, G^{-1}(0.25|\theta))$ and $B_\theta(01) = [G^{-1}(0.25|\theta), G^{-1}(0.5|\theta))$, each having equal probability, 0.25, under the Weibull(α, λ) model. Similarly $B_\theta(1)$ is split into two subsets $B_\theta(10) = [G^{-1}(0.5|\theta), G^{-1}(0.75|\theta))$ and $B_\theta(11) = [G^{-1}(0.75|\theta), \infty)$, each with Weibull probability 0.25. This defines the first and second partitions of the Polya tree: $B_\theta(0), B_\theta(1) \in \Pi_{\theta 1}$, and $B_\theta(00), B_\theta(01), B_\theta(10), B_\theta(11) \in \Pi_{\theta 2}$. For $\alpha = 2$ and $\lambda = 10$, $B_{(2,10)}(0) = [0, 2.63)$ and $B_{(2,10)}(1) = [2.63, \infty)$ at the first level and $B_{(2,10)}(00) = [0, 1.70)$, $B_{(2,10)}(01) = [1.70, 2.63)$, $B_{(2,10)}(10) = [2.63, 3.72)$, and $B_{(2,10)}(11) = [3.72, \infty)$ at the second.

Nested partitions are sequentially defined in this manner by splitting each set in $\Pi_{\theta j}$, having probability 2^{-j} under Weibull(α, λ), into two sets in $\Pi_{\theta, j+1}$, each having probability $2^{-(j+1)}$. Let $\epsilon_1 \epsilon_2 \dots \epsilon_j$ be a binary expansion that indexes a set $B_\theta(\epsilon_1 \dots \epsilon_j) \in \Pi_{\theta j}$. Then $B_\theta(\epsilon_1 \dots \epsilon_j) = B_\theta(\epsilon_1 \dots \epsilon_j 0) \cup B_\theta(\epsilon_1 \dots \epsilon_j 1)$. Here, $B_\theta(\epsilon_1 \dots \epsilon_j) = [G^{-1}(N/2^j), G^{-1}((N+1)/2^j))$, where N is the decimal representation of $\epsilon_1 \dots \epsilon_j$ and ranges over the integers from 0 to $2^j - 1$.

The probability of an observation T_i falling into $B_\theta(0)$ is denoted $X(0) = G(B_\theta(0))$. Then the probability of T_i falling into the companion set $B_\theta(1)$ is 1 minus this, $X(1) = G(B_\theta(1)) = 1 - G(B_\theta(0))$. Given that $T_i \in B_\theta(\epsilon_1 \dots \epsilon_j)$, the *conditional probability* of T_i falling into $B_\theta(\epsilon_1 \dots \epsilon_j 0)$ versus its companion set $B_\theta(\epsilon_1 \dots \epsilon_j 1)$ is given by $X(\epsilon_1 \dots \epsilon_j 0)$ versus $X(\epsilon_1 \dots \epsilon_j 1)$. That is, for $\epsilon_1 \epsilon_2 \dots \epsilon_j \in \{0, 1\}^j$, $X(\epsilon_1 \dots \epsilon_j 0) = P(T_i \in B_\theta(\epsilon_1 \dots \epsilon_j 0) | T_i \in B_\theta(\epsilon_1 \dots \epsilon_j))$ and $X(\epsilon_1 \dots \epsilon_j 1) = 1 - X(\epsilon_1 \dots \epsilon_j 0) = P(T_i \in B_\theta(\epsilon_1 \dots \epsilon_j 1) | T_i \in B_\theta(\epsilon_1 \dots \epsilon_j))$.

Let $E_J = \bigcup_{j=1}^J \{0, 1\}^j$ denote all binary numbers from 0 to $2^J - 1$ and let $\mathcal{X}_J = \{X(\epsilon) : \epsilon \in E_J\}$ be the set of all conditional probabilities up to level J that define G . A fully specified Polya tree has an infinite number of levels ($J \rightarrow \infty$). A finite Polya tree has J levels. If J is chosen to be large, one can further assume G to be flat on intervals $B_\theta(\epsilon)$ of finite length at level J [2]. Alternatively, one can assume

2 Polya Trees

Figure 1 (a) Weibull(2, 10) ($J = 0$) density, (b–d) $J = 1, 2, 3$ respectively, (e) all four levels on same plot, (f) PT and MPT densities

that G follows the Weibull(α, λ) on sets at level J [3] – the approach taken here. When $X(\epsilon) = 0.5$ for all $\epsilon \in E_J$, G is simply the Weibull(α, λ) density we started with.

Let us see how particular choices of conditional probabilities affect the density. Figure 1(a) shows a Weibull(2, 10) density. This is also the density of G governed by a Polya tree but with all conditional probabilities $X(\epsilon_1 \cdots \epsilon_j) = 0.5$. In Figure 1(b), fixing $X(0) = 0.45$ serves to adjust the Weibull density at the first level of the tree on the sets $B_{(2,10)}(0)$ and $B_{(2,10)}(1)$. Figure 1(c) shows the density further refined at the second level from fixing the conditional probabilities $X(00) = 0.4$ and

$X(10) = 0.6$. Figure 1(d) shows a finite Polya tree with three levels obtained by further fixing $X(000) = 0.3$, $X(010) = 0.3$, $X(100) = 0.6$, and $X(110) = 0.3$. Figure 1(e) shows the original density along with the three refinements. Figure 1(f) is obtained by keeping the fixed values in $\mathcal{X}_3$ above, but by considering a mixture of Polya trees (MPT) from taking $\alpha \sim N(2, 0.1^2)$ independent of $\lambda \sim N(10, 0.5^2)$. In the mixture, $E(\alpha) = 2$ and $E(\lambda) = 10$ so the prior on G is centered at the same Weibull(2, 10) density, but by allowing the mixing parameters (α, λ) to be random the partitioning effects (e.g., jagged edges in the density at partition interval endpoints) apparent in the simple Polya tree are smoothed over. This is

because the partition sets Π_{θ_j} are random under the mixture.

Instead of treating the conditional probabilities as fixed, unknown parameters, the Bayesian considers them random. The probability of an observation T_i falling into $B_{\theta}(0)$ is modeled as $X(0) = G(B_{\theta}(0)) \sim \beta(\alpha(0), \alpha(1))$. That is,

$$\begin{bmatrix} X(0) \\ X(1) \end{bmatrix} = \begin{bmatrix} G(B_{\theta}(0)) \\ G(B_{\theta}(1)) \end{bmatrix} \sim \text{Dirichlet} \left(\begin{bmatrix} \alpha(0) \\ \alpha(1) \end{bmatrix} \right) \quad (2)$$

Recall that, in general, for $\epsilon_1 \epsilon_2 \dots \epsilon_j \in \{0, 1\}^j$, $X(\epsilon_1 \dots \epsilon_j 0) = P(T_i \in B_{\theta}(\epsilon_1 \dots \epsilon_j 0) | T_i \in B_{\theta}(\epsilon_1 \dots \epsilon_j))$ and $X(\epsilon_1 \dots \epsilon_j 1) = 1 - X(\epsilon_1 \dots \epsilon_j 0) = P(T_i \in B_{\theta}(\epsilon_1 \dots \epsilon_j 1) | T_i \in B_{\theta}(\epsilon_1 \dots \epsilon_j))$. Rewritten in compact notation, for $\epsilon \in \{0, 1\}^j$, $X(\epsilon 0) = P(T_i \in B_{\theta}(\epsilon 0) | T_i \in B_{\theta}(\epsilon))$ and $X(\epsilon 1) = 1 - X(\epsilon 0) = P(T_i \in B_{\theta}(\epsilon 1) | T_i \in B_{\theta}(\epsilon))$. These pairs of conditional probabilities are also Dirichlet:

$$\begin{bmatrix} X(\epsilon 0) \\ X(\epsilon 1) \end{bmatrix} \sim \text{Dirichlet} \left(\begin{bmatrix} \alpha(\epsilon 0) \\ \alpha(\epsilon 1) \end{bmatrix} \right) \quad (3)$$

So the prior on G is in fact a tree of pairs of conditional probabilities of falling into one set *versus* an adjoining set. These pairs of probabilities are assumed to be independent. Recall that fixing $X(\epsilon) = 0.5$ for all $\epsilon \in E_J$ ensures that G is Weibull(α, λ). By setting $\alpha(\epsilon 0) = \alpha(\epsilon 1)$ for each $\epsilon = \epsilon_1 \dots \epsilon_j \in E_J$, random G is instead *centered* at the Weibull(α, λ) distribution on all partition sets:

$$E\{G(B_{\theta}(\epsilon))\} = \int_{B_{\theta}(\epsilon)} dG(t | \alpha, \lambda) \quad (4)$$

from the fact that $E(X(\epsilon)) = 0.5$ for all $\epsilon \in E_J$. The parameters $\alpha(\epsilon_1 \dots \epsilon_j)$ are often set to $\alpha(\epsilon_1 \dots \epsilon_j) = c_j^2$ for $c > 0$ in applications. This ensures that the conditional probabilities get more highly concentrated around 0.5 as the level J increases, giving larger sets at lower levels more flexibility to adapt to large trends or clumps in the observed data.

The tree structure and independence among probability pairs in $\mathcal{X}_J$ gives the measure of any set

$$G\{B_{\theta}(\epsilon_1 \dots \epsilon_j)\} = \prod_{i=1}^j X(\epsilon_1 \dots \epsilon_i) \quad (5)$$

A key result for Polya trees is that the conditional probability pairs in $\mathcal{X}_J$ given data $\mathbf{T} = (T_1, \dots, T_n)$

are again independent Dirichlet vectors, and are thus easily sampled for a given (α, λ) . This conjugacy result has played a part in several papers that involve Polya tree priors (e.g., [2, 4, 5]) but in many models conjugacy is lost and more sophisticated methods for obtaining posterior inference, such as Markov chain Monte Carlo (MCMC), are employed (*see Markov Chain Monte Carlo, Introduction*).

The definition of a Polya tree can be more complicated than what is outlined so far, but this gives a particular development that has been used with great success in a number of papers. More general Polya trees involve definition of elements $\mathcal{A} = \{\alpha(\epsilon)\}$ one at a time and consideration of different partitions $\{\Pi_1, \dots, \Pi_J\}$. An MPT prior on G assumes $\theta = (\alpha, \lambda)$ is random in addition to the elements in $\mathcal{X}_J$. See [6] and [7] for more details and definitions. Figure 1 illustrates that the MPT prior smooths over partitioning effects apparent in a simple Polya tree; see [6, 8].

Polya Trees and Survival Modeling

The literature on survival modeling with Polya trees can be sorted into two categories: the no-covariates case focusing on the estimation of survival, hazard, and density functions; and semiparametric models that extend these models to include **covariate** information.

Ferguson [9] codifies and fleshes out various results published in the 1960s on Polya trees. This paper also contrasts Polya trees to the special case of the Dirichlet process [1]. Lavine [6, 7] carefully develops and catalogs many additional aspects of Polya tree and MPT theory and methodology; these papers were foundational, and provided core material from which many further developments grew. Lavine [6] analyzes reliability data on the lifetimes of spherical pressure vessels from four different MPT models, each with different sets $\mathcal{A} = \{\alpha(\epsilon)\}$, centered at the exponential family $G(t | \alpha) = 1 - \exp(-\alpha t)$. The data considered in [6] were observed exactly; censored survival data is considered by Muliere and Walker [10] through the construction of Polya trees with some partition points coinciding with censored observations. The resulting estimator reduces to that of Kaplan and Meier [11] as a limiting case. When the partition is fixed ahead of time, i.e. not picked to coincide with censored values, Neath [12] shows that

the posterior distribution for G is an MPT, derives the mixing distribution, and provides a reanalysis of data considered in [10, 11].

These approaches all consider survival data without covariates. Often in reliability settings such as accelerated testing, covariates for the i th experimental unit $\mathbf{x}_i$ are fixed at predetermined values and the resultant lifetime T_i , or possibly a censoring time, is recorded. In survival analysis settings, patient information such as age, treatment, gender, etc., are collected into $\mathbf{x}_i$ and a time to event T_i observed. In either case, the covariates $\mathbf{x}_i$ are linked to T_i through a probability model. In what follows, let $S_i(t) = P(T_i > t)$ be the survival function of subject i with covariates $\mathbf{x}_i$ given all model parameters.

Walker and Mallick [2] develop an accelerated failure time model

$$\log T_i = \mu + \mathbf{x}_i' \boldsymbol{\beta} + \sigma \epsilon_i \quad (6)$$

where the ϵ_i are independent and identically distributed (i.i.d.) from a distribution G assigned a Polya tree prior; this model is also considered in [13]. In applications, $\sigma = 1$ is fixed and the Polya tree is centered at a median-zero **normal distribution** with a large variance. Hanson [8] considers proportional hazards

$$S_i(t) = S_0(t)^{\exp(\mathbf{x}_i' \boldsymbol{\beta})} \quad (7)$$

proportional odds

$$\frac{1 - S_i(t)}{S_i(t)} = \exp(\mathbf{x}_i' \boldsymbol{\beta}) \frac{1 - S_0(t)}{S_0(t)} \quad (8)$$

and a reparameterized version of equation (6),

$$S_i(t) = S_0\{\exp(\mathbf{x}_i' \boldsymbol{\beta})t\} \quad (9)$$

where equations (7–9) assume the same MPT prior centered at the Weibull(α, λ) family for baseline survival S_0 . Mallick and Walker [5] develop a semiparametric transformation model

$$h(T_i) = \mu + \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i \quad (10)$$

where $h(\cdot)$ is a monotone function modeled as a transformation of a small mixture of beta cumulative distribution function (cdf's). As in equation (6), the ϵ_i are i.i.d. from a distribution G assigned a Polya tree prior. This model reduces to the proportional odds model (8) when G is fixed to be the standard

logistic distribution, reduces to the proportional hazards model (7) when G is extreme value, and reduces to equation (6) when $h(\cdot) = \log(\cdot)$ but with a fixed scale $\sigma = 1$. All of these papers analyzed data on $n = 121$ patients diagnosed with small cell lung cancer, considered in the next section. The accelerated failure time model was found to fit these data better than the proportional odds and proportional hazards models [8, 5].

Hanson and Johnson [3] allow for random σ in equation (6), rather than a simple Polya tree, smoothing out partitioning effects. A frailty version of this model has been used to analyze data on fetal lifetime in cows with parametric frailties accounting for different herd effects [14]. Damien *et al.* [15] considered the analysis of reliability data through equation (9). The proportional odds model (8) was extended by Hanson and Yang [16] to include parametric frailties. Survival data on the lifetimes of $n = 97$ men with advanced, inoperable lung cancer were analyzed by Mallick and Walker [5] and Hanson and Yang [16]. The proportional odds model was picked to be superior in both papers.

Walker and Mallick [4] consider a Polya tree prior on the random effects distribution in generalized linear mixed models, and, in particular, use a Polya tree to model frailties in the Cox model [17]. The use of Polya trees to model random effects in hierarchical models was further developed in [8]. These models are in contrast to the models considered in [5, 14, 16], which considered parametric frailty models coupled with semiparametric survival models. Although common, parametric frailty assumptions are typically made for computational convenience; the MPT model provides a powerful method to relax these strict parametric assumptions in survival and reliability modeling.

In related work, Karabatsos and Walker [18] consider estimation of distributions from several populations that are subject to a stochastic order constraint, and apply their methodology to data comprising the reaction times of schizophrenics and nonschizophrenics.

An Example: Survival Data on Lung Cancer Patients

Data on the treatment of limited-stage small cell lung cancer in $n = 121$ patients were analyzed by Walker

and Mallick [2], Mallick and Walker [5], Hanson [8], and Walker *et al.* [13] among others. In the study, it was of interest to determine which sequencing of the drugs cisplatin and etoposide increased the lifetime from time of diagnosis, measured in days, of those with limited-stage small cell lung cancer. Treatment *A* applied cisplatin followed by etoposide, while treatment *B* applied etoposide followed by cisplatin; $x_{i1} = 0, 1$ for treatments *A, B* respectively. The patients' ages in years at entry into the study, x_{i2} , were also included so $\mathbf{x}_i = (x_{i1}, x_{i2})'$. Treatment *A* was administered to 62 patients, while treatment *B* was administered to 59 patients; 23 patients were administratively right censored.

Here we consider model (9) with an MPT baseline S_0 centered at the Weibull(α, λ) family of distributions. The flat prior $p(\alpha, \lambda, \beta_1, \beta_2) \propto 1$ was assumed. The remaining parameters were fixed at $c = 1$ and $J = 4$ and inference obtained *via* MCMC [8]. The estimated age effect $\hat{\beta}_2$ and 95% credible interval is 0.004 (−0.005, 0.034); for treatment the estimated effect $\hat{\beta}_1$ and 95% credible interval is 0.36 (0.15, 0.71). Treatment *A* is estimated to prolong mean and median life by a factor of $e^{0.36} \approx 1.4$ times, or about 40%, relative to *B*.

The MPT approach models the baseline survival distribution S_0 in tandem with the regression coefficients β , so, arbitrary posterior functionals of (S_0, β) are easily obtained from the MCMC output. For example, one can obtain the hazard ratio for treatment *B versus A* at any time point t , the predictive density at t , arbitrary survival quantiles, etc. Figure 2(b) is a plot of the estimated posterior median hazard ratio for treatment *B versus A* at the mean entry age of 61,

$$hr(t|\text{data}) = \frac{h_{(1,61)}(t)}{h_{(0,61)}(t)}|\text{data} \quad (11)$$

versus time with pointwise 95% credible intervals. Here $[1 - S_x(t)]$ by just $S_x(t)$, the hazard function at t . We see that those under regimen *B* are typically about 1.5 times more likely to die at any instant *versus* those under *A*, but there is considerable variability of the hazard ratio over time. For example, we see peaks under 500 days where those under *B* are estimated to be almost three times as likely to instantaneously expire. In Figure 2(a) we have the two predictive densities at baseline age 61 for treatments *A* and *B*. Note that unlike the Weibull model, the MPT generalization allows for multimodality in these predictive distributions which may have biological interpretations in some applications.

Discussion

This paper introduces the Polya tree prior as a generalization of a parametric family of distributions, and provides a review of literature on the use of Polya trees in reliability and survival analysis. Details of model development and fitting are left to the references. Good references on Polya tree and MPT modeling include [6–9, 13].

One aspect of Polya tree distributions that can be exploited in the modeling of survival data is that the tails of an MPT G retain the parametric flavor of the centering family, essential in some cure-rate models and reliability settings where extrapolation is common. Also, MPT survival models can accommodate arbitrarily censored and truncated data. For example, interval-censored and right-truncated data are easily handled in the proportional hazards model. This is not typically the case with other nonparametric Bayesian survival models.

Calibration

Introduction

Calibration is the task of establishing common scales/units of measurement for commerce, construction, weather, and scientific study. Some of the earliest properties for which calibration was found useful include weight, mass, volume, purity, distance, area, size, speed, pressure, and temperature. The origin of the word calibration is itself more recent and has its roots in the words caliber and caliper, which initially related to the measurement and manufacturing of firearms that were capable of using bullets of similar size. As measurement devices became more sophisticated, the quantification of contents such as percentages of each component material, bulk properties, trace properties, particle size distributions, and morphology became feasible *via* calibration [1, 2].

Calibration gradually became synonymous with the gradations on scales, thermometers, barometers, and other measurement scales. The success of the industrial revolution rested largely on the ability to produce and use products with standardized properties. As measurement processes continued to become more sophisticated, calibration was then (and is now) used to generally describe the process by which a mathematical relationship is used to systematically relate known measurements (standards) to different, related, but directly measurable properties. This calibration, a mathematical relationship that is statistically estimated, allows the property of interest to be either directly measured or estimated from the indirect measurement(s).

Calibration may be direct or indirect in nature. Calibration is most direct when the measurement scale is in some sense a copy of the standard (a standard defines a known measurement quantity). This occurs with measurement devices such as a ruler, which measures distance directly on its gradations of distance. A mercury thermometer appears to allow the direct measurement of temperature, but instead relies on the manufacturer's calibration relating temperature to the expansion of mercury in a custom tube. The manufacturer has already provided a mechanism for directly reading temperature. A scale that uses springs, appears to directly measure weight, but instead is making use of the relationship between spring compression and the mass placed on the scale

to report a weight. On such devices, calibration has already been performed by the scale manufacturer and these devices may allow a limited degree of user adjustment to the manufacturer's calibration to remove scale bias. If nothing is placed on the scale, a weight of zero is expected. If the scale provides a nonzero result with nothing on it, then an adjustment knob allows the scale to be reset to zero.

For indirect calibration, an instrument measures a response to another variable and this variable can be related to the property of interest through the process of calibration. Most modern analytical instruments such as gas chromatographs (GC), ion-coupled plasma mass spectrometers (ICP-MS), liquid chromatographs (LC), and atmospheric pressure ion mass spectrometers (APIMS) rely on an indirect calibration process. All such instruments require standards to relate what each of these instruments actually measure to the quantified composition of a measured material. For example, with a GC the instrument collects response data over a time domain. Response data from a particular range of time domains can be associated with the response to the concentration of interest. Often the peak area of the data under the curve of the instrument response to the concentration of interest is used as the instrument's response for the purpose of calibration. A GC does not measure concentration directly; rather it measures a signal that can be related to concentration if the relationship between instrument response and concentration can be quantified. This is typically accomplished *via* a mathematical model whose parameter(s) are statistically estimated. Establishing such a quantification of a relationship between instrument response and the measurement of interest is calibration. Most modern measurement instruments rely on indirect calibration (the measuring instrument is not itself a standard). American National Standards Institute (ANSI) defines calibration as the process of determining the deviation of indicated values of an instrument from those of a standard with known uncertainty traceable to the National Institute of Standards and Technology (NIST).

Elements and Styles of Calibration

The elements of calibration include the following:

- an analytical instrument or methodology that serves as a scale;

2 Calibration

- a standard or a series of standards whose properties are known;
- a measurement procedure for using the standard(s) to perform calibration;
- typically a statistical **estimation**/modeling procedure to establish the instrument's scale by relating to how the instrument responds to the measurement of the standard(s); and
- a measurement procedure for the analysis of sample(s).

The process of calibration involves at least several of the following series of statistical concepts:

- accuracy (bias)
- precision
- experimental design
- modeling
- confidence and tolerance intervals
- change detection

Calibration is often performed in two very different modes: research and production. Research-mode calibration is often performed by analytical professionals who are developing and verifying the performance of a measurement method/calibration model. It involves greater effort in that more data than are ultimately required for calibration are collected and evaluated to determine either an optimal or simply a reasonable calibration model/measurement strategy. Production calibration is often performed by laboratory technicians or production personnel using established measurement protocols. Production calibration tends to be minimal in its approach; the calibration model used and the number of measurements utilized are often the minimum required for the task.

Nature of Calibration Models

Many calibration models are univariate in nature, where only one instrument response is being related to the property of interest. Univariate calibration models tend to be monotonic functional forms and tend to have high R^2 values compared to many other general regression modeling situations. The simplest quantitative calibration model is a line that passes through the origin. This model form has only one parameter, the slope. It can be estimated from as little as one measurement from a single standard (single-point calibration, see Figure 1). Although calibration

professionals often chafe at the use of a single standard for the purpose of calibration, even when it is prepared and/or measured multiple times to establish calibration, single-point calibration is often practiced in production environments. Single-point calibration typically relies on a linear model that is assumed to pass through the origin. Use of the origin assumes that when nothing is present or nothing is happening in the system, the measurement instrument will provide a response of zero. Good calibration practice is to verify that one's calibration system either behaves in the assumed manner or if it does not, that the errors introduced are acceptably small. In such a system, the calibration model is defined by the line passing through the two points; the origin and the average response to the single level of calibration standard studied. Although estimation of a single-point calibration model can be done *via* basic geometry, further discussion takes the perspective of calibration models being estimated through some form of regression analysis.

A single-point calibration model is of the form $Y = b \times X$ where Y is the average response, X is the "known" value of the single standard used to establish calibration, and b is the slope of the line. In the traditional regression framework, the "known" is the dependent variable and the variable subject to random measurement error (the response) is illustrated as the independent variable. The issue of how error enters into the calibration standard (the "known") will be discussed later. Expressing the model in this manner is most satisfactory for the statistician since such a model formulation yields the best chance of having an appropriate interpretation of model significance, confidence limits on parameters, and **confidence interval** for the model or an individual point. Such statistical quantification does require the single level of standard to have been measured more than once. This formulation is not convenient for the calibration practitioner. The intent is to use the calibration model to predict estimates of the "known" scale from measured values of response. This requires the inverse of the model, $X = Y/b$. A common calibration shortcut (especially with harder-to-invert calibration model forms) is to reverse the roles of the independent and dependent variables for the purpose of model estimation. While this reversal has *no* impact on the estimated calibration model for single-point calibration, such a variable reversal does impact multipoint calibration.

Figure 1 Single-point calibration model

In multipoint calibration, a relationship is estimated from two or more different levels of standards. The calibration relationship may be linear (Figure 2) or nonlinear in nature. When estimating such a model using regression analysis, as long as an equal number of measurements are taken on each combination of each unique level of standard utilized, the *identical* estimated calibration model will result, regardless of whether the model was estimated using the average response at each point or all of the individual measurements as separate points. If the number of measurements is unbalanced this will not be the

case. Even in the balanced data collection case where the same calibration model is estimated regardless of the data level used, the statistical interpretation of the results will differ significantly. The best statistical interpretation will result from performing the regression analysis that does best in terms of meeting the assumptions implicit to the form of regression analysis utilized.

In multipoint calibration models, reversal of the independent and dependent variables will almost always result in a *different* calibration model even when a model as simple as a line is fit. This

Figure 2 Linear multipoint calibration model

4 Calibration

phenomenon originates from the assumption of the typical regression algorithm that the independent variable(s) are known and the measurement of the dependent variable is subject to random error as well as the impact of the independent variable(s). Models with high explanatory power will be impacted the least by such variable reversal. The reliability of the statistical interpretation of a calibration model is contingent on having met the key assumptions utilized in model fitting. Fitting should be done where assumptions (form of the calibration model and nature of the error model) are best met using a statistically appropriate fitting criterion. Another reason calibration practitioners will often select the measured quantity to take the role of the independent variable in regression analysis (besides simpler inversion) is that any predictions as well as statistical confidence intervals will then be directly expressed in terms of what the calibration model is ultimately targeted at predicting. Such variable reversal has potential ability to corrupt much of the statistical interpretation of a calibration model, *if* doing so violates key assumptions of the statistical analysis methodology used in model estimation.

If a method's measured response is the appropriate dependent variable and the variables are not

reversed, then the statistical confidence intervals are with respect to the dependent variable. To obtain intervals for the independent variable one needs to generate tolerance intervals for the predictions (Figure 3). Specialized regression methodologies that allow for random errors in both the response variable and the levels of the standards used in calibration exist. Such errors-in-variables (EIV) model algorithms are relatively uncommon in laboratory software and are often difficult to use properly with small data collections; even more so with ones that include nonindependently generated working standards. In the classical regression framework in which the errors are implicitly assumed to be only in the dependent variable in the least-squares fitting process, variable reversal for a linear calibration model ultimately has little impact on both the prediction and the confidence intervals for an individual prediction, other than introducing some relatively negligible patterned bias in both. This occurs since linear calibration models generally have high explanatory power.

Instrument manufacturers strive to make their instruments provide as simple a calibration model as possible. Much energy is expended by instrument manufacturers to devise instruments with a linear response over as broad a range as possible. Linear

Figure 3 Tolerance interval example

models allow for easy calibration, model inversion, and relatively straightforward model estimation. The assumption of linearity in a calibration model should routinely be checked before using a linear calibration model.

Multivariate Calibration

Although measurement methods and instruments are often designed to be as univariate as feasible, this is not always possible to achieve. A more difficult calibration situation occurs when instrument responses are multivariate rather than a univariate. In such a situation, each instrument response is a joint function of at least two things that the instrument can either measure or be impacted by and can be simultaneously present in samples and standards. Such joint effects are often called *matrix effects*. The most basic tool for dealing with matrix effects is the method of *standard addition*. This is a calibration study that uses a sample with an unknown level in conjunction with one or more samples that have been spiked with known additional amounts of the component of interest. In standard addition, the calibration is typically specific to the sample being measured. If only one spiked sample is utilized, the underlying calibration model is nothing more than a line forced through the origin (single-point calibration equivalent). Attempting more complex model forms through standard addition can be a relatively risky exercise in estimation. If standard addition is not sufficiently reliable to resolve matrix effects, a multivariate calibration model is required [3].

Multivariate models require extra effort in every way. They are more difficult to invert, more difficult to specify, more difficult to name a reasonable error model for, more difficult to obtain appropriate fitting software for, more difficult to get statistical prediction intervals for the quantities of primary interest, require more calibration standards that may also be more difficult to manufacture, and typically require use of DOE (design of experiments) methodologies to obtain efficient calibration sets. Most violations of assumptions in a multivariate modeling situation add patterned bias to the calibration model's predictions. A particular aspect of the multivariate calibration model is that being inside the multivariate region bounded by the lower and upper limits for each of the related variables contained in the standard does

not a guarantee that a prediction did not originate from a "hidden extrapolation" of the model. As with all prediction methodologies, model extrapolations of calibration models typically yield less-reliable forecasts than model interpolations.

Fitting Criteria

Fitting criteria, the version of **least squares** that is used to estimate a calibration model is often critical. For some methods, the traditional "ordinary" least-squares (OLS) approach used in elementary statistics texts is sufficient. For some instruments, a weighted least-squares (WLS) approach will provide more reliable calibration models and estimates. For some (often multivariate) calibration problems, partial least squares (PLS) can be useful. For many instruments used in the measurement of trace contaminant levels, WLS analysis is more appropriate than OLS analysis [4, 5].

Checking Calibration

Calibration is typically checked in a variety of ways. One way is to independently make or obtain standards that are then not used in the process of calibration. These independent standards are then measured as samples and these measurements *versus* the known values serve as a check of the reliability of the calibration. A *recovery study* is another means by which calibration can be checked. Recovery studies involve adding a known amount of a material that also can be present in a given sample and measuring both the sample and the "spiked" sample and observing by differencing how well the measurement method recovers the value of the known spike. When multiple measurements and samples/standards are involved in such studies summary statistics such as the mean and standard deviation are used sometimes in conjunction with *t* tests, *F* tests, and ANOVA (analysis of variance) methodologies.

When calibration is an issue between multiple laboratories, a common statistical tool is a round-robin study. In a typical **round robin**, each laboratory measures the "same" samples some number of times each while possibly also doing this for multiple operators, multiple dilutions, multiple extractions, multiple preconcentrations or any other key processing steps,

and/or multiple instruments from within each laboratory. Round-robin studies are typically focused on how well different laboratories can measure the same thing. DOE methodologies are often used to build such studies and ANOVA techniques are frequently used to analyze such data.

Working Standards and Traceability

Laboratories frequently need to rework an out-of-range primary standard into the working standards that span the range of interest of their applications for calibration. For example, NIST may only provide a 1-ppm standard for the constituent in question. The practitioner may require a 1-, 2-, 5-, 10-, and 20-ppb standard for their calibration process. Frequently, such working standard manufacturing processes may involve another dilution or even a sequence of multiple dilutions. There is a great deal of statistical science involved with how to optimally perform a given dilution in terms of the best number of dilution steps required *versus* the accuracy and precision characteristics of the dilution process. A common labor-saving shortcut used by practitioners for some multistep dilution sequences is to do a serial dilution (each dilution is based on the prior dilution and not by starting the dilution sequence with the primary standard again). This strongly impacts the resulting error structure in that any precision error in the first dilution step shows up as an accuracy error in any subsequent dilution step. Dilution is not the only way in which working standards derived from primary standards are prepared; in some instances preconcentration may be required.

Calibration standards also may or may not have traceability. Traceability is the process that leads back to the primary standard and this standard's value and estimated reliability. If a working standard is traceable to a primary standard, then it may be possible to quantify the likely reliability of such a working standard through appropriate application of techniques such as simulation or propagation of errors.

Limit of Detection Concepts

Another key calibration-related concept is that of limit of detection (LOD). LOD is an important figure of merit for a measurement process when the measurement process may be utilized in a range

of values close enough to zero to provide relatively unreliable measurements. There are many other alternative acronyms for LOD or LOD-related concepts including LLOD (lower limit of detection), LDL (lower detectable limit), LOGD (limit of guaranteed detection), MDL (method detection limit), and LOQ (limit of quantification). Many LOD concepts estimate the smallest value that is statistically distinguishable from zero. Numerous organizations and technical publications have defined many differing techniques for LOD determination and for some techniques there are published variants to address perceived weaknesses [6, 7, 8, 9].

For the consumers of the data produced from calibration processes, the most useful version of a detection limit is an MDL although versions of detection limits that focus only on a detector's reliability (example: detector signal to noise definitions) or other parts of a measurement method can be useful for a measurement professional to understand as well. Good MDL definitions include the variability from the calibration process as part of the definition. This is because the reliability of any measured result that has inherently utilized calibration also has been impacted by the uncertainty introduced by the calibration process itself. Some examples of good MDL definitions in this respect include the ISO and the SEMI MDL definitions [10].

Limitations of Statistical Toolsets

Statistical tools, in current common usage in calibration practice, do not directly incorporate many of the characteristics inherent to common calibration processes. Commonly used statistical methods do not distinguish between standards that have been manufactured independently from those that have been manufactured from another standard in a serial fashion. Commonly used regression or other fitting tools do not fully incorporate the error hierarchy that takes place for a given measurement. For example, a standard may have been sampled once, prepared once, and this sample/preparation may have been measured four times. This is a very different error structure/statistical scenario from a standard having been sampled four times, with each of these four samples having been independently prepared and measured once each. The former scenario requires much less effort to obtain the four measurements than the

latter. Such important distinctions are often routinely ignored in subsequent modeling of calibration data. Much further work needs to be done in this area to develop and refine statistical tools that appropriately integrate the substructure of typical calibration processes and get these tools, with appropriate training, into the hands of analytical professionals.

Other Issues

Some of the other areas in calibration in which statistical tools or comparisons are particularly useful include tasks such as instrument tuning, selection of the best instrument response or responses to use in calibration, calibration model identification algorithms, signal averaging, drift correction, and the evaluation of the state of calibration, or determining the optimal frequency or strategy of when to recalibrate. Analytical professionals have also adopted many specific calibration referencing strategies such as the use of internal standards or external standards as part of a calibration process to have the capability of statistically removing certain systematic errors that may impact a given measurement or a group of measurements. Other bias-removal techniques are based on the use of DOE strategies [11].

THOMAS J. BZIK

Kano Analysis

Overview

In the early 1980s, Dr. Noriaki Kano of Tokyo Rika University introduced several concepts aimed at understanding quality better as the customer defines it. They were intended for application in **quality function deployment** (QFD), but can also be used as stand-alone concepts to help companies improve their quality, and respond to market opportunities and needs.

One of these concepts is called *attractive quality* and *must-be quality* [1]. It describes the continuum over which a customer values a particular feature or attribute of a product or service.

Attractive quality is a feature that the customer does not necessarily expect but is delighted when it is present. When properly implemented, attractive-quality features typically add to a company's market share, depending on the added cost to the customer. In 2007, an automobile with a built-in GPS (global positions system) was introduced and this feature would fall on the attractive-quality side of the continuum.

Must-be quality is a feature that the customer expects to be present and will not pay extra for it. If a must-be-quality feature is not present or is poorly implemented, the company can incur serious customer dissatisfaction and possibly lose market share. Today, antilock brakes on cars would fall on the must-be-quality side of the continuum.

Dr. Kano points out that the position of any quality feature is not static on this scale over time. What starts as an attractive quality, a delight to customers when it is present, often moves to be a must-be quality over time as more companies provide this feature routinely. A good example of this is air bags on automobiles. Originally an attractive-quality feature, air bags first appeared on just the driver's side; soon all manufacturers had them. Then they were added to the passenger's side, and now all new cars have them there, too – a reflection of their must-be status. More recently, side air bags have been added, and so forth. Similarly, cameras on cell phones have moved rapidly over time from attractive quality to nearly must-be quality.

Kano analysis is also commonly called the *Kano model*. This incorporates additional analyses of quality from a customer's perspective and has been actively studied and applied [2].

DEBRA SHENK

Change Management, Stakeholder Assessment in

Introduction

The stakeholder assessment process is used by project leaders in change management to understand each stakeholder's level of influence, authority, and control in the organization as well as his level of involvement and commitment to support a particular project. The process is used by those leading projects that change processes, systems, equipment, software, and facilities. The goal of change management is to ensure that the organization is fully prepared to function once the project is completed and turned over to the organization to operate. Organizational changes may include new or revised roles and reporting relationships, staffing levels, facilities, procedures, education and training, and workplace culture [1, 2].

Stakeholder Definition

For this article on change management, "stakeholder" is defined as an individual or group of individuals with an interest (stake), something to be gained or something to be lost, in the outcome of the change initiative and whose interests must be recognized for the project to be successful. Freeman and McVea propose that by adopting a view of stakeholders as real people with names and faces rather than roles, project leaders can understand how collections of individuals can work together in organizations to create value that benefits all those who are affected [3].

The types of stakeholders can be both internal and external to the organization. They include customers, suppliers, end users, project team members, leaders, and functional groups having a governing responsibility such as, environment, health and safety, legal, procurement, facilities, logistics, and information technology.

Stakeholder Assessment Objective

The objective of stakeholder assessment is to ensure success of an organizational change initiative by identifying, gaining, and keeping the appropriate

levels of support and involvement of all individuals and groups having a stake in the project's outcome.

Stakeholder Assessment Process

There are two components to the assessment. First, the project leader collects data assessing each stakeholder's level of involvement and commitment to the project. Stakeholder interviews reveal whether they will most likely oppose, allow, assist, perform, or even sponsor the project as described in Table 1. Second, an assessment is made whether they will exert a high, medium, or low level of influence, authority, or control over the project. The project leader will plot the resulting assessment of each stakeholder on the matrix in Figure 1.

Stakeholder Involvement and Commitment

The benefit of understanding a stakeholder's level of support for a particular project is to (a) identify those in the organization who can support the project by providing resources and/or performing work and (b) understand early on where the project may face serious challenges from those who do not support the project and may work against the project team's efforts. With this understanding, project leaders will be able to formulate a strategy and take action to minimize the effect of those who oppose, and leverage those who support to expedite the project.

High					
Influence Authority Control					
Low					
	Oppose	Allow	Assist	Perform	Sponsor
	Involvement & Commitment				

Figure 1 Influence and Involvement Matrix

2 Change Management, Stakeholder Assessment in

Table 1 Stakeholder Involvement and Commitment Descriptions

Oppose	This stakeholder clearly opposes the project and will attempt to block an action taken by the project team.
Allow	This stakeholder may not agree with the project, but, will allow the project to proceed. He may not directly support it.
Assist	This stakeholder agrees with the project and while not taking a leadership role, will help in some way to ensure the success of the project.
Perform	This stakeholder usually has a strong interest in the project's success and will take responsibility for a significant portion of the project.
Sponsor	This stakeholder is required on every project and will provide the resources, leadership, and visibility at the top of the organization necessary for the success of the project.

Using Table 1, project leaders will select the category that best represents each stakeholder.

Stakeholder Influence, Authority, and Control

The second assessment is to understand a stakeholder's ability to affect the behavior of others in the organization through the control of information, expertise, resources, or authority. This is a key understanding in that the stakeholder's influence can impact the project in a favorable or unfavorable manner.

Stakeholder Assessment Summary

The project leader will record the results of the stakeholder assessment in a format similar to the one shown in Table 2. Each entry identifies what is at stake including what each expects to gain (or lose) once the project is completed.

Influence and Involvement Matrix

Matrix Objective

The objective of the matrix is to provide a graphic representation of the stakeholder assessment results

and from this to develop strategies to increase support for the project and remove the barriers to the project's success.

Project Sponsor

If the project sponsor has not been identified yet, the first step is to identify one. This step is very important and a project's likelihood for success is extremely low without an effective project sponsor.

The project sponsor is accountable for the project's business benefits realization and has macro-level scope control. The project sponsor will also ensure the project is appropriately resourced to achieve the intended results and will undertake regular project reviews and make necessary adjustments. The project sponsor may also hold the executive role as well. Staying connected to the executive or top governing level in the organization is necessary to ensure the project has the appropriate level of visibility and support in the organization to be successful. If the project sponsor does not hold the executive role, he will need to periodically inform the executive of the progress the project is making against the intended objectives.

Table 2 Stakeholder Assessment Summary

[illegible]

To identify a project sponsor, project leaders look for stakeholders with a high level of influence and involvement, someone who believes in the value of the project and is willing to use influence to ensure that the project is completed successfully. The matrix can be used in discussions with potential sponsors to illustrate the other stakeholders' positions on the project.

Influence and Involvement Gaps

Project leaders next look for gaps on the matrix where there is insufficient support. These influence and involvement gaps can occur where a high level of influence and low level of involvement exists. In this case, the stakeholder has power in the organization but does not currently support the project. The goal is to develop strategies to increase support for the project or remove the barriers. This can be accomplished by moving "high-influence" and "low-involvement" stakeholders to "high-influence" and "high-involvement" positions. If these stakeholders understand how the project will benefit them, they will use their influence to make it happen. However, if they continue to oppose the project, the project leader's goal is to lessen their influence by moving

them to a "low-influence" and "low-involvement" position on the matrix. This may be accomplished through intervention by the project sponsor or senior leaders of the organization.

Additionally, insufficient support occurs where a low level of influence and high level of involvement exists. These stakeholders are very supportive of the project yet lack the influencing ability to push the project along. Increasing their influence may be accomplished by involving them in governing the project, perhaps through steering committees and enhanced project roles.

Stakeholder Action Plan

With each stakeholder's current position located on the matrix, and gaps in influence and commitment identified, the project leader will develop a strategy and action plan to resolve issues and reposition stakeholders to the desired locations. Project leaders will record the action plan in a table similar to Table 3.

Table 4 provides a summary of the stakeholder assessment process and is used by project leaders as a "to-do" list to communicate with others and to keep the assessment process moving forward.

Table 3 Stakeholder Action Plan

Stakeholder	Current Position	Desired Position	Action Plan to Resolve Issues and Reposition Stakeholders

Table 4 Stakeholder Assessment Process Summary

1. Identify individuals or groups that will be most affected by the outcome of the project and list them as stakeholders.
2. Determine their current level of involvement and commitment.
3. Determine their current level of influence, authority, and control.
4. Locate each stakeholder's current position on the influence and involvement matrix.
5. Identify the interests and outstanding issues associated with each stakeholder.
6. Identify the desired location for the stakeholder and draw an arrow from their current location to the desired location.
7. Create a strategy and action plan to resolve the issues and reposition stakeholders by changing their influence and/or involvement.

Summary

Projects, by their nature, create change within organizations. Some changes are subtle and others monumental. Understanding how those who have a stake in the outcome are involved enables project leaders to plan and implement strategies for increasing support and reducing barriers to project success.

Bridges clarifies the difference between change and transition. “*Change* is situational: the new site, the new boss, the new team roles, the new policy. *Transition* is the psychological process people go through to come to terms with the new situation. Change is external, transition is internal.” Using stakeholder assessment is a way in which project leaders may favorably influence organizational changes by involving key individuals, with names and faces, in the change process [4].

THOMAS F. TRABERT

Policy Deployment for Performance Improvement

Introduction

Organizations that win in the long term “plan their work and work their plan”. Realization of strategy – the long-term vision of an organization is achieved by a disciplined approach to setting direction and then executing that direction through the effective use of the organization’s resources. In Japan this method is called *policy deployment* – which has also been called the *secret weapon* in the Japanese management system. Policy deployment is the strategic direction-setting methodology used to identify business goals, as well as to formulate and deploy major change management projects throughout an organization. It describes how strategy cascades from vision to execution in the workplace through a collaborative engagement process that also includes implementation details like performance, self-assessment, and management review. It describes a systematic relationship between strategy development and the organization’s daily imperative to measure and manage its operations using a system that aligns the actions of its people to produce collaboration among the various business functions and processes to produce requirements for customers.

Historical Development of Policy Deployment

What were the circumstances under which policy deployment originated? Interest in strategy, market focus, and long-term, balanced planning were generated by the visits of Dr. Peter F. Drucker to Japan in the early 1950s [1]. As a result of his teaching, “policy and planning” was added to the Deming Prize checklist in 1958. Bridgestone Tire Corporation first used *hoshin kanri*, the Japanese term for policy deployment, in 1965. In 1976, Dr. Yoji Akao and Dr. Shigeru Mizuno were involved in the implementation of *hoshin kanri* in Yokagawa Hewlett–Packard (YHP) as part of its pursuit of the Deming Prize. By 1982, YHP had used *hoshin* to manage a strategic change that moved it from the

least profitable Hewlett–Packard (HP) division to the most profitable. In 1985, this *hoshin* methodology was introduced to the rest of HP as a lesson learned from the YHP Deming Prize journey. From HP this methodology was transferred to other leading companies including Proctor & Gamble, Ford, Xerox, and Florida Power & Light, involving several advisors and councilors of the Union of Japanese Scientists and Engineers (JUSE). The work of the GOAL/QPC research committee also extended the managerial technology of policy deployment and was a key ingredient in introducing policy deployment across North America and through multinational companies, to the world [2].

Foundations of Policy Deployment

Mizuno defined *hoshin kanri* as the process for “deploying and sharing the direction, goals, and approaches of corporate management from top management to employees, and for each unit of the organization to conduct work according to the plan”. *Hoshin kanri* is a comprehensive, closed-loop management planning, objectives deployment, and operational review process that coordinates activities to achieve desired strategic objectives. The word *hoshin* refers to the long-range strategic direction that anticipates competitive developments while the word *kanri* refers to a control system for managing the process [2].

This management system does not encourage random business improvement, but focuses the organization on projects that move it toward its strategic direction. It builds strength from its relationship with the daily management system that is focused on *kaizen* – continuous improvement. *Hoshin* seeks breakthrough improvement in business processes by allocating strategic business resources (both financial and human resources) to projects that balance short-term business performance to sustain improvement toward its long-term objectives. In a policy deployment management system this two-pronged approach integrates operational excellence in the daily management system with architectural design of its long-term future. This planning process contains two objectives: *hoshin* – the long-range planning objectives for strategic change that allow an organization to achieve its vision and *nichijo kanri* – the daily, routine management control system (or daily management system) that translates the strategic objectives into the

2 Policy Deployment for Performance Improvement

Figure 1 The system of hoshin kanri of managing policy

work that must be accomplished for an organization to fulfill its mission. The blending of these two elements into a consensus management process to achieve a shared purpose is the key to success for the policy deployment process. In a *hoshin* planning system, strategy is observed through the persistence of its vision – how it is deployed across cycles of learning in project improvement projects that move the performance of the organization’s daily management system toward its direction of desired progress.

The fundamental premise in policy deployment is that the best way to obtain desired results for an organization is for all employees to understand the long-range direction and participate in designing the practical steps to achieve the results. This form of participative management evolved and was influenced by the Japanese refinement of Drucker’s management by objectives (MBO) through the birth and growth of the quality circle movement. To manage their workplace effectively, workers must have measures of their processes and monitor these measures to assure that they are contributing to continuous improvement as well as closing the gap toward the strategic targets. Policy deployment became the tool that Japanese business leaders used to engage their workers in a strategic dialog and align their work with the consensus strategic direction of their firm. When HP first implemented *hoshin* planning, many of its business leaders explained how it worked by calling it “turbo-MBO”.

Policy deployment links breakthrough projects that deliver the long-term strategic direction to achieve sustainable business strength while, at the same time, delivering an operating plan to achieve short-term performance. The methods of policy deployment anticipate long-term requirements by focusing on annual plans and actions that must be met each year to accumulate into long-term strength. Policy deployment processes begin when senior management identifies the key issues or statements of vulnerability, where improvement will have its greatest impact on business performance. This perspective

is an essential starting point for policy deployment and allows management to focus a strategic dialog to solicit ideas from frontline workers regarding the opportunities for improvement that exist in their workplace. As Dr. Noriaki Kano of the Tokyo Science University points out, without such direction “the ship would be rudderless”. The communication of the focus area or theme for improvement provides a cohesive direction to assure alignment of the entire organization and to build consensus between the management team and the workers on business priorities.

Hoshin helps to create the type of organization that William McKnight, former CEO of 3M, expressed as his desire: “an *organization* that would continually self-mutate from within impelled forward by employees exercising their individual initiative” [3]. In this type of organization, creativity is managed through a combination of self-initiated improvement projects, which engage teams to combine individual capabilities for achieving strategic projects that make a difference to the whole organization. How does this change management process work at the frontline where these strategic *hoshin* projects interface with the organization’s routine work processes?

Perhaps the reason *hoshin kanri* took hold within HP is that this methodology demonstrated its ability to translate qualitative, directional, or strategic goals of an organization into quantitative, achievable actions that focus on fundamental business priorities achieving significant competitive breakthroughs – in short, the leaders at HP recognized *hoshin kanri* as MBO done right!^a The extension of this methodology beyond HP to other leading firms came about because HP was recognized as possessing the best practice for linking its strategic direction with its operational management systems.

Daily Management System

Policy deployment uses a systems approach to manage organization-wide improvement of key business

processes. It combines the efforts of focused teams on breakthrough projects with the efforts of intact work groups who continuously improve the performance of their work processes. All strategic change occurs in projects that accomplish those activities that are necessary to achieve the stretch business objectives that assure sustained success for the organization. Policy deployment systematically plans ways to link strategic direction with those business fundamentals that are required to run the business routine successfully. Policy deployment allows management to commission change projects for implementation and to review the implementation of a system of projects and thereby to manage change. It seeks opportunities disguised as problems – and elevates those high-priority changes required for the improvement of the daily management system and work processes into business change objectives that are accomplished as *hoshin* projects.

Routine operation of the daily management system requires a foundation in management by fact, or the combination of business measurement with statistical analysis and graphical reports that illustrates the current state of performance, historical trends, and is able to extrapolate trends through statistical inference. A key ingredient is the business fundamentals measurement system that includes the set of basic process results measures that are monitored at control points within the organization where the flow of its throughput can be managed based on the requirements that are driven (using a pull system) by the customer requirements. This measurement system should include both predictive and diagnostic capabilities.

HP embedded its daily management system into a work process measurement system that they initially called *business fundamentals tables*. Other companies refer to the set of measures that translate strategic goals into operational measures of work (in units such as quality, cost, and time) as either a customer dashboard or a balanced scorecard. These systems are used to monitor the daily operations of a business and to report to the management on the progress in the process for developing and delivering value to customers. This measurement process must operate in close-to-real time to permit process owners to take appropriate corrective action that will limit the “escapes” of defects to external customers by catching and correcting errors before they are released from the organization, and finding and fixing

mistakes as they occur at the source. Such measures of core work processes are called *business fundamentals* because they must operate under control for the business to achieve its fundamental performance objectives.

These measures must also be captured at the point where control may be exercised by process operators to adjust the real-time operation of the process and assure meeting the customer’s performance requirements on a continuing basis. As the great Dutch architect Miles van der Rohe once observed “God is in the details” and it is in these details that business must effectively operate. A daily management system defines the details of an organization’s operations. Thus, the measurement and the point at which it is both monitored and controlled are parts of the daily management system and at this point they must be related to their contribution to deliver organizational performance objectives. In the language of Six Sigma, a “Business *Y*” (such as “profitable growth”) that must be achieved is the strategic goal, while a “Process *X*” (such as “creditworthy customers”) delivers this result by process-level performance through the **transfer function** $Y = f(X)$ and the “*X*” is therefore a fundamental business measure of the organization’s daily management system.

Collins and Porras describe how leading companies stimulate improvement by *evolutionary progress*. “Evolutionary” describes progress that resembles the organic growth or the way that species evolve and adapt to their natural environments. Evolutionary progress differs from the big hairy audacious goals (BHAG) of strategic progress in two ways. First, whereas BHAG progress involves clear and unambiguous goals (“We are going to climb *that* mountain”), evolutionary progress involves ambiguity (“By trying lots of different approaches, we’re bound to stumble onto something that works; we just don’t know ahead of time what it will be”). Second, whereas a BHAG involves bold discontinuous leaps, evolutionary progress begins with small *incremental* steps or mutations, often in the form of quickly seizing unexpected opportunities that eventually grow into major – and often unanticipated – strategic shifts. Evolutionary progress represents a means to take advantage of unplanned opportunities for improvement that are observed at the point of application – the daily management system. The accumulation of many evolutionary improvements results in what looks like part of a brilliant overall

4 Policy Deployment for Performance Improvement

strategic plan [4]. Both types of change are needed to stimulate the organic growth of an enterprise. If an organization can make improvements in the “right X’s” then it will improve its performance on the critical Business Y.

Choosing Strategic Direction

Hoshin kanri begins with a process for choosing strategic change. In most firms, this process is called strategic planning. Proposed changes are usually identified to either increase the competitive performance of a process or to create the competitive “attractiveness” of a product to its targeted market. Strategic choice in both dimensions is essential to have a globally competitive organization. As pointed out by Dr. Hiroshi Osada, many Japanese companies have not paid enough attention to the critical aspects of strategy formulation as they have to the deployment of their strategy using *hoshin kanri*. This leads to an error of effectively deploying a poorly chosen strategy. When management confuses the mechanistic aspects of policy deployment with its own crucial obligation to establish strategic direction, then they create a grievous error that is truly an abrogation of leadership. An organization may effectively deploy management’s strategic choice, however, if the choice of strategy is not carefully directed it will not lead to improvement [5].

Osada notes that in traditional Japanese management systems, ideas flow “bottom-up” from the workplace to the management. However, in policy deployment, there is also a top-down approach to planning change. As Osada comments, policy deployment “is a simple tool for effectively deploying a given policy, and has therefore been broadly adopted by Japanese industry, it does not aid in policy formulation. Even when employing management by policy (MBP), therefore, the question of whether or not a given policy is appropriate will remain. It is thus possible for an inappropriate policy to be effectively deployed – to a counterproductive effect” [6]. Strategic direction must be determined by discovering the alternatives for achieving the organization’s vision and choosing the direction that will accomplish it. This direction is modified through the power of the incremental change to act as the “rudder” that steers the ship by making “finely tuned” changes to the general direction of the strategy.

What are the essential ingredients in choosing strategic direction? This process of management integrates strategic planning, change management, and project management with the performance management methods that focus on delivering results. Some specific work activities in designing and implementing a policy deployment system include the following:

- identifying critical business assumptions and areas of vulnerability,
- identifying specific opportunities for improvement,
- establishing business objectives to address the most imperative issues,
- setting performance improvement goals for the organization,
- developing change management strategies for addressing business objectives,
- defining goals project charters for implementing each change strategy,
- creating operational definitions of performance measures for key business processes, and
- defining business fundamental measures for all subprocesses to the working level.

Once a strategy has been set, the next challenge is to align the strategic direction with the work that is being performed in the daily management system.

Aligning Operations with Strategies

A critical challenge for organizations is to align their strategic direction with their daily work systems so that they work in concert to achieve the desired state. Alignment must include linking cultural practices, strategies, tactics, organization systems, structure, pay and incentive systems, building layout, accounting systems, job design, and measurement systems – *everything*. In short, alignment means that all elements of the company work together much like an orchestra leader integrates the various instruments to conduct a coordinated symphony. Organizations that apply the most mature aspects of policy deployment do not put in place any random mechanisms or processes, but they make careful, reasoned strategic choices that reinforce each other and achieve synergy. These organizations will “obliterate misalignments”. If you evaluate your company’s systems, you can probably identify some

specific items that have misaligned with its vision and impede its progress. These “inappropriate” practices have been maintained over time and have not been abandoned when they no longer align with the organizational purpose. “Does the incentive system reward behaviors inconsistent with your core values? Does the organization’s structure get in the way of progress? Do goals and strategies drive the company away from its basic purpose? Do corporate policies inhibit change and improvement? Does the office and building layout stifle progress? Attaining alignment is not just a process of adding new things; it is also a never-ending process of identifying and doggedly correcting misalignments that push a company away from its core ideology or impede progress” [7].

The System for Policy Management

Policy deployment combines both the “target and the means to achieve the target” into a consensus-generating, management decision-making process. Improvement targets are described using four elements: a performance measure to be improved, direction and rate of improvement desired, targeted improvement magnitude, and timeframe for achievement of the target. A means to achieve the target describes a set of specific actions that will be taken to deliver the desired results. These means may differ across the organization, based upon the initial, local management self-assessment, or “current state analysis” that is conducted to assess the business area’s starting point for change and determine the magnitude and nature of the performance gap to be closed by the change management or *hoshin* project to deliver the desired state.

Peter Drucker once commented “for full effectiveness all the work needs to be integrated into a unified *program for performance*” [8]. The program for performance is designed by the top management team to provide a specific, effective course of action to achieve its desired results. To achieve these results, all the dimensions of the business must be consistent with each other. This is the job of the policy deployment system.

This system for managing policy consists of *kanri* or control mechanisms that deploy business policy through four essential steps in order to execute management’s program for the business direction using a systematic sequence of steps that achieve *hoshin*

project objectives within the constraints of assigned resources. These four steps define policy setting (or establishment of *hoshin* projects), deployment (or propagation of these projects throughout the organization), implementation (or integration of the results of change into the daily management system), and review (or assessment of the results achieved from the process) (see Figure 1). These four steps will be described in the next four sections of this chapter.

Policy Setting

Policy setting is a top-down “catchball” whereby management conducts “strategic dialog” with employees to collect ideas and opinions about chronic major problems and their aspirations regarding the business future, and then processes this information in conjunction with environmental data analysis and scenario analysis to formulate the annual business change objectives (which some organization call their *hoshin* projects): strategic change projects (identified by both targets to be achieved and means for achievement). In this phase, organizations recognize the most critical projects that must be accomplished to eliminate vulnerabilities or capture the benefits from potential change initiatives or newly emerging improvement opportunities. For organizations to succeed they must undergo a rigorous analysis of both their fundamental work processes to identify business imperatives (things that must change) and their current strategic direction to determine potential business vulnerabilities from competitive, economic, or technological changes.

This system structures application of continuous improvement into strategic and operational dimensions. David Packard incessantly used the term *continuous improvement* beginning in the early 1940s – it is not a new term – but as Collins and Porras describe its adaptation in leading companies that have adapted to change, they observe that it is an essential structural ingredient in those companies that have been *Built to Last*: “Visionary companies apply the concept of self-improvement in a much broader sense than just process improvement. It means long-term investments for the future, it means investment in the development of employees; it means adoption of new ideas and technologies. In short, it means doing *everything* possible to make the company stronger tomorrow than it is today” [9].

Most organizations operate on three levels of managerial thinking: enterprise thinking assures their

long-term viability; strategic thinking focuses on products, markets, and customers; and operational thinking focuses on the daily work that delivers the organization's results. Strategies align to these three areas of focus: "Management strategies can be classified into three types – corporate strategy, business strategy, as well as functional and cross-functional strategy – depending on the level of the corporate organization to which they apply. The corporate strategy, which delineates the fundamental direction of the whole company, is certainly very important for realizing a management vision; but it would be no exaggeration to say that the success or failure of the corporate strategy is determined by the particular business strategies, since it is through these business strategies that the aims of the corporate strategy are actually implemented" [10]. The portfolio of specific strategies that any organization pursues must be managed to deliver the risk – benefit performance desired by the organization in order to achieve its desired results – whether for breakthrough results or just for incremental improvement of a specific business area.

How is this approach to planning conducted? The corporate planning process should deliver increasing business brand value to balance financial risk and reward. This planning process consists of three elements: strategic planning, business planning, and functional planning that must all fit together in an integrated planning system. The strategic planning process is conducted at the enterprise level of the business thinking to identify which business opportunities to exploit and how to sustain the ability of the organization to meet or exceed its annual performance objectives. The business planning process is conducted at the business level of thinking and its objectives are to drive market share to accelerate financial payback, build customer loyalty, and decrease market risk. At the operational level of thinking, the functional planning process improves all process performance to reduce cost, cycle time, and defects while enhancing responsiveness to customers and delivering customer satisfaction.

A business strategy should deliver "visionary" performance: strategy is the persistence of a vision over the long term – and it requires both vision setting and vision deployment to assure alignment in strategic direction. Policy deployment provides direction to guide these plans and assures that the organization moves in a coherent direction. The more robust a plan for required change, the more

effective the organization's ability is to accomplish this plan. Robustness is a function of the management team's ability to see beyond its operating horizon and understand what may occur in its planning horizon that requires its focus and attention today.

What is a planning horizon? It is the distance that an organization "sees" into the future to study and understand the potential impacts of events on its policies and prepare it for evolving situations that may impact its current or future performance. Organizations tend to have four distinct planning horizons.

- **Business foresight**

Managing for the long term to assure that the organization is not surprised by changes in the assumptions that it has made in the design of its business model and product line strategy (focusing on a 3–10-year business outlook).

- **Strategic direction**

Managing for the intermediate-term changes in technology and competitive dimensions to assure that vulnerabilities in the business model are not exploited and to bridge the chasm that may exist between product line introductions (focusing on the next 3–5 years of business operation, depending on the degree of change that is anticipated in the business environment).

- **Business plans**

Managing the short-term fluctuations of the market – a planning horizon that delivers against short-term fluctuations in demand or supply (focus on quarterly and annual operating plans).

- **Business controls**

Managing the current state of a business – a planning horizon that delivers today's performance and assures rapid responses for corrective actions required to sustain advertised service levels (focus on the daily–weekly–monthly–quarterly operating plans to deliver the targeted results in the annual plan).

How is strategic policy formulated? Strategic direction is best established using cross-functional dialog to capture all the inputs of the organization and to build a common direction, based on the consensus of how to boost organizational strengths and overcome organizational weaknesses in the face of critical business threats to capture the most important market opportunities. Most organizations have just two kinds of strategic decisions: those that may

be executed within the areas of their direct oversight of top management (e.g., personnel decisions, budgeting, merger, capital budgeting, etc.) and those that require cross-organizational collaboration for implementation. These cross-functional projects require special attention and project management to realize the objectives of the change initiative. Such change strategies that require mutual consent and collaboration are ideal for a policy deployment system. In addition to planned continuous improvement that is a result of problem solving, continuous improvement may also result from process management, whenever a process is consciously enhanced over time.

Osada encourages strategic engagement of all employees through the following ways:

- recognizing product life stage (product life cycle analysis)
- analyzing business and product position objectively (positioning analysis)
- analyzing competitiveness (competitive analysis)
- perceiving strengths and weaknesses of products (SWOT analysis)
- forecasting future competitiveness using **time series** data (time series analysis)
- maintaining transparency through visualization (visual method); involving all employees [11].

Osada encourages using seven strategic tools (the S-7 tools) in policy setting:

1. environment analysis
2. product analysis
3. market analysis
4. product–market analysis
5. product portfolio analysis (product portfolio management, PPM)
6. strategic elements analysis
7. resource allocation analysis [12].

But, all these tools and methods are employed as staff-directed preconditions for strategic planning in the planning approaches of many Western organizations where they link the three planning systems (strategic, business, and functional) with the business and environmental assessment analyses that precede strategic decision-making. While this linkage may be a bit weaker in Japanese firms, in Western firms, such issues do not appear to be a critical shortfall. However, without complete integration of these planning processes it is difficult to obtain the degree of

effectiveness in deployment of shared resources that permits breakthrough achievement to occur. What is breakthrough achievement in management? Breakthroughs represent at least an order-of-magnitude change in performance that is accomplished over a relatively short period of time. Breakthrough is achieved by developing a capability to choose the right objectives for planned change and then aggressively executing these objectives. This requires two factors: identification of what to change and the timing of when to change it. The job of top management is to decide which lever of change must be pulled in order to accomplish the desired result.

Other success factors that are significant in achieving breakthrough plans include the right action to achieve the desired state of change. Right does not mean comprehensive or exhaustive, but it implies a budgeting of energy that focuses an organization on catalytic actions that stimulate organizational response in the desired direction – applying a limited capital budget and the best people to accomplish those important objectives that they have been personally developed to concentrate on. A second success factor in the management of breakthrough projects is the capacity of an organization to convert objectives into results. Excellence comes from execution of plans, not just from planning. To execute, an organization must be mobilized to consolidate their energy and coordinate their actions to achieve shared objectives for the common good of the organization as an organism – a living entity that requires appropriate nourishment and execution of all its bodily functions. A third critical success factor for breakthrough management is the capacity of an organization to integrate specific improvements into standard operating practices that are consolidated across the entire organization for maximum leverage effect. This success factor is based on the existence of a business control management system that holds the gains from improvement projects and is able to assure that performance degradation does not occur – people do not slip back into their “old way of doing things”, but that they embrace the new methods as their routine way of working. This success factor is addressed in the policy deployment and policy implementation steps.

It should be noted that breakthrough change projects can only be accomplished if the daily work processes are operating under reasonable control. If a business is not operating under control, then

8 Policy Deployment for Performance Improvement

the “breakthrough” activity should focus on bringing itself under control before making a significant investment in strategic change. When an organization’s daily management system is operating under control, then more time is available for strategic change because management is not “fighting fires” or “expediting execution” of routine work. This requires that the management start this journey by evaluating its readiness to make strategic changes in its operating system.

To maximize the effectiveness of policy deployment, the strategic direction setting and implementation processes should identify the highest priority business process improvement projects and the requirements for accomplishing them. For instance, only some of these projects will require the degree of diagnostic sophistication that is available from a Six Sigma Black Belt while others will require intensive capital investment or software development to accomplish their objectives. Only when management chooses change projects that improve the infrastructure of its business processes – work processes whose performance contributes to the common cause variation of the business performance – can the most significant gains be realized from a comprehensive business improvement effort. How does management achieve this focus? The short answer is that management must put in place the methods to “recognize” their priority business improvement needs by linking their choice of change management projects to the strategic direction of their business so that the portfolio of change management projects drives the policy changes that are necessary to achieve the long-term performance objectives of the organization. Some of the questions that must be addressed during policy setting include the following:

- What is our business and what results do we expect to achieve? How will we know that we have achieved these results? Is this the best we could do?
- What are our assumptions about society, the economy, market and customers, technology, and knowledge? Are they still valid?
- Has anything happened that would change the dynamics of our industry or markets?
- What would change mean for our business position?

- Are there any opportunities that we should anticipate and capitalize upon to our long-term advantage?
- Where should we choose to excel? Can we take action on this opportunity?

Policy Deployment

While policy setting sets organizational policy, the policy deployment step deploys policy change to the organization by changing the way that effective work is accomplished in the daily management system.

How are the *hoshin* or strategic change objectives deployed? Policy deployment is the heart of this policy management system and has received much attention because of the “catchball” approach that aligns the objectives of the organization and then balances work by resource leveling and prioritization of improvement activities. An implementation plan for a change project is a living document – it acts like a compass to guide an organization while allowing employees to take ownership by participating in choices that define the reasoning behind the project as well as the steps in the project’s execution. Change projects can identify two types of improvement effort – either by a breakthrough project or by a continuous improvement project – to change the way work process activities function. Breakthrough activities are strategic change projects that make a significant shift in the organization’s capability to perform routine operational work processes or deliver products (either goods or services) to the marketplace. Work process continuous improvement (*kaizen*) activities are part of a daily management system that defines how work is accomplished. The *kaizen* change activities are the responsibility of all work process owners. This planning approach focuses on guidelines for major improvement projects (while small incremental or continuous improvements are made through the regular course of continuous improvement of the daily routine work). The distinction between these activities is twofold: first, more of the organization’s resources are focused on breakthrough projects, and second, accomplishment of a breakthrough project usually occurs over a multiple-year period (or as a series of coordinated improvement projects). One important management consideration in choosing breakthrough projects is that the combination of all the annual breakthrough projects (also called the *portfolio of change projects*) will define the steps that an organization chooses for

accomplishing strategic change in the range of its midterm planning horizon (1–3 years).

To achieve “saturation” of policy (which consists of both targets and the means for their achievement) in the organization – or complete deployment of change projects within the whole organization that is affected by the defined policy change – and assure collaboration of all the affected work groups, the objectives cascade of an action plan for a particular improvement project must involve not only functional deployment of policy but also engage its cross-functional aspects. It is across the functional seams of an organization where most significant difficulties are encountered and these boundaries represent focus areas for management to assure continuous collaboration in the execution of change projects and consensus among the various functional organizations that engage all the decision-making managers in the areas where the change will have a direct effect. To understand the difficulty that the boundary condition dynamics have, consider what happens as change is managed when organizations shift work activities from internal to external units (e.g., from internal manufacturing to an external contract manufacture). At such boundary conditions, conflicting objectives and political issues of the organizations often can interfere with performance improvement work and it is the job of the management team to eliminate any such barriers to the success of their project team. This also happens within organizations at their functional boundaries.

Catchball is the process that is used to build a consensus through dialog about the targets and means to achieve the change. This process is data driven and uses tools that permit management by facts. Catchball links annual change projects to midrange and long-term plans – deployment prior to annual fiscal year commencement, incorporated into target setting and annual employee objectives cascade; coordinated both vertically within functions and horizontally across processes and negotiated across the processes to allocate resources (competence, funding, and equipment) to achieve the shared and agreed objectives. The catchball process includes four activities:

- building alignment through linked cascade of means

- setting business performance targets and objectives
- cascading business objectives to the workplace (*gemba*)
- achieving alignment of improvement and effective resource allocation.

Policy deployment is a structured, systematic, and standardized process and it has an ability to empower organizations to achieve strategic change. Policy deployment includes a few key elements that assure that an organization is properly and fully engaged in change projects:

- *Policy* – a general rule or operating principle that describes a management-approved process to approach a business condition or situation based on how it chooses to control its work and manage risk. Once the right policy has been determined, then the organization can handle similar situations with a pragmatic response by adapting its policies to the concrete situation that it faces. Truly unique business situations that run counter to the critical business assumptions require the full attention of the senior management team to evaluate how these situations challenge the boundary conditions of the business model and threaten its policies of operations with change that is imposed from externalities. Policies consist of targets and means.
- *Target* – the measurable results that are to be achieved within a specific timeframe for performance. Targets have checkpoints.
- *Checkpoints* – a measurement point that is used to evaluate an intermediate state in the policy deployment process to demonstrate that progress is being made. The data collected at a checkpoint can be reported to management in interim project status reports. The checkpoint of one process is the control point of the next process – the checkpoints and control points work together to formulate a “waterfall” that cascades across the implementation plan flow and is part of the business measurement system.
- *Check items* – check items and process or project variables that are evaluated to enable organizations to understand the causes that contribute to the outcome of a particular policy.
- *Means* – the sequence of actions that an organization will take to implement a policy or choice of the management team that is an outcome of the

strategic direction-setting process. Means have control points.

- *Control points* – a point in a sequence of work activities where corrective action may be taken or countermeasures are put in place to resolve a concern or issue that has been identified at a checkpoint.
- *Control items* – control items verify whether results agree with the established goals – does the work demonstrate progress in accomplishments that will enable the final achievement of targets?
- *Deployment* – the process of engaging the entire organization in an appropriate participation in the strategic direction both vertically (within functional areas) and horizontally (across the functional areas) by creating shared ownership of the implementation actions. The entire system of deployment is “connected” from the long-term vision to the daily management activities. The plans are progressively more detailed as they are refined in deployment from the top levels of the organization to the frontline employees and teams. The plan is deployed through an organization by negotiating the means between management layers (levels) as well as across the functional departments. Targets are not negotiated.
- *Catchball* – the joint analysis process that encourages a strategic dialog between levels of organizational deployment is called a *catchball*. The means at one level become the desired outcomes of the subsequent level. This cascading of targets and means establishes the linkage and alignment of objectives across organizational levels. Mutual discussion between the parties – a two-way communication that is both top-down in general direction and bottom-up in adaptation to the workplace using the existing hierarchical management structure and matrix process structure to engage all parts of the organization in the dialog. This dialog is a negotiation process (see *nemawashi* and *sureawashi* below) that arrives at a collective wisdom to develop and refine the implementation plan.
- *Nemawashi* – negotiation – prior consultation to achieve consensus; careful preparation of the roots of a plant for transplantation; and seeking to achieve *wa* or harmony, consensus, and absence of conflict.
- *Sureawashi* – the sharpening of a sword requires four ingredients: a blade, a template for the angle to be produced, oil to ease the process, and a sharpening stone to remove the unwanted material. This analogy is used for policy deployment. The use of data makes the objectives cascade a fact-based process, not just a subjective negotiation process. Mutual consultation occurs between the organizational levels in order to test the feasibility of planned process improvements and to refine any conflicts between the objectives of the organizational layers. This process opens communication channels and establishes both agreement and alignment in the way people work. This dialog is necessary to obtain buy-in and define achievable plans that middle managers are committed to implement.
- *Shibui* – a state of uncluttered, beautifully efficient austerity – the perfect balance or harmony (*wa*) between not enough and too much – used to describe the desired state or vision of a business system.

Peter Drucker quotes the Roman law in order to focus management on the things that are most important: “*De minimis non curat praetor*” (The magistrate does not consider trifles) [13]. This warning to management against what has been called “micro-management” is a reason for senior executives to focus on the vital few issues that are critical in the business that they manage. If they do not take the time to manage these important things, then no one else will. If they choose to spend their time focused at the detail level of project execution, then they will squander a more effective use of their time on those vital activities that engage the higher thinking levels of the organization that cannot be reasonably delegated to others for effective action. Management must work on a long-term planning horizon in order to deliver sustained organizational strength. It must also review current actions to assure that short-term profitability is being achieved. But, whenever management spends more time on the short-term issues than it does on the long-term ones, it sacrifices future strength in favor of current results – and displays to the entire organization its lack of trust in the ability of the organization to perform its daily work. This behavior signals to the entire organization that a crisis exists and reinforces stagnation as the workers wait for the top management to intervene and make the decisions that they

should more properly make. A very important benefit of an effective policy deployment system is delegation of appropriate decision rights to the proper place in the organization where the best information exists and where action will be taken to implement that decision.

Some of the questions that are addressed during policy deployment include the following:

- What are the consequences of not doing this project?
- What are the risks inherent in this project?
- What will happen to the business if this project does not succeed?
- What will success in this project commit the business to?
- How does this project add to the total economic results of performance?
- Have we assigned our best people to work on breakthrough opportunities?
- Have we communicated clearly and taken into consideration all objections before chartering the project?

Policy Implementation

Policy implementation consists of the execution of the project plan – both the actions taken by the team involved in the change and the in-process management reviews. All change is implemented on a project-by-project basis according to management's priorities and the logical sequence for attacking each opportunity for improvement. The project plan typically will use a Gantt chart to assign clear responsibility for each improvement item in the implementation plan and to record its activity progress in accomplishing the project subtasks. Senior managers should also conduct regular progress reviews of each change project to monitor team progress in improvement, assure that the projects advance, and eliminate any possible barriers, roadblocks, or bottlenecks that restrict the project's advancement. Senior management should also monitor the execution of the change projects that they sponsor to assure that these projects will deliver the desired gain in the daily management system. If the project review indicates that insufficient progress is being made, then they can develop some countermeasures or reallocate resources so that appropriate corrective actions are taken to assure continued progress.

Another activity that occurs during the policy implementation is publication of information about the ongoing change projects so that the entire organization is informed of the actions being taken to improve performance. This communication can help the organization to align other activities with progress being made on these strategically focused change projects. As a guideline for communication, the management should inform all involved parties of any changes to the change project team's mission, vision of the outcome, guiding principles, or objectives. If the management team communicates effectively and often, then it will translate the planning rhetoric into action realities. Peter F. Drucker observed that "The most time consuming step in the process is not making the decision, but putting it into effect. Unless a decision has degenerated into work it is not a decision; it is at best a good intention" [14].

Some of the questions addressed during policy implementation include the following:

- Have we placed the right people in the right jobs to give the project the best opportunity to succeed?
- Does this project team have everything that it needs to get the job done?
- Are all the people who need to know about this project being informed?
- Are all the right actions across the organization being taken to assure success?
- Is this project implementation the best utilization of the knowledge and ability of the organization's people?
- Does this project implementation make the best overall contribution from use of the organization's limited resources (people, time, and money)?

Policy Review

As the annual cycle of change projects nears completion, results of project implementation efforts should be evaluated to determine performance against targets, shortfalls from expected performance, completion rate, and causes for both under- and overachievement. Specific action must be identified to compensate for performance deficiencies and prevent recurrence of such problems in future change management projects. Diagnosis of the performance of the policy planning process is conducted to drive improvements in planning systems. "Feedback has to

be built into the decision to provide a continuous testing, against actual events, of the expectations that underlie a decision” [15].

Policy review is accomplished in two ways: through management self-assessment (by senior managers as well as by local managers evaluating their activities to determine where they have opportunities for improvement: either performance enhancements or problem resolution) and through operating reviews of the results produced by the local organization where senior managers identify areas where results are not aligned with expectations for performance. Policy review applies two subprocesses to perform these duties: performance review and business measurement.

Aligning Objectives through Performance Review. The review process seeks to identify conformance to plans (e.g., is there any shortfall or overachievement in targets?). Once nonconformity is identified, then the root cause of the deviation is discerned to determine an appropriate response to the out-of-control type of condition. Both corrective actions and countermeasures are identified to realign the process and assure that process integrity and stability are achieved in the business control system. The following actions may be taken in response to an out-of-control condition:

- emergency countermeasures to alleviate the immediate issue, concern, or problem;
- short-term corrective action to prevent the specific problem from recurring; or
- long-term preventive action to remove problem root causes and mistake-proof the process making a permanent solution and preventing the problem from recurring.

The review step facilitates organizational learning by examining problem areas and critical success factors to discover what directional shifts need to be accomplished in order to achieve the desired end state or vision of the business. Strategy is the persistence of the vision – achieved one project at a time through exercising constancy of purpose in the business planning process. These project reviews are conducted to assess achievement relative to the following planning elements:

- change project objectives
- business planning objectives and corporate commitments

- business improvement plans
- economic plans and projections
- customer requirements and expectations
- competitive performance analysis
- business excellence self-assessment.

Questions addressed during this policy review include the following:

- What results have been demonstrated from this project?
- Which results were expected and which results were unexpected?
- What will this project’s outcome do for customers?
- What have we done well that our competitors have done poorly?
- What have we done poorly that our competitors seem to have no problem with?

Business Control and Management Responsibility. The ultimate objective of MBP is to establish a reliable organization – one that creates predictable results through the effective coordination of value-adding work that customers perceive as meeting their needs. In this environment, all employees are aware of their personal contribution to the objectives of the entire organization and are able to make local choices that are aligned with the strategic direction because they understand how the strategy affects their work and *vice versa*. To assure that these local decisions are aligned with strategic direction, it is the responsibility of the management team to develop a measurement system that provides employees with the visible line of sight from their work activities to its contribution to strategic direction. In this measurement system, it is essential that causal linkages (e.g., built using a Six Sigma $Y = f(X)$ transfer function) be established so that effective control can be executed at the local operating level.

Benefits of Policy Deployment

A policy deployment system orchestrates continuous improvements with breakthroughs to assure that the organization attains its long-range goals. Those elements of long-range plans that can be achieved in a one-year period are identified and become the focus or “vital few” goals to be achieved during that year. Policy deployment plans the way that change is implemented in an organization’s daily management

process. Accomplishments of such a planning system include

- communicating the vision required for sustained success,
- identifying and choosing breakthrough activities or projects required for the vision,
- orchestrating the direction of an organization's change,
- developing plans and projects that support the business objectives,
- aligning the organization's change efforts both vertically and horizontally,
- ensuring that the plan is effectively and efficiently executed,
- reviewing the progress in executing plans,
- changing plans when it is proved necessary to achieve targets,
- learning from the experience of planning and executing.

"If you can think of new methods to preserve the core, then by all means put them in place. If you can invent powerful new methods to stimulate progress, then give them a try. Use the proven methods *and* create new methods. You must do both" [16]. The imperative for organizations that endure is to do both breakthrough improvement and evolutionary improvement – both change management and routine management – at the same time. This is what Collins and Porras call "the genius of AND" – an inclusive approach to planning and executing change that requires organizations to embrace both aspects of change simultaneously.

The most important thing about priority decisions that face a business is that they are made and communicated deliberately and conscientiously. In a system of MBP, all the important decisions are visible and there is an opportunity for dialog to guide these decisions into the direction that the organization, as a whole, is influenced by the knowledge of all its members. In such a system the key decisions that drive toward its common goals are not made haphazardly, but with the full awareness of the organization. Such open decision processes elicit cooperation of the entire organization in the implementation and review of its activities to assure that it will be able to meet its desired outcomes. The responsibility of the management is to put in place a system of decision-making that generates this degree of collaborative work toward the common end.

Criticisms of Policy Deployment

Despite their application in many leading companies, policy deployment systems have been criticized for their mechanistic use of forms and templates that some see as restricting individual creativity. Some also believe that these planning systems lack strategic emphasis and do not engage the full organization as participants in strategy formulation. Osada summarizes the shortcomings of policy deployment as observed in some Japanese companies.

1. It is difficult for those at the middle management level and below to understand the process of formulating strategic policy. Compared with [editor note: the process for] policy deployment, the process of policy formulation is unclear [editor note: poorly understood and communicated] an indication of management's view that such form of communication is of little value.
2. Strategic policy is ostensibly based on the long-term interests of the firm, but there is no way to judge whether a policy is appropriate, or even truly 'strategic' [editor note: in the essential nature of the policy itself].
3. Several problems in formulating a long-term strategic plan are not addressed, for instance:
 - 3a. Changes in operating environment and other uncertainties are not adequately accounted for; possible difficulties are therefore not foreseen.
 - 3b. Positioning of business is not perceived objectively. The question of whether business aims are optimum and clear is not addressed.
 - 3c. Only one part of the staff, at the top level, participates in strategic policy formulation; it is therefore difficult to judge whether a policy reflects the reality at the "front line" of operations [10].

It must be observed that not all of these objections are strongly negative. Organizations must ask if they must really involve frontline employees actively in formulating strategy. Nokia Mobile Phones uses a current state analysis for self-assessment of front-line operations and then rolls this data into their strategy-setting process. They also create a "strategic dialog" that builds participation of midlevel managers in conversations about strategy. Other organizations open communication lines through email forums and

internal surveys. In such instances, the objection is not critical to the total impact of policy deployment implementation. Additionally, any argument that says “Every employee should have an *interest* in matters of strategic policy” is a very different argument than saying that every employee should be actively involved in *formulation* of business strategy. Satisfying employee interest in strategy can be addressed by improving communications. Also, a broad involvement of employees in formulation of strategy increases risk of inappropriate public statements or inadvertent disclosure of the company’s strategy in venues where competitors may discover sensitive information that can be used against the organization. Whenever this occurs, a company loses its competitive advantage. The challenge for management is to build a strong consensus, without risking disclosure of their strategic direction to competition. It is another challenge of the management to balance these concerns in a way that is appropriate to their way of working and business culture.

Summary

Policy deployment, when coupled with a statistically based business measurement system, has been observed in several leading companies to create a robust management process that engages an entire organization in the strategic planning process. It assures line of sight from the strategic goals of the organization to the operational tasks that workers perform at the front line as they do the work that produces the organization’s goods or services. The nature of this process can be described using the term “robustness” – a statistical state in which a process is able to accept variation in its inputs, without influencing the variation of its outputs. Such a process is capable of performing consistently – delivering consistent results according to its design intent. Because policy deployment engages the workforce in achieving its common goal of sustained success, this methodology has become a strategic tool for assuring sustained competitive advantage over current and potential business rivals.

Sustained success must be “dynamic” to achieve its enduring state. That is, it must provide continuous advantage despite changes in the environment, regulatory shifts, technological breakthroughs, or competitive market. Anticipating potential actions by rivals is critical to delivering sustained success. To

enjoy such sustained success, an organization must master the skills of priority setting and project management to assure that they effectively define and deploy the right initiatives that result in sustained success. Advantage means staying ahead of rivals and this requires that organizations not only make continuous improvements but also use “breakthrough” opportunities to distinguish themselves in their marketplace as a differentiated provider of products and services. This type of management requires managerial competence in three areas: business vulnerability analysis, action planning administration, and operational excellence. The best implementations of policy deployment will engage its employees in the strategy-setting processes as well as the organization’s change management process.

End Note

^a It must be noted that Peter F. Drucker initially discussed MBO in Japan in the mid-1950s. Drucker taught management concepts to the Japanese along with Dr. Joseph M. Juran and Dr. W. Edwards Deming. At that time Dr. Juran and Dr. Deming worked in the Graduate Management School of New York University under the supervision of Dr. Drucker.

GREGORY H. WATSON

Classification and Regression Tree Methods

Introduction

Classification and regression are two important problems in statistics. Each deals with the prediction of a response variable y given the values of a vector of predictor variables $\mathbf{x}$. Let $\mathcal{X}$ denote the domain of $\mathbf{x}$ and $\mathcal{Y}$ the domain of y . If y is a continuous or discrete variable taking real values (e.g., the weight of a car or the number of accidents), the problem is called *regression*. Otherwise, if $\mathcal{Y}$ is a finite set of unordered values (e.g., the type of car or its country of origin), the problem is called *classification*. In mathematical terms, the problem is to find a function $d(\mathbf{x})$ that maps each point in $\mathcal{X}$ to a point in $\mathcal{Y}$. The construction of $d(\mathbf{x})$ requires the existence of a *training sample* of n observations $\mathcal{L} = \{(\mathbf{x}_1, y_1), \dots, (\mathbf{x}_n, y_n)\}$. In computer science, the subject is known as *supervised learning*. The criterion for choosing $d(\mathbf{x})$ is usually mean squared prediction error $E\{d(\mathbf{x}) - E(y|\mathbf{x})\}^2$ for regression, where $E(y|\mathbf{x})$ is the expected value of y at $\mathbf{x}$, and expected misclassification cost for classification.

If $\mathcal{Y}$ contains J distinct values, the classification solution (or *classifier*) may be written as a partition of $\mathcal{X}$ into J disjoint pieces $A_j = \{\mathbf{x} : d(\mathbf{x}) = j\}$ such that $\mathcal{X} = \cup_{j=1}^J A_j$. A *classification tree* is a special form of classifier in which each A_j is itself a union of sets, with the sets being obtained by recursively partitioning the $\mathbf{x}$ space. This permits the classifier to be represented as a *decision tree*. A *regression tree* is similarly a tree-structured solution in which a constant or a relatively simple regression model is fitted to the data in each partition.

To illustrate, consider a dataset of new cars for the 2004 model year from the *Journal of Statistics Education Data Archive* (www.amstat.org/publications/jse/jse_data_archive.html). After filling in missing values and correcting errors, we obtain a dataset with complete information on 15 variables for 428 vehicles. Table 1 gives the definitions of the variables and Figure 1 shows two classification trees for predicting the *Region* variable, that is, whether the vehicle manufacturer is from Asia, Europe, or the United States (there are 158 Asian, 120 European, and 150 US vehicles in the dataset). Each

intermediate node has a condition associated with it. If an observation satisfies the condition, it goes down the left branch; otherwise it goes down the right branch. Each leaf node is labeled with a predicted class, with cross-hatched, light gray, and dark gray denoting Asia, Europe, and the United States, respectively. Beneath each node is a fraction, giving the number of misclassified samples divided by the number of samples. It is easily seen from the trees that *Dcost* is an important predictor for European cars: 125 of 159 cars with *Dcost* greater than \$30,045 are European. Of cars with *Dcost* less than or equal to \$30,045, those with 3.5-l or larger engines are six times as likely to be American, while those with smaller engines are predominantly Asian.

A classification or regression tree algorithm has three major tasks: (a) How to partition the data at each step? (b) When to stop partitioning? and (c) How to predict the value of y for each $\mathbf{x}$ in a partition? There are many approaches to the first task. For ease of interpretation, a large majority of algorithms employ *univariate* splits of the form $x_i \leq c$ (if x_i is noncategorical) or $x_i \in B$ (if x_i is categorical). The variable x_i and the split point c or the split set B are often found by an exhaustive search that optimizes a *node impurity criterion* such as entropy (for classification) or sum of squared residuals (for regression). There are also several ways to deal with the second task, such as stopping rules and tree pruning. The third task is the simplest: the predicted y value at a leaf node is the class that minimizes the estimated misclassification cost (for classification) or the fitted value from a model estimated at the node (for regression).

We review and compare below a few of the more established and widely available algorithms. First, we introduce some notation. Let N_j be the number of class j training samples and let $\pi(j)$ be the prior probability of class j . At each node t , let $N_j(t)$ be the number of class j training samples in t and let $p(j|t) = \pi(j)N_j(t)/N_j$ denote the estimated probability that an observation in t belongs to class j . It is easily verified that $p(j|t) \propto N_j(t)$ if $\pi(j) \propto N_j$.

CART and RPART

We first discuss CART [1] classification with the *Gini index* as node impurity criterion, $i(t) = 1 - \sum_{j=1}^J p^2(j|t)$. Suppose a split divides the data in

2 Classification and Regression Tree Methods

Table 1 Variables in the car dataset

Name	Definition	Values (#unique values in parentheses)
Region	Manufacturer region	Asia, Europe, or United States (3)
Make	Make of car	Acura, Audi, etc. (38)
Type	Type of car	Car, minivan, pickup, sports car, sport utility vehicle, or wagon (6)
Drive	Drive type	Front, rear, or four-wheel drive (3)
Rprice	Suggested retail price	US dollars (410)
Dcost	Dealer cost	US dollars (425)
Engnsz	Size of engine	Liters (43)
Cylin	Number of cylinders	−1 for the rotary-engine Mazda RX-8 (8)
Hp	Horsepower	Hp (110)
City	City miles per gallon	Miles (29)
Hwy	Highway miles per gallon	Miles (32)
Weight	Weight of car	Pounds (347)
Whlbase	Length of wheel base	Inches (40)
Length	Length of car	Inches (66)
Width	Width of car	Inches (18)

Figure 1 RPART (a) and QUEST (b) trees for Region. At each intermediate node, an observation goes to the left branch if and only if the condition shown at the node is satisfied. Leaf nodes that are cross-hatched, light gray, and dark gray are classified as Asia, Europe, and the United States, respectively. The fraction below a leaf node gives the number misclassified divided by the sample size. The total numbers misclassified are 119 for RPART and 106 for QUEST

t into a left node t_L and a right node t_R . Let p_L and p_R be the proportions of data in t_L and t_R , respectively. CART selects the split that maximizes

the decrease in impurity $i(t) - p_L i(t_L) - p_R i(t_R)$. Instead of employing stopping rules, CART generates a sequence of subtrees by growing a large tree

and pruning it back until only the root node is left. Then it uses cross-validation to estimate the misclassification cost of each subtree and chooses the one with the lowest estimated cost. The tree in Figure 1(a) is produced by RPART [2], a version of CART implemented in R [3].

Like the AID and THAID [4, 5] algorithms before it, CART has some undesirable properties. First, the splitting method is biased toward variables that have more distinct values. This is because a variable with m distinct values allows $(m - 1)$ splits if it is noncategorical and $(2^{m-1} - 1)$ splits if it is categorical. The bias was first noted in [6] and is discussed in [7]. Second, the exponential number of splits for categorical variables causes serious computational difficulties when m is large and y takes more than two values (a computational trick reduces the number of splits searched to $(m - 1)$ if y takes two values). Finally, the algorithm is also biased toward variables with more missing values. This is due to the impurity function depending only on the sample proportions, not the sample sizes. During split selection, if a variable x_i has missing values, only the observations nonmissing in both x_i and y are used in computing the decrease in impurity. Thus it is easier to “purify” a node by splitting on a variable with more missing values [8].

For regression, CART uses the sum of squared **residuals** as the impurity function and builds a piecewise-constant model with each leaf node fitted by the training sample mean. Everything else remains the same as in classification. For example, Figure 2 displays a RPART tree for predicting H_p with variables Region, Type, Drive, Engnsz, Cylin, Weight, Whlbase, Length, and Width. The predicted values beneath the leaf nodes show that H_p tends to increase with Cylin and tends to be higher for sports cars.

Piecewise-constant regression trees tend to have lower prediction accuracy compared to other regression methods that have more smoothness. In fact, CART regression trees typically have lower accuracy than even the classical multiple linear model – see, for example, [1, p. 227] and [9]. In the example here, the RPART model has an R^2 value of 75%, compared to 81% for the multiple linear model. One way to increase the accuracy of the piecewise-constant model is to use a larger tree, that is, with less pruning. The correct amount of pruning is, however, usually difficult to determine. Besides, a

Figure 2 RPART tree for predicting H_p . The number in italics beneath each leaf node is the predicted value

large tree is undesirable because it is more difficult to interpret.

QUEST and CRUISE

QUEST [7] is a classification method. It avoids the selection bias and categorical variable computational problems of CART by first selecting the variable x_i and then selecting its split point or split set. This saves a significant amount of computation, because the algorithm does not have to search for the split points or split sets of the other variables. QUEST uses hypothesis tests to choose the split variables, namely, analysis of variance F tests for noncategorical variables and χ^2 tests for categorical variables. The variable with the smallest significance probability is selected to split a node. If the dataset has more than two classes, they are grouped into two superclasses prior to split point or split set selection. This superclass grouping allows application of the CART two-class computational shortcut for splits on categorical variables. The QUEST tree for our dataset is shown in Figure 1(b). It has the same splits at the top two levels as the RPART tree.

CRUISE [8] is another classification algorithm with unbiased variable selection. It differs from QUEST in three important respects: (a) each node can be split into as many as J branches, with one class forming a majority in each branch, (b) the significance tests include interactions between pairs of variables, and (c) it can fit linear discriminant models in each leaf node [10]. Being able to split

Figure 3 CRUISE tree for predicting Region. Cross-hatched, light gray, and dark gray leaf nodes are classified as Asia, Europe, and United States, respectively. The fraction below a leaf node gives the number of misclassified divided by the sample size. Total number of misclassified is 115

Figure 4 CRUISE tree with linear discriminant node models for predicting Region. The fraction below a leaf node gives the number of misclassified divided by the sample size

a node into J branches can be advantageous if J is large, because it increases the probability that at least one leaf node is assigned to each class. For example, Figure 3 shows the CRUISE tree for predicting Region. The vehicles in the left branch ($\text{Dcost} \leq 23\,256$) are mostly from Asian manufacturers and those in the right branch ($\text{Dcost} > 32\,775$) are mostly European.

Figure 4 shows the corresponding CRUISE tree where a linear discriminant model is fitted to the data in each leaf node. Notice how compact it is. This is due to part of the model complexity being absorbed by the discriminant models whose boundaries and data points are displayed in Figure 5. The plot for

node 3 reveals a very expensive car with Dcost more than \$170 000. It is a Porsche.

C4.5 and J48

C4.5 [11] is also a classification tree algorithm. If the variable x_i chosen to split a node is noncategorical, the node is divided into two using a split of the usual form $x_i \leq c$. On the other hand, if the variable is categorical taking m values, the node splits into m branches, with one branch for each categorical value. As a consequence, C4.5 has no difficulty dealing with categorical variables regardless of the size of m . The algorithm chooses the splits as follows. Suppose a node t is split into subnodes $t_1, t_2, \dots, t_k$. Let $e(t) = -\sum_j p(j|t) \log\{p(j|t)\}$ be the entropy at t and define the *gain* of the split as $e(t) - N(t)^{-1} \sum_i e(t_i)N(t_i)$. Define the *gain ratio* as the gain divided by $N(t)^{-1} \sum_i N(t_i) \{\log N(t_i) - \log N(t)\}$. C4.5 chooses the split that yields the highest gain ratio. C4.5 also grows a large tree and then prunes it back to a smaller size. But instead of cross-validation, it uses a conservative estimate of the error at each node for pruning.

Figure 6 shows a C4.5 tree, obtained using the J48 implementation in WEKA [12], with *Drive* as the response variable and *Make* as one of the predictor

Figure 5 Data and linear discriminant boundaries for the nodes of the CRUISE tree in Figure 4. Asian, European, and US cars are denoted by the symbols A, E, and U, respectively. Node 3 has only one boundary: it serves to separate the European and US cars

Figure 6 C4.5 (J48) tree for Drive, with black, white, and, gray leaf nodes denoting front-wheel, rear-wheel, and four-wheel drive, respectively

variables. As anticipated, when *Make* is chosen, the node splits into many branches. This is not a problem in itself, for we can manually merge the leaf nodes associated with the same predicted class. The problem is that each node before merging has too few samples to support further splitting. Hence the tree may be too short.

The avoidance of searching for binary splits on categorical variables and of cross-validation for pruning makes C4.5 one of the fastest classification tree algorithms. Its trees, however, tend to have more leaf nodes than those of other methods [13]. Like CART, it is biased toward selecting variables that allow more splits.

GUIDE

GUIDE [14] constructs piecewise-constant, multiple linear, and simple polynomial tree models for least-squares, quantile, Poisson, and proportional hazards regression. Like CRUISE and QUEST, its variable selection is unbiased. This is accomplished by recursively carrying out the following steps at each node: (a) fit a model to the training data there, (b) cross-tabulate the signs of the residuals with each predictor variable to find the one with the most significant χ^2 statistic, and (c) search for the best split on the selected variable, using the appropriate loss function. After a large tree is constructed, it is pruned with the cross-validation method of CART.

Figure 7 shows the GUIDE tree for predicting H_p when the best simple linear model is fitted to the data in each node (two cars with rotary engines are removed due to the *Cylin* variable being undefined for them). The sample mean value of H_p and the best linear predictor variable are given beneath each leaf node. The first two splits divide the tree into three main branches, with Asian, European, and American makes occupying the left, middle, and right branches, respectively. The most important linear predictors are *Cylin* and *Engnsz*. A major advantage of this model, compared to a piecewise multiple linear model, is that the data and the fitted regression functions can be visualized graphically, as demonstrated in Figure 8. We see from node 5 that European sports cars with large engines have among the highest H_p values. For American cars, H_p increases linearly with

Engnsz, irrespective of the other variables. This GUIDE model has an R^2 value of 84%, which is higher than that of the RPART and multiple linear models discussed in the section titled “CART and RPART”.

Conclusion

All the above algorithms can deal with datasets that have missing values. CART uses “surrogate splits” to pass observations with missing split values through its nodes. CRUISE follows a similar approach, but using an alternative set of splits. It is not known if one method is better than the other. C4.5 uses weights, passing an observation with a missing split value down every branch, where the weight is proportional to the number of observations with nonmissing values in the split variable. GUIDE and QUEST employ nodewise plug-in estimates for the missing values.

CART, CRUISE, and QUEST accept user-specified class prior probabilities and unequal misclassification costs. Class priors are useful if the training dataset is not a random sample. The three algorithms also allow splits on linear combinations of variables. Although such splits are hard to interpret, there is empirical evidence that they have much better prediction accuracy than trees with univariate splits [13]. C4.5 does not

Figure 7 GUIDE piecewise simple linear model for predicting H_p . Beneath each leaf node are the sample mean of H_p and the name of the linear predictor

Figure 8 Data and simple linear regression models at the nodes of the GUIDE tree in Figure 7. The abbreviation *spc* stands for sports car. A plot of H_p versus $Engnsz$ for the whole dataset is given in (i) for comparison

have these capabilities. GUIDE is also restricted to univariate splits, but empirical studies with real datasets suggest that the prediction accuracy of its piecewise multiple linear models is, on average, comparable to that of the best methods, including spline models [9].

There are many other tree algorithms, but space restrictions prevent their discussion here. The interested reader is referred to CHAID [15, 16] for classification, RECPAM [17] for classification and

regression, M5 [18, 19] for regression, LOTUS [20] for logistic regression, and Bayesian CART [21, 22].

In terms of statistical theory, methods based on recursive partitioning are known to be *risk consistent* under certain regularity conditions. Specifically, the expected **mean squared error** of piecewise-constant regression trees and the expected misclassification cost of classification trees converge to the lowest possible values as the training sample size increases

[1]. Further, for piecewise linear regression trees, the predicted values converge to the unknown regression function values pointwise, at least for least-squares [23], logistic, Poisson [24], and quantile [25] regression.

Optimal Reliability Design– Algorithms and Comparisons

Introduction

Optimal reliability design problems are known to be NP hard [1]. Finding efficient optimization algorithms is always a hot spot in this field. Classification of the literature by **reliability optimization** techniques is summarized in Table 1. This paper reviews and compares the recent developments of heuristic algorithms, metaheuristic algorithms, exact methods, and other optimization techniques in optimal reliability design. Owing to their robustness and feasibility, metaheuristic algorithms, especially genetic algorithms (GAs), have been widely and successfully applied (*see Genetic Algorithms in Reliability*). To improve computation efficiency or to avoid premature convergence, an important part of this work has been devoted in recent years to developing hybrid GAs, which usually combine a GA with heuristic algorithms, simulation annealing methods, **neural network** techniques, or other local search methods. Though more computation effort is involved, exact methods are particularly advantageous for small problems, and their solutions can be used to measure the performance of the heuristic or metaheuristic methods [2]. No obviously superior heuristic method has been proposed, but several of them have been well combined with exact or metaheuristic methods to improve their computational efficiency.

Metaheuristic Methods

Metaheuristic methods inspired by natural phenomena usually include the GAs, tabu search, simulated annealing algorithm, and ant colony optimization method. ant colony optimization (ACO) has been recently introduced into optimal reliability design, and it is proving to be a very promising general method in this field. Altıparmak *et al.* [10] provide a comparison of metaheuristics for the optimal design of computer networks.

Ant Colony Optimization Method

ACO is one of the adaptive metaheuristic optimization methods developed by M. Dorigo for traveling salesman problems in [75]. It is inspired by the behavior of real-life ants that consistently establish the shortest path from their nest to food. The essential trait of the ACO algorithm is the combination of *a priori* information about the structure of a promising solution with *posteriori* information about the structure of previously obtained good solutions [76].

Liang and Smith [3] first develop an ant colony metaheuristic optimization method to solve the reliability–**redundancy** allocation problem for a **k-out-of-n**: G series system. The proposed ACO approach includes four stages:

- Construction stage: construct an initial solution by selecting component j for subsystem i according to its specific heuristic η_{ij} and pheromone trail intensity τ_{ij} , which also sets up the transition probability mass function P_{ij} .
- Evaluation stage: evaluate the corresponding system reliability and penalized system reliability providing the specified penalized parameter.
- Improvement stage: improve the constructed solutions through local search.
- Updating stage: update the pheromone value online and offline given the corresponding penalized system reliability and the controlling parameter for pheromone persistence.

2 Optimal Reliability Design– Algorithms and Comparisons

Nahas and Noureldath [5] present an application of the ant system in a reliability optimization problem to maximize the system reliability subject to the system budget, with multichoice constraints incorporated at each subsystem. It also combines a local search algorithm and a specific improvement algorithm that uses the remaining budget to improve the quality of a solution.

The ACO algorithm has also been applied to a multiobjective reliability optimization problem [6] and to the optimal design of multistate series–parallel power systems [4].

Hybrid Genetic Algorithm

GA is a population-based directed random search technique inspired by the principles of evolution. Although it provides only heuristic solutions, it can be effectively applied to almost all complex combinatorial problems, and, thereby, it has been employed in a large number of references as shown in Table 1. Gen and Kim [77] provide a state-of-the-art survey of GA-based reliability design.

To improve computational efficiency, or to avoid premature convergence, numerous researchers have been inspired to seek effective combinations of GAs with heuristic algorithms, simulation annealing methods, neural network techniques, steepest-descent methods, or other local search methods. The combinations are generally called hybrid GAs, and they represent one of the most promising developmental directions in optimization techniques.

Considering a complex system with a known system structure function, Zhao and Liu [49] provide a unified modeling idea for both active and cold-standby redundancy optimization problems. The model prohibits any mixture of component types within subsystems. Both the lifetime and the cost of redundancy components are considered as random variables, so stochastic simulation is used to estimate the system performance, including the mean lifetime, percentile lifetime, and reliability. To speed up the solution process, these simulation results become the training data for training a neural network to approximate the system performance. The trained neural network is finally embedded into a GA to form a hybrid intelligent algorithm for solving the proposed model. Later, Wattanapongsakorn and Levitan [54] used random fuzzy lifetimes as the basic parameters and employed a random fuzzy simulation to generate the training data.

Lee *et al.* [42] develop a two-phase NN-hGA in which NN is used as a rough search technique to devise the initial solutions for a GA. By bounding the broad continuous search space with the NN technique, the NN-hGA derives the optimum robustly. However, in some cases, this algorithm may require too much computational time to be practical. To improve the computation efficiency, Lee *et al.* [43] present an NN-flcGA to effectively control the balance between exploitation and exploration, which characterizes the behavior of GAs. The essential features of the NN-flcGA include the following:

- combination with an NN technique to devise initial values for the GA;
- application of a fuzzy logic controller when tuning strategy GA parameters dynamically; and
- incorporation of the revised simplex search method.

Later, Lee *et al.* [44] proposed a similar hybrid GA called f-hGA for the redundancy allocation problem of a series–parallel system. It is based on

- application of a fuzzy logic controller to automatically regulate the GA parameters;
- incorporation of the iterative hill climbing method to perform local exploitation around the near-optimum solution.

Hsieh and Hsieh [40] considered the optimal task allocation strategy and hardware redundancy level for a cycle-free distributed computing system so that the system cost during the period of task execution is minimized. The proposed hybrid heuristic combines the GA and the steepest-descent method. Later, Hsieh [41] seeks similar optimal solutions to minimize system cost under constraints on the hardware redundancy levels.

Tabu Search

Although Kuo [2] described the promise of tabu search, Kulturel-Konak *et al.* [51] first developed an tabu search (TS) approach with the application of near feasible threshold (NFT) [78] for reliability optimization problems. This method uses a subsystem-based tabu entry and dynamic length tabu list to reduce the sensitivity of the algorithm to selection of the tabu list length. The definition of the moves in this approach offers an advantage in efficiency, since

it does not require recalculating the entire system reliability, but only the reliability of the changed subsystem. The results of several examples demonstrate the superior performance of this TS approach in terms of efficiency and solution superiority when compared to that of a GA.

Other Metaheuristic Methods

Some other adaptive metaheuristic optimization methods inspired by activities in nature have also been proposed and applied in optimal reliability design. Chen and You [56] developed an approach based on immune algorithms inspired by the natural immune system of all animals. It analogizes antibodies and antigens as the solutions and objection functions, respectively. Rocco *et al.* [58] proposed a cellular evolutionary approach combining the multi-member evolution strategy with concepts from cellular automata [79] for the selection step. In this approach, the selection of the parents is performed only in the neighborhood in contrast to the general evolutionary strategy that searches for parents in the whole population. And a great deluge algorithm is extended and applied to optimize the reliability of complex systems in [57]. When both accuracy and speed are considered simultaneously, it is proved to be an efficient alternative to ACO and other existing optimization techniques.

Exact Methods

Unlike metaheuristic algorithms, exact methods provide exact optimal solutions though much more computation complexity is involved. The development of exact methods, such as the branch-and-bound approach and lexicographic search, has recently been concentrated on techniques to reduce the search space of discrete optimization methods.

Sung and Cho [66] consider a reliability–redundancy allocation problem in which multiple choice and resource constraints are incorporated. The problem is first transformed into a bicriteria nonlinear integer programming problem by introducing 0–1 variables. Given a good feasible solution, the lower reliability bound of a subsystem is determined by the product of the maximal component reliabilities of all the other subsystems in the solution, while the upper bound is determined by the maximal amount of available sources of this subsystem. A branch-and-bound

procedure, based on this reduced solution space, is then derived to search for the global optimal solution. Later, Sung and Cho [67] even combine the lower and upper bounds of the system reliability, which are obtained by variable relaxation and Lagrangian relaxation techniques, to further reduce the search space.

Also, with a branch-and-bound algorithm, Djerdjour and Rekab [59] obtain the upper bound of series–parallel system reliability from its continuous relaxation problem. The relaxed problem is efficiently solved by the greedy procedure described in [80], combining heuristic methods to make use of some slack in the constraints obtained from rounding down. This technique assumes that the objective and constraint functions are monotonically increasing. Ha and Kuo [61] present an efficient branch-and-bound approach for **coherent systems** based on a one-neighborhood local maximum obtained from the steepest-ascent heuristic method. Numerical examples of a bridge system and a hierarchical series–parallel system demonstrate the advantages of this proposed algorithm in flexibility and efficiency.

Apart from the branch-and-bound approach, Prasad and Kuo [63] present a partial enumeration method for a wide range of complex optimization problems based on a lexicographic search. The proposed upper bound of system reliability is very useful in eliminating several inferior feasible or infeasible solutions as shown in either big or small numerical examples. It also shows that the search process described in [84] does not necessarily give an exact optimal solution due to its logical flows.

Lin and Kuo [62] develop a strong Lin and Kuo heuristic to search for an ideal allocation through the application of the reliability importance (*see Component Reliability Importance*). It concludes that, if there exists an invariant optimal allocation for a system, the optimal allocation is to assign component reliabilities according to *B*-importance ordering. This Lin and Kuo heuristic can provide an exact optimal allocation.

Assuming the existence of a convex and differential reliability cost function $C_i(y_{ij})$, $y_{ij} = \log(1 - r_{ij})$ for all components j in any subsystem i , Elegbede *et al.* [60] prove that the components in each subsystem of a series–parallel system must have identical reliability for the purpose of cost minimization. The solution of the corresponding unconstrained problem provides the upper bound of the cost, while a doubly minimization problem gives its

lower bound. With these results, the algorithm ECAY, which can provide either exact or approximate solutions depending on different stop criteria, is proposed for series–parallel systems.

Other Optimization Techniques

For series–parallel systems, Ramirez-Marquez *et al.* [69] formulate the reliability–redundancy optimization problem with the objective of maximizing the minimal subsystem reliability. Assuming linear constraints, this problem is equivalent to a linear formulation through an easy logarithm transformation [81], which can be solved by readily available commercial software. It can also serve as a surrogate for traditional reliability optimization problems by sequentially solving a series of max–min subproblems. Lee *et al.* [68] present a comparison between the Nakagawa and Nakashima method [82] and the max–min approach used by Ramirez-Marquez from the standpoint of solution quality and computational complexity. The experimental results show that the max–min approach is superior to the Nakagawa and Nakashima method in terms of solution quality in small-scale problems, but the analysis of its computational complexity demonstrates that the max–min approach is inferior to other greedy heuristics.

You and Chen [72] develop a heuristic approach inspired by the greedy method and a GA. The structure of this algorithm includes (a) randomly generating a specified population size number of minimum workable solutions, (b) assigning components either according to the greedy method or to the random selection method, and (c) improving solutions through an inner-system and intersystem solution revision process.

Kevin and Sancho [73] apply a hybrid dynamic programming/depth-first search algorithm to redundancy allocation problems with more than one constraint. Given the tightest upper bound, the knapsack relaxation problem is formulated with only one constraint, and its solution $f_1(b)$ is obtained by a dynamic programming method. After choosing a small specified parameter e , the depth-first search technique is used to find all near-optimal solutions with objectives between $f_1(b)$ and $f_1(b) - e$. The optimal solution is given by the best feasible solution among all of the near-optimal solutions. Also with dynamic programming, Yalaoui *et al.* [74] consider a reliability–redundancy allocation problem

in series–parallel systems with components chosen among a finite set. This pseudopolynomial YCC algorithm is composed of two steps: the solution of the subproblems, one for each subsystem, and the global resolution using previous results. It shows that the solutions converge quickly toward the optimum as a function of the required precision.

Comparisons and Discussions of Algorithms Reported in the Literature

In this section, we provide a comparison of several heuristic or metaheuristic algorithms reported in the literature. The compared numerical results are from the GA in Coit and Smith [78], the ACO in Liang and Smith [3], TS in Kulturel-Konak *et al.* [51], linear approximation in Hsieh [81], the immune algorithm (IA) in Chen and You [56] and the heuristic method in You and Chen [72]. The 33 variations of the Fyffe *et al.* problem, as devised by Nakagawa and Miyazaki [83], are used to test their performance, where different types are allowed to reside in parallel. In this problem set, the cost constraint is maintained at 130 and the weight constraint varies from 191 to 159.

As shown in literature, ACO [3], TS [51], IA [56], and heuristic methods [72] generally yield solutions with a higher reliability. When compared to GA [78],

- ACO [3] is reported to consistently perform well over different problem sizes and parameters and improve on GA's random behavior.
- TS [51] results in a superior performance in terms of best solutions found and reduced variability and greater efficiency based on the number of objective function evaluations required.
- IA [56] finds better or equally good solutions for all 33 test problems, but the performance of this IA-based approach is sensitive to value-combinations of the parameters, whose best values are case-dependent and only based upon the experience from preliminary runs and more CPU time is taken by IAs.
- The best solutions found by heuristic methods [72] are all better than, or as good as, the well-known best solutions from other approaches. With this method, the average CPU time for each problem is within 8 s.
- In terms of solution quality, the linear approximation approach in [81] is inferior, but very efficient,

and the CPU time for all of the test problems is within 1 s.

- If a decision-maker is considering the max–min approach as a surrogate for system reliability maximization, the max–min approach [69] is shown to be capable of obtaining a close solution (within 0.22%), but it is unknown whether this performance will continue as problem sizes become larger.

For all the optimization techniques mentioned above, it might be hard to discuss about which tool is superior because in different design problems or even in the same problem with different parameters, these tools will perform varyingly.

Generally, if computational efficiency is of most concern to designers, linear approximation or heuristic methods can obtain competitive feasible solutions within a very short time (few seconds), as in [72, 81]. The proposed linear approximation [81] is also easy to implement with any LP software. However, the main limitation of those reported approaches is that the constraints must be linear and separable.

Owing to their robustness and feasibility, metaheuristic methods such as GA and the recently developed TS and ACO could be successfully applied to almost all NP-hard reliability optimization problems. However, they cannot guarantee the optimality and sometimes can suffer from premature convergence because they have many unknown parameters and neither use a prior knowledge nor exploit local search information. Compared to traditional metaheuristic methods, a set of promising algorithms, hybrid GAs [40–44, 49, 50], are attractive since they retain the advantages of GAs in robustness and feasibility, but significantly improve their computational efficiency and searching ability in finding a global optimum by combining heuristic algorithms, neural network techniques, steepest-descent methods, or other local search methods.

For reliability optimization problems, exact solutions are not necessarily desirable because it is generally difficult to develop exact methods for reliability optimization problems that are equivalent to methods used for nonlinear integer programming problems [2]. However, exact methods may be particularly advantageous when the problem is not large. More importantly, such methods can be used to measure the performance of heuristic or metaheuristic methods.

Conclusions and Discussions

Heuristic, metaheuristic, and exact methods are significantly applied in optimal reliability design. Recently, many advances in metaheuristics and exact methods have been reported. Particularly, a new metaheuristic method called *ant colony optimization* has been introduced and demonstrated to be a very promising general method in this field. Hybrid GAs may be the most important recent development among the optimization techniques since they retain the advantages of GAs in robustness and feasibility but significantly improve their computational efficiency.

Optimal reliability design has attracted many researchers, who have produced hundreds of publications since 1960. Owing to the increasing complexity of practical engineering systems and the critical importance of reliability in these complex systems, this still seems to be a very fruitful area for future research. From the view of optimization techniques, there are opportunities for improved effectiveness and efficiency of reported ACO, TS, IA, and great deluge algorithm (GDA), while some new metaheuristic algorithms such as harmony search algorithm and particle swarm optimization may offer excellent solutions for reliability optimization problems. Hybrid optimization techniques are another very promising general developmental direction in this field. They may combine heuristic methods, NN or some local search methods with all kinds of metaheuristics to improve computational efficiency or with exact methods to reduce search space. We may even be able to combine two metaheuristic algorithms such as GA and SA or ACO in future research on optimal reliability design.

Monitoring of Safety in EU Railways

ERA, the Ambitious Projects on Safety of a Newcomer, under Directive 2004/49/EC

Railway is the safest land transport mode and one of the overall safest transport modes. Directive 2004/49/EC, on railway safety, has been put in place to support the creation of an integrated European railway area by facilitating market opening through the harmonization of safety management and regulation. Directive 2004/49/EC will also contribute to improve safety by: a cultural shift from a deterministic to a risk-based approach, the establishment of safety management systems, the introduction of a system for independent accident investigation, as well as by moving from self-regulation to regulation by independent authorities (National Safety Authorities – NSAs). This aims to create a basis for mutual trust between member states (MSs), mainly through the development of common and transparent methods to monitor safety performance, to set targets and to manage the introduction of significant changes in railway systems with a risk-based systematic approach.

Collection and Publication of Information on Safety

Purpose

Safety information is collected mainly to provide input to the development of an objective tool for setting common safety targets (CSTs) and assessing their achievement. CSTs will be developed in subsequent sets, on the basis of safety performances in MSs and their possible economic impact in terms of costs and benefits. The European Railway Agency (ERA) is in charge of these projects, carried out in conjunction with industry and MSs in working groups of experts.

Development of Common Safety Indicators (CSIs) and Accidents Investigation

The working group on common safety indicators (CSIs) is developing and defining indicators structured as follows:

Safety performances

- type of accidents
- fatalities and injuries classified in categories of people
- precursors to accidents.

Economic aspects of safety performances

- societal benefits and costs of improving and worsening safety performances.

CSIs are expressed in total of events and consequences (fatalities and injuries) per unit of time (1 year), normalized mainly by traffic performances (train*km, passenger*km).

The flow of information and data exchange on safety issues between the concerned parties is completed by the activity of accidents investigation, carried out by National Investigation Bodies (NIBs) and communicated to ERA; the aim of this is to better understand the causes of accidents, which, together with the aforementioned statistics on accidents, precursors to accidents, and economic aspects of safety, provides the necessary information to ERA to set CSTs at EU level (see Figure 1).

Data Sources of CSIs

ERA relies on data from two sources, Eurostat and NSAs. Eurostat has been collecting EU-wide harmonized data on “type of accidents, related consequences, and traffic performances”, since 2004; NSAs have been publishing data on CSIs every year, starting from 2006 and according to a common format developed with ERA. Therefore, both Eurostat and NSAs will collect data on accidents and related consequences. In addition, NSAs will also report on precursors to accidents and economic aspects of safety. This double collection of accidents data should be temporary and it is a consequence of the further development, introduced by Directive 2004/49/EC, of the type of accidents classification and categorization of people; ERA and Eurostat are working together to eliminate these differences and to harmonize **data collection** processes.

Consistency between Eurostat and NSAs. ERA has informally collected 2004 and 2005 data on CSIs from NSAs, with the view to improving data reliability through the appraisal of consistency between

Figure 1 Flow of information to set CSTs

NSAs and Eurostat statistics. The differences identified between NSAs and Eurostat statistics have been registered and sent to both sources, inviting them to further discuss with each other, to eliminate existing inconsistencies.

Collection and Analysis of Time Series of National Data on Railway Safety. In the context of ERA's work to develop CSTs, it has been necessary to complement data delivered by Eurostat and data on CSIs with longer **time series** of national data on railway safety. This in order to provide appropriate input to the analysis aimed at identifying for each MS the

current safety performance of national railway systems in terms of risk. The need to look at long time series of data derives from the high degree of oscillation which data on accidents and related consequences (i.e., fatalities and serious injuries) typically show from year to year, making difficult the identification of the current risk levels attributable to national railway systems. Being, in fact, the risk calculated as a product of consequences of accidents and their respective frequencies, the oscillation of data both on frequency and consequences is systematically transmitted to risk estimates. This oscillation is the cumulative effect of rarity and statistical randomness of the events under consideration. Accidents with multiple fatalities and injuries represent rare events, therefore they are considered as high-impact and low-frequency events and generate outliers in time series.

Different techniques have been considered for smoothing down the outliers due to multiple fatality accidents and to calculate the underlying, intrinsic risk levels of national railway systems. These techniques use moving averages or moving **percentiles** (i.e., moving median or upper quartile), which respectively average and cut out isolated outliers in the same moving n -year time window.

The random behavior of accident statistics over time, cumulated with the intrinsic rarity of significant accidents, may also lead to recursive zero values in time series, especially for small, modern railway networks with low traffic volumes. This makes it difficult to estimate the underlying risk levels of these systems through robust statistical methods, especially when adequate time series of data are not available. Empirical solutions are needed in these cases for identifying and targeting risk levels, such as the adoption of empirical tolerance intervals $[0, \sigma]$ for the risk levels of the system, where σ is a predetermined standard deviation from a mean which is assumed to be equal to zero.

Bias in Modeling and Monitoring Health Outcomes

A Brief Background on Control Charts

Suppose we wish to monitor the rate of a particular health outcome in a specified population or health facility, there are several **control charts** that can be used, including Shewhart, cumulative sum (CUSUM), **exponentially weighted moving average** (EWMA), and variable life-adjusted display (VLAD). Each of these is now a standard textbook procedure and is described elsewhere in this publication.

For charts such as the Shewhart chart, signals occur on the basis of the extremity, or unusualness, of the most recent observation only. For other charts, such as the EWMA and CUSUM, where past data are taken into account, the occurrence of clusters of extreme events can also cause signals. The Shewhart chart can also be adapted to incorporate past data, by use of runs rules such as those suggested by the Western Electric Company [1].

Monitoring the Incidence of a Disease

Consider a scenario where we wish to monitor the incidence of a disease in a population. At any point where a signal occurs on the control chart used, we would most likely want to revise our original estimate of the rate of infection, from which we were monitoring for change, so that the control chart could be recalibrated and monitoring continue anew. The question as to what is the new infection rate is part of the larger question: “why was there a signal?”

The example data: re-estimating an infection rate following a signal

Results from a Shewhart and an EWMA chart. Figure 1 shows infection rates of methicillin-resistant *Staphylococcus aureus* (MRSA) in a UK NHS Trust at 6-monthly intervals in the period April 2001 to September 2005 [2]. The observed rates are the number of blood samples taken that tested positive

for MRSA divided by the number of bed-days in thousands in a 6-monthly interval. The observed rates are shown in black, accompanied by the outer pair of dotted lines, which are 99.8% Shewhart limits. These Shewhart limits are calculated using the rate across the first four 6-monthly intervals as a “target” rate (central dotted line) and assuming counts follow a Poisson distribution where the denominator is bed-days in thousands. An EWMA of the data is shown in gray, as are the EWMA chart limits (the inner pair of dotted lines). The smoothing parameter value used is $\kappa = 0.5$. The chart limits are 95% gamma limits centered on the target rate, with precision (or effective number of observations) equal to $(1 - \kappa)^{-1} = 2$ [3].

In the **quality control** literature, the state of the process being monitored is often described as either “in control” or “out of control” at any one time, and signals indicating that the process has moved away from an in-control state, then, are described as either false or true. In practice, however, it may be difficult to know whether a signal was truly warranted. In Figure 1, suppose that we have just observed the signal in interval 6 (October 2003–March 2004). How might we go about re-estimating the true underlying infection rate at this juncture?

Results from a CUSUM, and general concerns about bias. Figure 2 shows a Poisson CUSUM for the same data, testing for a 20% increase in the rate from the level over the period April 2001–September 2002 (intervals 1–4), and thus testing whether a rate of 0.26 is more plausible than a rate of 0.22. There is a signal in period 6 for this chart too. We might

Figure 1 MRSA rates in a UK NHS Trust. Central dotted line: rate over first four periods; outer lines: transformed 99.8% Poisson limits, given bed-days; inner lines: 95% gamma limits, given bed-days

re-estimate the underlying rate following the signal using only the data since the chart was last at zero, because this is where the chart indicates that the process was last “in control”. For the example, this gives an estimate of 0.37. Alternatively, we could use all the available data up to signal (giving an estimate of 0.24), but may be mixing data from different underlying sources and hence biasing the estimate of the rate from the “true” source. We might attempt to exclude outlying data points. For instance, if it were decided that the observation in interval 6 was anomalous for some reason, the estimate would be equal to the original estimate, 0.22. In any case, it remains difficult to determine whether the underlying infection rate has changed, and likewise whether the original estimate was reasonable. In this example, the subsequent data points are consistent with the observed rate upon signal (the rate over the last four periods is 0.39) and the CUSUM continues to accumulate in favor of the alternative with respect to the null.

Estimation following an early signal (one before the planned study end) of benefit of the treatment is of particular interest in the application of sequential **clinical trials** [4, 5]. A quick decision about whether the apparent benefit is real (that is, whether patients would benefit from future treatment) is desirable, but the estimate of the effect of the treatment may be biased if it is based on insufficient data, or a chance run of unlikely data under a null, or negligible effect. To be careful that the estimate of the effect of the treatment is not overstated, it might be **bias-adjusted** [6] or made more conservative according to some prior or external information [7].

More about the EWMA as both a chart and an estimator

In contrast to the CUSUM, which accumulates the log-likelihood ratio in favor of one hypothesis over another, the EWMA is a direct estimator for the rate [3]. As illustrated in Figure 1, it is formed by a weighted average on all past data (in the dataset used), where the data are weighted exponentially according to their contemporaneity.

It appears as though the use of the EWMA or other estimators in a testing scheme provides a way of simultaneously estimating and testing. Charts based on smoothers like the EWMA have inertia [8], because they do not give full weight to the most recent observation, and so are robust to **outliers** yet at the same time less adaptive to new process conditions. If we are primarily interested in estimating the rate directly after signals of a change in rate, inertia, combined with the nature of the chart stopping rule, restricts the estimate.

In the event of the EWMA chart signalling, the chart statistic is necessarily larger than the threshold. So, for an endemic disease, EWMA values following signal may be upwardly biased in terms of predicting future typical behaviour of the disease if the signal is caused by an isolated cluster of observations that, in retrospect, is difficult to account for. If the underlying infection rate suddenly increases, the EWMA value just after signal may underestimate the increase. In the example, the EWMA value in period 6 (0.29), if biased, could be an overestimate of the rate if the true rate is closer to the observed rate over the first four periods (0.22), or an underestimate if it is closer to that over the last four periods (0.39).

Though the EWMA value is already smoothed (or, results from an assumption that the underlying true process is smooth), we might wish to adjust it toward the initial target or an external value from peer processes. In that way, the re-estimate of the infection rate would be conservative and protect against subsequent regression to the mean if the true underlying rate were unchanged. However, it may happen that after adjustment the value is below the signaling threshold. For example, the EWMA value in period 6 in the example might be adjusted halfway toward the initial target if there were external information, with weight equal to the observed data, that the rate was unchanged. This

would lead to a supported value for the rate, at that point, of 0.25.

If the adjusted value is taken to be the current estimate for the infection rate and is, as in our example, lower than the threshold for a signal (in the example, this is 0.26), we might ask whether we consider that a signal has still occurred. In both cases, inferences on the estimation and testing front would seem to contradict each other, because we either have a signal and an estimate lower than the prespecified threshold, or do not have a signal but have an estimate higher than the threshold (if adjustment is only carried out given the presence of a signal). A solution would perhaps be to adjust the estimate no further than the threshold, but this would again present as a restriction on the parameter space of the estimate.

Conclusion

To conclude, combined estimation and **hypothesis testing** through the use of control charts may produce results that are difficult to analyze because of the issue of bias, and lead to possible contradictions in the inferences made. Hawkins and Olwell note that “even a somewhat biased estimate is better than no estimate at all.” This is reminiscent of Box’s words, “All models are wrong, but some are useful”. Perhaps faith in tangible models should override concerns of bias from truth.

Mixture Models, Multivariate: Aging and Dependence

Introduction

In this article, we maintain the same language and notation of the article **Aging and Positive Dependence** and consider vectors of lifetimes $(T_1, \dots, T_n)$ with joint survival function of the specific form

$$\bar{F}(t_1, \dots, t_n) = \int_{R^m} \prod_{j=1}^n \bar{G}_j(t_j | \theta_1, \dots, \theta_m) \times dH(\theta_1, \dots, \theta_m) \quad (1)$$

where, for some $m \geq 1$, H is an m -dimensional probability distribution and, for any vector $(\theta_1, \dots, \theta_m)$, $\bar{G}_j(\cdot | \theta_1, \dots, \theta_m)$ is a one-dimensional survival function ($j = 1, 2, \dots, n$). We can think of H as the joint distribution of a nonobservable random vector $\Theta = (\Theta_1, \dots, \Theta_m)$ such that $T_1, \dots, T_n$ are conditionally independent, given Θ . Generally, neither $\Theta_1, \dots, \Theta_m$ nor $T_1, \dots, T_n$ are independent random variables.

Models of the form in equation (1) are known as *multivariate mixture models*; they arise in several different fields and in a great variety of situations of applied interest. In particular, they can be used to model heterogeneity; for a discussion about the concept of heterogeneity in the field of reliability (see e.g., [1] the references indicated therein).

It is quite natural to analyze multivariate mixture models in the frame of a Bayesian approach. In such a frame, we will discuss here some aspects of aging and positive dependence.

$T_1, \dots, T_n$ are conditionally independent, generally nonidentically distributed, given Θ . Special multivariate mixture models of interest are defined by the conditions:

1. $\bar{G}_j(t | \theta_1, \dots, \theta_m)$, as a function of $(\theta_1, \dots, \theta_m)$, depends only on θ_j and
2. $\bar{G}_j(t | \theta_1, \dots, \theta_m)$, as a function of t and θ_j , has a general form that does not depend on j .

Such conditions can be summarized by writing that $\bar{G}_j(t | \theta_1, \dots, \theta_m)$ is of the form

$$\bar{G}_j(t | \theta_1, \dots, \theta_m) = \rho(t | \theta_j) \quad (2)$$

and describe special *frailty models*.

In several cases of interest, as an additional condition on these frailty models, we have that $\Theta_1, \dots, \Theta_m$ are exchangeable. As a remarkable feature, in these cases, we have heterogeneity and similarity at the same time: also $T_1, \dots, T_n$ turn out to be exchangeable. However, $T_1, \dots, T_n$ generally do not have an identical conditional distribution, given Θ . We point out then that we obtain in this way exchangeable variables, for which conditional independence is not, however, paired with identical conditional distributions.

Specially relevant cases of exchangeability are met when $\Theta_1, \dots, \Theta_m$ are independent and identically distributed, or when $P\{\Theta_1 = \dots = \Theta_m\} = 1$. The latter case is the basic one encountered in Bayesian statistics: $T_1, \dots, T_n$ are conditionally independent and identically distributed, given a same scalar parameter Θ ; in the former case, instead, $T_1, \dots, T_n$ are themselves independent and identically distributed. Several other models of interest, however, can also be met in between these two extreme cases.

For these models we also notice that, irrespective of the special form of dependence among $\Theta_1, \dots, \Theta_m$, the one-dimensional marginal distribution of T_j ($j = 1, 2, \dots, n$) is a mixture distribution with a survival function of the form

$$\bar{F}(t) = \int_R \rho(t | \theta) dH^{(1)}(\theta) \quad (3)$$

$H^{(1)}$ being the one-dimensional marginal of H .

In a general multivariate mixture model, as in equation (1) (not necessarily exchangeable), the marginal distributions of T_j ($j = 1, 2, \dots, n$), are univariate mixture distributions with survival functions given by

$$\bar{F}_j(t) = \int_{R^m} \bar{G}_j(t | \theta_1, \dots, \theta_m) dH(\theta_1, \dots, \theta_m) \quad (4)$$

In applications, there are different kinds of situations that give rise to univariate mixture distributions. The difference between different situations is not, sometimes, very clear. From a probabilistic point of view, however, one can simply say that these

2 Mixture Models, Multivariate: Aging and Dependence

situations are described by distributions obtained as marginals of different multivariate mixture models, just with different types of mixing distributions $H(\theta_1, \dots, \theta_m)$.

Aspects of Ageing

A fact of recurrent interest in quality and reliability is related with aging properties of (univariate) mixtures as in equation (4) and can be roughly summarized as follows: *whereas negative aging tends to be maintained by mixtures, positive aging tends to be lost under mixtures*. This fact has been made precise by formulating different probabilistic results; at the same time, it has been explained in terms of several heuristic interpretations or empirical analysis. It is, in particular, well-known that the property of decreasing failure rate (DFR) is maintained under mixtures (see e.g., [2]); on the other hand, several interpretations have been given of the fact that increasing failure rate (IFR) may, on the contrary, be lost under mixtures. In a reliability framework, well-known papers on this topic are [3, 4], the latter being in particular based on a Bayesian approach.

Here we want to illustrate the basic idea behind all that, still maintaining a Bayesian approach. To this purpose, we assume simplifying conditions of stochastic monotonicity that more easily allow us to explain the reasons why DFR is maintained by mixture, while IFR can be lost (see also [5–8]). Same type of arguments can also be, respectively, worked out for other notions of positive and negative aging.

Consider a lifetime T and a single positive random variable Θ ; T is the (observable) lifetime of a component and Θ is a nonobservable factor that affects the probability distribution of T ; Θ can have e.g., a meaning such as the quality or the frailty of the component. For the sake of technical simplicity, we consider cases where the joint probability distribution of (T, Θ) admits a joint probability, described as follows: the marginal distribution of Θ , that is concentrated over $[0, +\infty)$, admits a density $\pi(\cdot)$ and the conditional distributions of T , given $\{\Theta = \theta\}$ admits conditional failure rates $r(t|\theta)$, for $\theta \geq 0$; denote by $R(t|\theta)$ the conditional cumulative failure rate of T given $\{\Theta = \theta\}$:

$$R(t|\theta) = \int_0^t r(u|\theta) du \quad (5)$$

The marginal distribution of T , obtained by integrating out θ , has then survival function, density function, and failure rate, respectively given by

$$\begin{aligned} \bar{F}(t) &= \int_0^\infty \exp\{-R(t|\theta)\} \pi(\theta) d\theta, \\ f(t) &= \int_0^\infty r(t|\theta) \exp\{-R(t|\theta)\} \pi(\theta) d\theta \end{aligned} \quad (6)$$

and

$$\lambda(t) = \frac{f(t)}{\bar{F}(t)} = \int_0^\infty r(t|\theta) \pi_t(\theta) d\theta \quad (7)$$

where we set

$$\pi_t(\theta) = \frac{\exp\{-R(t|\theta)\} \pi(\theta)}{\int_0^\infty \exp\{-R(t|\theta)\} \pi(\theta) d\theta} \quad (8)$$

As an immediate application of Bayes formula, $\pi_t(\theta)$ can be interpreted as the conditional density of Θ , given the event $\{T > t\}$. In many practical situations, it can be reasonable to assume that $r(t|\theta)$ is, for any fixed t , an increasing function of θ : the bigger the value taken by θ , the stochastically smaller is T , in the hazard order sense; it can be easily shown, in such a case, that the distribution with density π_t is stochastically decreasing in t .

Compare now, for fixed t and for two different densities π', π'' , the expressions

$$\int_0^\infty r(t|\theta) \pi'(\theta) d\theta, \int_0^\infty r(t|\theta) \pi''(\theta) d\theta \quad (9)$$

Since, for fixed t , $r(t|\theta)$ is increasing in θ , we have

$$\int_0^\infty r(t|\theta) \pi'(\theta) d\theta \leq \int_0^\infty r(t|\theta) \pi''(\theta) d\theta \quad (10)$$

whenever the distribution with density π' is smaller than the distribution with density π'' , in the sense of the ordinary stochastic order.

Put now, for two values $0 < t' < t''$, $\pi'(\theta) = \pi_{t'}(\theta)$, $\pi''(\theta) = \pi_{t''}(\theta)$. For a same fixed value $\tau > 0$, we can then write, since π_t is stochastically decreasing in t and $r(t|\theta)$ is increasing in θ ,

$$\int_0^\infty r(\tau|\theta) \pi_{t'}(\theta) d\theta \geq \int_0^\infty r(\tau|\theta) \pi_{t''}(\theta) d\theta \quad (11)$$

Suppose T is conditionally DFR given θ , i.e. $r(t|\theta)$ is decreasing in t . By fixing e.g., $\tau = t'$, we

can immediately conclude that T is DFR; in fact

$$\lambda(t') = \int_0^\infty r(t'|\theta)\pi_{t'}(\theta) d\theta \geq \int_0^\infty r(t''|\theta)\pi_{t''}(\theta) d\theta = \lambda(t'') \quad (12)$$

Suppose now that T is IFR in the conditional distribution. Even if, for $t' < t''$, it is then $r(t'|\theta) \leq r(t''|\theta)$, we cannot generally conclude that $\lambda(t') \leq \lambda(t'')$, since in any case $\pi_{t'}$ is stochastically larger than $\pi_{t''}$.

This explains why the distribution of T , which is a mixture of IFR distributions and has the density function given by

$$f(t) = \int_0^\infty r(t|\theta) \exp\{-R(t|\theta)\} \pi(\theta) d\theta \quad (13)$$

may potentially be not IFR!

In passing we have to notice however that, under special conditions, a mixture of IFR distribution can still be IFR (see [9] and [10]).

This specific phenomenon that a mixture of IFR distribution is not generally IFR (and that the mixture can, however, be IFR, under specific conditions), has also been discovered and extensively analyzed in several other fields, related with reliability, such as demography, population dynamics, survival analysis, and medicine, (see e.g., [11–13]); it has also been remarked that the phenomenon is somewhat related to the *Simpson's paradox* (e.g., [13, 14]).

More generally, the aging behavior of univariate distributions obtained by mixtures has often been found to be relevant in different applications and related statistical analysis; the main problem is that many different types of behavior are possible when failure rates, of the distributions which are mixed, are not decreasing. Therefore, studies on the aging properties of mixtures, in an analytical viewpoint, have quite a long history (see e.g., reviews in [15–18]). Specific aspects about this theme concern the asymptotic (or tail) behavior (see e.g., [15, 19]) and conditions that give rise to *bathtub* distributions (see [20] and references therein).

An important problem in reliability is to understand what are the situations under which **burn-in** procedures are justified. From a Bayesian viewpoint, deciding whether it is convenient to adopt some *burn-in* procedure is just a decision problem (see

e.g., the introductory discussion in [21]) and establishing the duration of burn-in is just an optimal stopping problem (see [22, 23] and references therein).

Roughly speaking, burn-in is useful in cases of *infant mortality*. For this reason a special interest has been devoted to the theme of negative aging; the issues of concern are understanding what negative aging really means, which analytical conditions imply it, and what real reliability models can manifest such a behavior. In this respect, there are several ways to interpret the fact that, in some practical situations where mixtures appear, burn-in procedures are actually convenient (see also e.g., [6, 23, 24] and references therein). From a mathematical point of view, one can say that infant mortality and univariate negative aging often arise in the case of mixtures.

One can imagine, however, that multivariate mixture models also manifest some kind of negative multivariate aging. Multivariate properties of the Bayesian type (see in particular [18, 23, 25, 26] and the brief sketch in **Aging and Positive Dependence**) have been dealt with in [27] for these models in the exchangeable case; sufficient conditions that guarantee some multivariate negative aging have been proved therein, under suitable assumptions of positive dependence for the vector Θ and stochastic monotonicity of the conditional distributions of $T_1, \dots, T_n$, given Θ .

As one conclusion of main interest for this article, we point out that in cases of (univariate) mixture distributions and of multivariate mixture models one can encounter some form of negative aging.

Positive Dependence Properties

Let us now pass to analyze positive dependence for multivariate mixture models. In this analysis, we have to distinguish between the two cases where the unobservable factor Θ , w.r.t. which $T_1, \dots, T_n$ are conditionally independent, is a random scalar or a random vector. It is a general fact, however, that stochastic monotonicity of the different lifetimes $T_1, \dots, T_n$ with respect to Θ , combined with suitable positive dependence properties of Θ , gives rise to positive dependence properties for $\mathbf{T} = (T_1, \dots, T_n)$. This fact admits a rather direct heuristic interpretation in a Bayesian view (see also **Aging and Positive**

Dependence, the section titled “Notions of Positive Dependence”). When Θ reduces to a scalar Θ (i.e., if $m = 1$), no assumption is needed for Θ .

A basic result in this direction was given by Jogdeo in [28] (see also [29]).

Theorem 1 *Let $T_1, \dots, T_n$ be conditionally independent, given Θ and each of them stochastically increasing (or decreasing) in Θ , in the ordinary stochastic order. Then $T_1, \dots, T_n$ are associated.*

By postulating stronger types of stochastic monotonicity for $T_1, \dots, T_n$, one can obtain stronger conditions of positive dependence. Examples of that are the following results, proved in [30].

Theorem 2 *Let $T_1, \dots, T_n$ be conditionally independent, given Θ and each of them stochastically decreasing (or increasing) in Θ , in the hazard rate order. Then $\mathbf{T} = (T_1, \dots, T_n)$ is weakened by failure.*

For the following result, we need to assume that the support $\mathcal{D}$ of the distribution of $\mathbf{T}$ is a lattice, i.e., $\mathbf{u}, \mathbf{v} \in \mathcal{D} \implies \mathbf{u} \wedge \mathbf{v} \in \mathcal{D}, \mathbf{u} \vee \mathbf{v} \in \mathcal{D}$.

Theorem 3 *Let $T_1, \dots, T_n$ be conditionally independent, given Θ and each of them stochastically decreasing (or increasing) in Θ , in the likelihood ratio order. Then $\mathbf{T}$ is multivariate totally positive of order 2.*

Let us consider now cases in which $T_1, \dots, T_n$ are conditionally independent, given a vector Θ . In these cases, the space R^m of possible values of Θ is to be thought of as (partially) ordered in the component-wise sense. Theorem 1 above can be generalized as follows (see again [28]).

Theorem 4 *Let $T_1, \dots, T_n$ be conditionally independent, given Θ and each of them stochastically decreasing (or increasing) in Θ , in the ordinary stochastic order; furthermore, let Θ be associated. Then $T_1, \dots, T_n$ are associated.*

Theorem 1 is clearly a special case of Theorem 4, in fact, a scalar random variable Θ can be seen as a special case of an associated random vector. Analogously, Theorems 2 and 3 have also been respectively generalized in suitable ways to the case of a vector Θ ; in such results, Θ is to be assumed multivariate totally positive of order 2 (see [30]).

For some other aspects of dependence properties for mixture models, see also [31].

A general concept of positive dependence for a random vector $(X_1, \dots, X_r)$ is that of *dependence by total positivity with degree $(k_1, \dots, k_r)$* (see in particular [32, 33]). This concept is important since several different notions of positive dependence can just be obtained as special cases of it. In the paper [34], Kirmani and Kochar extended the aforementioned results in order to prove *dependence by total positivity with degree $(k_1, \dots, k_r)$* for vectors of lifetimes $T_1, \dots, T_n$, jointly distributed according to multivariate mixture modes.

Conclusions

We mentioned that multivariate mixture models are of remarkable interest for applications and that, in particular, they can be used to model heterogeneity. Some other examples of applications are mentioned, e.g., in [30].

We want to conclude this article, however, by stressing that multivariate mixture models are also relevant for the following aspect of conceptual character: they can likely manifest positive dependence along with some form of negative aging.

Repair Data, Sets of: How to Graph, Analyze, and Compare

Introduction

Purpose

Many products accumulate repeated repairs and repair costs over time. Analysis of such recurrence data requires special statistical models and methods not covered in basic reliability books. This article presents a simple and informative model and plot for analyzing data on numbers or costs of repeated repairs of a random sample of units. The plot is illustrated with transmission repair data from preproduction cars on a track test. This article also presents a method for comparing two such datasets, illustrated with automatic and manual transmissions. Computer programs that calculate and make the plots and comparisons with confidence limits are surveyed.

Information

The plot given here is a nonparametric graphical estimate of the population mean cumulative number or cost of repairs per unit *versus* population age. This estimate can be used to

1. evaluate whether the population repair (or cost) rate increases or decreases with age; this is useful for product retirement and **burn-in** decisions;
2. predict future numbers and costs of repairs;
3. compare two random samples from different designs, production periods, maintenance policies, environments, operating conditions, and so on;
4. reveal unexpected information and insight, an important advantage of plots.

Life Data

Most models and analysis methods for product reliability data are suitable for life data. Life data on a unit consists of a *single* failure time, the unit's end of life. Some sample units may be still unfailed. Then each such unit has a failure time that is beyond its current running time. Such lifetimes are modeled with

a life distribution, such as the Weibull distribution, which is fitted to the mix of failures and nonfailures. For example, Nelson [1] and Abernethy [2] present such models and data analyses, which are unsuited to repair data, which can have any number of repair events for a unit, not just one.

Overview

The next section describes typical repair data. The subsequent section "The Population Model and Its Mean Cumulative Function" presents the basic population model and its mean cumulative function (MCF) for the number or cost of repairs. The section "Estimate and Plot of the MCF" shows how to calculate and plot a sample estimate of the MCF from data from units with a mix of ages. "How to Interpret and Use a Plot" explains how to use and interpret such plots. The section "Comparison of Sets of Repair Data" provides a graphical comparison and confidence limits for the difference of two sample MCFs. The last section references further information on analysis of recurrence data.

Repair Data

Transmission Data

This section describes typical repair data from a sample of units. Table 1 displays a small set of typical repair data on a sample of 34 preproduction cars with an automatic transmission run on a severe test track. For each car the data consist of the car's mileage at each transmission repair and the latest observed mileage. For example, for car 024, the data are a repair at 7068 mi and its latest mileage 26 744 + mi; here + indicates the distance the car has been observed. Nelson [3–6] gives repair data on blood analyzers, residential heat pumps, window air conditioners, power supplies, and turbines. He also gives applications from other fields with repeated events data, including recurrent disease episodes, childbirths, auto accidents, and so on. Information sought from the transmission data includes

1. the mean cumulative number of repairs per car by 24 000 track miles (equivalent to 132 000 customer miles, the design life);

- the behavior of the population repair rate – increasing or decreasing as the population ages?

Censoring

A sample unit's latest observed age is called its (right) *censoring age*, because the unit's repair history to the right beyond that age is censored (unknown) at the time of the data analysis. Usually, such right-censoring ages differ and complicate the data analysis and require the method described below. A unit may have no failures; in such cases its data is just its censoring age. Other units may have one, two, three, or more repairs before its censoring age.

Age

Here “age” (or “time”) means any useful measure of unit usage, e.g., mileage, days, cycles, months, and so on.

Data Display

Figure 1 is a useful display of the data but not an analysis. Here each car history is displayed as a horizontal line segment whose length is the observed car mileage, and its censoring age is denoted by a vertical line. For a car, each transmission repair is marked with an × at the corresponding mileage on its line. This simple display suggests that earlier production has more repairs, which is expected, since production is being improved during start-up. A more informative analysis is given in the sections titled “Estimate and Plot of the MCF” and “How to Interpret and Use a Plot”.

The Population Model and its Mean Cumulative Function

Model

Most needed information on the repair behavior of a population of units is given by the population mean cumulative function (MCF) *versus* age t . The MCF (defined below) is a feature of the following population model, which has no censoring. Censoring is a feature of the sample data, not of the population model. At a particular age t , population unit i has accumulated a total cost (or number) of repairs $Y_i(t)$. These cumulative unit totals $Y_i(t)$ usually differ. Figure 2 depicts the population of such uncensored unit *cumulative history functions* for cost; they are shown as smooth curves for easy viewing and extend to any age of interest. In reality, such a history function $Y_i(t)$ is a staircase function where the rise of each step is the unit's repair cost or number of repairs at that age. However, staircase functions are hard to view in such a plot. In contrast, the data from a sample unit is from just the observed early portion of its history function, subsequent history being censored, that is, yet unobserved.

MCF

At a particular age t , there is a population distribution of cumulative cost of repairs, which is depicted

Figure 1 Display of automatic transmission data in production order [© SIAM, 2003.]

vertically in Figure 2 as a continuous density (which should be imagined perpendicular to the page). The distribution at age t has a mean value $M(t)$. In Figure 2, the heavy curve depicts $M(t)$ as a function of t . $M(t)$ is called the *mean cumulative function* (MCF) for the cost of repairs. It is simply the population mean curve for all the unit cumulative history functions. It provides most information sought from repair and other recurrence data. In practice, $M(t)$ is usually regarded as a smooth continuous function. Nelson [3, 6, 7] presents an unbiased estimate $M^*(t)$ for $M(t)$ from censored data; it

appears in the section titled “Estimate and Plot of the MCF”.

Number of Repairs

In Figure 2, a cost distribution is depicted as continuous. In contrast, for a count of the number of repairs, the corresponding vertical distribution for the cumulative numbers of repairs at age t is discrete and has the integers values 0, 1, 2, 3, and so on. Such discrete distributions are depicted in Figure 3 and should be imagined perpendicular to the page. In

4 Repair Data, Sets of: How to Graph, Analyze, and Compare

this case, $M(t)$ is the population mean curve for all unit staircase history functions.

Repair Rate

When $M(t)$ is the mean cumulative *number* of repairs, its derivative

$$m(t) \equiv \frac{dM(t)}{dt} \quad (1)$$

Figure 2 Population cumulative cost histories (uncensored) and cost distribution [Taken from TIS Report 89CRD239 © 1989.]

Figure 3 Discrete distributions for the cumulative number of repairs and MCF [Taken from TIS Report 89CRD239 © 1989.]

is assumed to exist and is called the population *instantaneous repair rate* at age t . It is also called the *recurrence rate* or *intensity function* for the number of other repeating occurrences. It is expressed in occurrences per unit time per population unit, e.g., transmission repairs per 1000 mi per car. Some mistakenly call $m(t)$ the *failure rate*, which causes confusion with the quite different failure rate (hazard function) of a life distribution for nonrepaired units (such as components). The failure rate for a life distribution has an entirely different definition, meaning, and use, as explained by Ascher and Feingold [8], Nelson [1], and Abernethy [2]. When $M(t)$ is the mean cumulative *cost* of repairs, $m(t)$ is the mean cost rate at age t , for example dollars per car per 1000 mi.

Estimate and Plot of the MCF

Purpose

This section shows how to estimate the population MCF.

Motivation

If all N sample units have been observed up to time t , the estimate of the population MCF is simple. Suppose that the cumulative number (or cost) of repairs on sample unit i by age t is $Y_i(t)$, $i = 1, 2, \dots, N$. Then the estimate of the MCF at age t is simply the sample average of the cumulative values at age t ; namely,

$$M^*(t) = [Y_1(t) + Y_2(t) + \dots + Y_N(t)]/N \quad (2)$$

When the time t is beyond any censoring ages, the MCF estimate is more complicated as follows.

Steps

The following steps yield a nonparametric estimate $M^*(t)$ of the population MCF $M(t)$ for the number of repairs from a simple random sample of N units; here $N = 34$ cars.

1. List all repair and censoring ages in order from smallest to largest, as in column 1 of Table 2. Denote each censoring age with a +. If a repair age of a unit equals its censoring age, put

Table 2 MCF calculations^a

1. Mileage	2. No. <i>I</i> in use	3. Mean No. 1/ <i>I</i>	4. Sample MCF

^a© John Wiley & Sons Ltd, 1998

the repair age first. If two or more units have a common age, list them in a suitable order, possibly random.

- For each sample age, write the number I of units then in use ("at risk") in column 2 as follows.

If the earliest age is a censoring age, write $I = N - 1$; otherwise, write $I = N$. Proceed down column 2 writing the same I value for each successive repair age. At each censoring age, reduce the I value by one. The last age is a censoring age and for it, $I = 0$.

- For each repair, calculate the observed mean number of repairs per unit at that age as $1/I$. For example, for the repair at 28 mi, $1/34 = 0.029$, which appears in column 3. For a censoring age, the observed mean number of repairs per unit is zero, corresponding to a blank in column 3. The censoring ages are taken into account since they determine the I values of the repairs.
- In column 4, calculate the sample MCF $M^*(t)$ for each repair by cumulating as follows. For the earliest repair age, this is the corresponding mean number of repairs, namely, 0.029 in Table 2. For each successive repair age this is the corresponding mean number of repairs (column 3) plus the preceding mean cumulative number (column 4). For example, at 19 250 mi, this is $0.038 + 0.261 = 0.299$. Censoring ages have no mean cumulative number and are ignored in column 4.
- For each repair, plot on graph paper its mean cumulative number (column 4) against its age (column 1) as in Figure 4. This plot displays the nonparametric estimate $M^*(t)$ for the population $M(t)$. $M^*(t)$ is a staircase function and is called the *sample MCF*. Censoring times are not plotted but are taken into account in the MCF estimate. One interprets such a plot as explained in the section titled "How to Interpret and Use a Plot".

Plot

Figure 4 was plotted by Nelson and Doganaksoy's [9] program MCFLIM, which does the calculations above. Each data point "1" in the plot corresponds to a repair at the corresponding age in the sample. This plot shows a flat horizontal line segment to the right of each 1, which extends to the age of the next 1. This nonparametric sample MCF estimate is a staircase. In practice, one regards the population MCF as a smooth curve. Thus one usually imagines or fits a smooth curve through the plotted points as an MCF estimate. Often the horizontal segments are omitted, as in Figure 6.

Figure 4 Automatic transmission sample MCF and 95% confidence limits “-” [© John Wiley & Sons Ltd, 1998.]

Confidence Limits

Figure 4 also displays vertical pairs of “-”, which are two-sided approximate 95% confidence limits for the corresponding population MCF at that age. Such a pair of pointwise limits encloses the population MCF with 95% confidence at any one age t . A pair of limits extends to the right to the next repair age. For example, the 95% confidence limits for the mean cumulative number of automatic transmission repairs at 24 000 track mi (read from Figure 4) are 0.1 and 0.5 repairs per car. Such pointwise limits do not simultaneously enclose the entire MCF curve over the range of the data with 95% confidence. Nelson’s [5, 6] complex calculations of these limits require a computer program like those described below. These limits employ a normal approximation to the sampling distribution of $M^*(t)$.

Assumptions

The nonparametric MCF estimate and approximate confidence limits above entail minimal assumptions described by Nelson [3, 5, 6]. In contrast, the parametric models and estimates presented by Englehardt [10] and Ascher and Feingold [8] apply to a single unit (not a sample of units) and require additional assumptions that may not be valid in applications. Rigdon and Basu [11] fit parametric non-homogeneous Poisson process models to repair data on a simple random sample of units; their models employ the often false assumption of independent increments.

Software

The following programs calculate and plot the MCF estimate and approximate confidence limits from data with exact ages and right censoring. They handle the number and cost (or value) of recurrences and allow for positive or negative values.

- MCFLIM of Nelson and Doganaksoy [9]. This software provided Figure 4.
- The RELIABILITY procedure in the SAS/QC software of the SAS Institute [12].
- The JMP software of the SAS Institute [13], pp. 565–572.
- SPLIDA features developed by Meeker and Escobar [14] for S-PLUS.
- A program developed for General Motors by Robinson [15].
- The ReliaSoft [16] Weibull++7 software has a recurrence data analysis (RDA) add-on.

How to Interpret and Use a Plot

MCF Estimate

The plot in Figure 4 displays a nonparametric estimate $M^*(t)$ of $M(t)$; that is, the estimate involves no assumptions about the form of $M(t)$ or the process generating the unit histories. This nonparametric estimate is a staircase function that is flat between repair ages, but the flat portions need not be plotted. The MCF of a large population is usually regarded as a smooth curve, and one usually imagines a smooth curve through the plotted points. Interpretations of such plots appear below. See Nelson [6] for more detail.

Mean Cumulative Number

An estimate of the population mean cumulative number of repairs by a specified age is read directly from such a staircase estimate or a curve through the plotted points. For example, from Figure 4, the estimate of this by 24 000 mi is 0.30 repairs per car, an answer to a basic question.

Repair Rate

The derivative of such a curve (imagined or fitted) estimates the repair rate $m(t)$. If the derivative increases with age, the population repair rate

increases as units age. If the derivative decreases, the population repair rate decreases with age. The behavior of the rate is used to determine burn-in, overhaul, and retirement policies. In Figure 4 the repair rate (derivative) decreases as the transmission population ages, providing the answer to a basic question.

Burn-In

Some products are subjected to a factory burn-in. Units typically are run and repaired until the instantaneous (population) repair rate decreases to a desired value m' . An estimate of the suitable length t' of burn-in is obtained from the sample MCF as shown in Figure 5. A straight line segment with slope m' is moved until it is tangent to the MCF. The corresponding burn-in age t' at the tangent point is suitable, as shown in Figure 5.

Other Information

Nelson [6] and Cook and Lawless [17] give other applications and show how to obtain other types of desired information.

Comparison of Sets of Repair Data

Purpose

This section presents a simple graphical comparison of the MCF estimates of two sets of repair data. This comparison also applies to recurrence

data on recurrent disease episodes, sociological and demographic applications such as childbirth, simulation of production processes, and other recurrent events. Nelson [6] and Cook and Lawless [17] give further examples of such comparisons.

Manual Transmission Data

Table 3 displays another set of repair data on a sample of 14 cars with a manual transmission. Information sought from these data include

1. the mean cumulative number of repairs per car by 24 000 mi (design life),
2. whether the population repair rate increases or decreases as the population ages, and
3. whether the automatic and manual sample MCFs differ statistically significantly.

Figure 6 is a plot of the sample MCF of the manual transmissions without the horizontal lines.

- A smooth curve through Figure 6 has a derivative $m^*(t)$ that decreases as the population ages. That is, the early repair rate decreases as the manual transmission population ages. This is typical of products with manufacturing defects.
- Figure 6 yields an estimate of 0.50 manual transmission repairs per car by 24 000 track mi. The corresponding estimate for automatic transmissions is 0.30.

Figure 5 Burn-in age t' for repair rate m' [Taken from TIS Report 89CRD239, © 1989.]

Figure 6 Manual transmission MCF and 95% confidence limits “-” [© John Wiley & Sons Ltd, 2000.]

Thus Figure 6 answers two of the questions listed above. Only the comparison of the automatic and manual transmission MCF estimates remains, which is described next.

Comparison

The following shows how to assess whether two sample MCFs differ statistically significantly, that is convincingly. A simple visual comparison of Figures 2 and 3 shows that the sample MCF of manual transmissions has a higher average cumulative number of repairs over time. The following method is like the one used to compare two sample means. However, here we are comparing two mean curves. To do this, we look at the difference between the two sample MCFs and the approximate two-sided 95% confidence limits for their difference. At an age t where those pointwise confidence limits do not enclose zero, that difference is statistically significant. Otherwise, the two sample MCFs at that age do not differ statistically significantly. Doganaksoy and Nelson [18] and Nelson [6] present the theory and calculations for these limits for the difference of two sample MCFs.

Transmission Comparison

Figure 7 displays the difference between the sample MCFs of the automatic and manual transmissions.

Figure 7 Difference of the MCFs (automatic minus manual) [© John Wiley & Sons Ltd, 2000.]

The plot includes pointwise 95% confidence limits for the difference. At essentially every age, the limits enclose zero. Thus the sample MCFs do not differ significantly over the range of the data. Of course, the two samples contain few cars and few repairs, and consequently the confidence limits are wide and the comparison is insensitive. In view of no significant difference, one might pool the two datasets to estimate a common MCF with greater accuracy, if that would be consistent with engineering knowledge.

Entire MCFs

The preceding comparison of two sample MCFs is pointwise. That is, the 95% confidence level is correct only for a single age. The limits do not enclose the *entire* difference of the true MCFs with 95% probability. Comparisons of the entire MCFs are given by Cook *et al.* [19], Cook and Lawless [17], and Nelson [20].

Software

All the previously referenced software calculate and plot the differences of two sample MCFs and corresponding pointwise confidence limits.

Further Information

The references, especially Nelson [6] and Cook and Lawless [17], and their references provide other applications and information on

1. predicting future numbers or costs of repairs for a fleet;
2. analyzing repair *cost* data or other numerical values associated with repairs;
3. analyzing such data on cost, downtime, and other measures of repair “value”;
4. analyzing history functions that increase and decrease (negative values) or are continuous;
5. analyzing availability data, which includes downtime for repairs;
6. analyzing data with more complex censoring, such as gaps in unit histories with missing repair data, Nelson [4];
7. analyzing data with a mix of types of repairs;
8. the minimal assumptions for the nonparametric estimate $M^*(t)$ and confidence limits;
9. data analyses and plots for samples other than simple random ones, such as cluster and stratified samples; and
10. estimating relationships, such as the **Cox model**, for the dependence of $M(t)$ on process, environmental, materials, and other engineering variables; see Cook and Lawless [17].

Literature

Many models and data analysis methods for repair data are parametric and involve more assumptions, which often are unrealistic. For example, Englehardt [10] and Ascher and Feingold [8] present models, analyses, and assumptions for a single unit, not for a sample of units. The simplest such parametric models are the **Poisson process** and **nonhomogeneous Poisson process**, presented in detail by Nelson [6] and Rigdon and Basu [11]. In contrast, the methods above extend to costs, downtimes, and other values associated with repairs, whereas previous methods apply only to simple counts of repairs.

Concluding Remarks

The simple plot here of the sample MCF is informative and widely useful. It requires minimal assumptions and is simple to make, interpret, and present to others.

Acknowledgment

Cumulative Hazard Function

Consider a random variable T denoting a failure time and the associated hazard function $h(t)$ (*see **Hazard Function***). The cumulative hazard function is defined as $H(t) = \int_0^t h(u) \, du$.

Intensity Function

Let $N(t)$, $t \geq 0$, be a point process and let $N(s, t]$, $s < t$, denote the number of events (failures) that occur in the interval $(s, t]$. Then the intensity function of the point process $N(t)$ is defined as

$$\lambda(t) = \lim_{\Delta t \rightarrow 0} \frac{P(N(t, t + \Delta t] \geq 1)}{\Delta t} \quad (1)$$

If the probability of simultaneous failures is zero, then the intensity function $\lambda(t)$ coincides with the ROCOF $\mu(t)$ (see **Rate of Occurrence of Failures**).

Hazard Function

Consider a random variable T denoting a failure time. The hazard function is defined as

$$h(t) = \lim_{\Delta t \rightarrow 0} \frac{P(t < T \leq t + \Delta t)}{P(T > t)} \quad (1)$$

The hazard function denotes the (conditional) probability that an item functioning at time t fails right after that time.

If T has density function $f(t)$ and reliability function (see **Reliability Function**) $R(t)$, then it follows that

$$h(t) = \frac{f(t)}{R(t)} \quad (2)$$

Since $f(t) = -R'(t)$ in the absolutely continuous case, it follows that, knowing either the density function or the reliability function, it is possible to determine the hazard function univocally. A similar result holds for discrete distributions.

Given the hazard function, it is possible to obtain the density function $f(t)$. In the absolutely continuous case, it follows that $f(t) = h(t)e^{-\int_0^t h(u) du}$.

Suppose that T has an exponential distribution, with density $\lambda e^{-\lambda t}$ and reliability function $e^{-\lambda t}$, $\lambda > 0$, $t \geq 0$. Therefore the hazard function is given by $h(t) = \lambda$. Since the hazard function univocally determines the distribution function, the constant failure rate is another typical property of the exponential distribution, which justifies the “memoryless” property commonly associated with it.

Mean Residual Life

Consider a random variable T denoting the failure time of an item. Suppose that the item has been functioning up to time t , then the mean residual life at time t is defined as

$$m(t) = E(T - t | T \geq t) \quad (1)$$

Given the reliability function (see **Reliability Function**) $R(t)$, it follows that $m(t) = \int_t^\infty R(u) du / R(t)$. There is a one-to-one correspondence between

mean residual life and reliability function since it holds that

$$R(t) = \frac{m(0)}{m(t)} e^{-\int_0^t (1/m(u)) du} \quad (2)$$

Suppose that T has an exponential distribution, with density $\lambda e^{-\lambda t}$ and reliability function $e^{-\lambda t}$, $\lambda > 0$, $t \geq 0$. Using the previous result about the link with the reliability function, it follows that $m(t) = 1/\lambda$, as another consequence of the “memoryless” property.

Mean Time Between Failures

Consider a random variable T denoting a time between two failures. The mean time between failures (MTBF) is defined as the expected value of T , provided it exists.

If T has a density function $f(t)$, then the MTBF is given by $\int_0^\infty t f(t) dt$ or $\sum_i t_i f(t_i)$, depending on whether T is absolutely continuous or discrete, respectively.

Suppose that T has an exponential distribution, with density $\lambda e^{-\lambda t}$, $\lambda > 0$, $t \geq 0$. Then the MTBF is given by

$$\int_0^\infty t \lambda e^{-\lambda t} dt = \frac{1}{\lambda} \quad (1)$$

Mean Time to Failure

Consider a random variable T denoting a time to failure. The mean time to failure (MTTF) is defined as the expected value of T , provided it exists.

If T has a density function $f(t)$, then the MTTF is given by $\int_0^\infty t f(t) dt$ or $\sum_i t_i f(t_i)$, depending on whether T is absolutely continuous or discrete, respectively.

Given the reliability function (*see Reliability Function*) $R(t)$, it follows that the MTTF equals $\int_0^\infty R(t) dt$ in the absolutely continuous case.

Suppose that T has an exponential distribution, with density $\lambda e^{-\lambda t}$ and reliability function $e^{-\lambda t}$, $\lambda > 0$, $t \geq 0$. Then the MTTF is given by

$$\int_0^\infty t \lambda e^{-\lambda t} dt = \int_0^\infty e^{-\lambda t} dt = \frac{1}{\lambda} \quad (1)$$

Mean Time to Repair

Consider a random variable R denoting the repair (or down) time after the failure of an item. The mean time to repair (MTTR) is defined as the expected value of R , provided it exists.

If R has a density function $f(r)$, then the MTTR is given by $\int_0^\infty r f(r) \, dr$ or $\sum_i r_i f(r_i)$, depending on whether R is absolutely continuous or discrete, respectively.

Given the distribution function $F(r)$, it follows

that the MTTR equals $\int_0^\infty [1 - F(r)] \, dr$ in the absolutely continuous case.

Suppose that R has an exponential distribution, with density $\lambda e^{-\lambda r}$ and distribution function $1 - e^{-\lambda r}$, $\lambda > 0$, $r \geq 0$. Then the MTTR is given by

$$\int_0^\infty r \lambda e^{-\lambda r} \, dr = \int_0^\infty e^{-\lambda r} \, dr = \frac{1}{\lambda} \quad (1)$$

Proportional Hazard Model

The proportional hazard model relates the hazard function (*see* **Hazard Function**) at two different conditions, x and the baseline x_0 , by

$$h(t; x) = g(x)h(t; x_0) \quad (1)$$

with $t > 0$ and g a positive function, e.g. $g(x; \beta) = e^{x\beta}$, where β is a parameter.

The links between the reliability function (*see* **Reliability Function**) and the distribution function and the baselines ones are given, respectively, by $R(t; x) = [R(t; x_0)]^{g(x)}$ and $F(t; x) = 1 - [1 - F(t; x_0)]^{g(x)}$.

Reliability Function

Consider a random variable T denoting a failure time. The reliability function is defined as $R(t) = P(T > t)$, for $t \geq 0$.

If T has a density function $f(t)$, then the reliability function is given by $\int_t^\infty f(u) du$ or $\sum_{t_i > t} f(t_i)$, depending on whether T is absolutely continuous or discrete, respectively.

Given the distribution function $F(t)$, it follows that $R(t) = 1 - F(t)$.

It can be shown that the reliability function $R(t)$ is linked to the hazard function $h(t)$ (see **Haz-**

ard Function) and the cumulative hazard function $H(t)$ (see **Cumulative Hazard Function**) by $R(t) = e^{-\int_0^t h(u) du}$ and $R(t) = e^{-H(t)}$, respectively. For the converse, see **Hazard Function**. Therefore, knowing either the hazard function or the cumulative hazard function, it is possible to determine the reliability function univocally.

Suppose that T has an exponential distribution, with density $\lambda e^{-\lambda t}$ and distribution function $1 - e^{-\lambda t}$, $\lambda > 0$, $t \geq 0$. Then the reliability function is given by

$$\int_t^\infty \lambda e^{-\lambda u} du = e^{-\lambda t} \quad (1)$$

Rate of Occurrence of Failures

Let $N(t)$, $t \geq 0$, be a point process and let $N(s, t]$, $s < t$, denote the number of events (failures) that occur in the interval $(s, t]$. Consider the mean function of the process $N(t)$, defined as $\Lambda(t) = EN(t)$, which denotes the expected number of events in

the interval $(0, t]$. If $\Lambda(t)$ is differentiable, then the ROCOF of the point process $N(t)$ is defined as

$$\mu(t) = \frac{d}{dt} \Lambda(t) \quad (1)$$

If the probability of simultaneous failures is zero, then the ROCOF $\mu(t)$ coincides with the intensity function $\lambda(t)$ (*see **Intensity Function***).

Contingency Table, Square

An $R \times C$ contingency table – that is, a contingency table with R rows and C columns – is frequently seen in biomedical studies. When $R = C$, the contingency table is often referred to as a *square table*. Square tables usually arise in repeated measures experiments, in which a subject has his or her outcome variable observed repeatedly. Examples of repeated measures studies include longitudinal studies (observing the same subject over time); rater agreement studies (two investigators rate each subject in the study); and paired data studies (data obtained from a husband and wife, father and son, or case and control).

First, we introduce some notation. Suppose that two discrete random variables, Y_{i1} and Y_{i2} , are observed on each of n independent subjects, where Y_{i1} can take on values $1, \dots, R$, and Y_{i2} can take on values $1, \dots, C$. Let the probabilities of the multinomial joint distribution of Y_{i1} and Y_{i2} be denoted by

$$p_{jk} = \Pr(Y_{i1} = j, Y_{i2} = k) \quad (1)$$

for $j = 1, \dots, R$ and $k = 1, \dots, C$. Since all the probabilities must sum to 1, there are $(RC - 1)$ nonredundant multinomial cell probabilities. We let $\mathbf{p}$ denote the $(RC - 1) \times 1$ probability vector of p_{jk} 's; for simplicity, we delete p_{RC} , and we take $R = C$ below. The marginal probabilities of the contingency table are $p_{j+} = \Pr(Y_{i1} = j)$ and $p_{+k} = \Pr(Y_{i2} = k)$, where the plus signs denote summing over the subscript they replace. We let n_{jk} denote the number of subjects with response level j on Y_{i1} and level k on Y_{i2} , and let $n = n_{++}$ be the total number of subjects in the study.

Models for square tables fall into three general classes – marginal models, loglinear models, and conditional models. Marginal models describe the similarity between the row and column marginal distributions. With loglinear models, we model the cell probabilities of the table. For example, the probabilities may be symmetric about the main diagonal, and a loglinear model can be used to describe this relationship among the cell probabilities. Conditional models model the conditional probabilities of the column variable given the row variable and are popularly

used in longitudinal studies, letting the row variable represent a response at time 1 and the column variable represent the response at time 2. Often, in square tables, we are not always interested in modeling the data, but are interested in determining the association or agreement between the row and column variables.

Marginal Models

In a crossover study, a subject is given one treatment, has a washout period, and is then given a new treatment. Suppose that the response to each treatment is success, partial success, or failure. We are often interested in whether the marginal distribution of the outcome is the same for both treatments, often called *marginal homogeneity*. Under marginal homogeneity, the sum of the cell probabilities (i.e., the marginal probability) in the j th row of the contingency table equals the sum of the cell probabilities in the j th column; that is, $p_{j+} = p_{+j}$ for $j = 1, \dots, R$. Lipsitz *et al.* [1] show that the maximum-likelihood estimates (MLEs) for the p_{jk} 's under marginal homogeneity can be obtained *via* a linear model of the form

$$\mathbf{p} = \mathbf{X}\boldsymbol{\beta} \quad (2)$$

for the appropriate “design” matrix $\mathbf{X}$, which we now describe for $R = 3$, but which generalizes to any R . For $R = 3$, we can write the vector $\mathbf{p}$ in terms of the four cell probabilities, $\{p_{11}, p_{12}, p_{21}, p_{22}\}$ and the four marginal probabilities, $\{p_{1+}, p_{2+}, p_{+1}, p_{+2}\}$, as follows:

$$\begin{bmatrix} p_{11} \\ p_{12} \\ p_{13} \\ p_{21} \\ p_{22} \\ p_{23} \\ p_{31} \\ p_{32} \end{bmatrix} = \begin{bmatrix} p_{11} \\ p_{12} \\ p_{1+} - p_{11} - p_{12} \\ p_{21} \\ p_{22} \\ p_{2+} - p_{21} - p_{22} \\ p_{+1} - p_{11} - p_{21} \\ p_{+2} - p_{12} - p_{22} \end{bmatrix} \quad (3)$$

Under marginal homogeneity, the row and column marginal probabilities are equal – that is, $p_{j+} = p_{+j} = p_j$ – which leads to the following linear model

2 Contingency Table, Square

for the cell probabilities:

$$\begin{aligned}
 \begin{bmatrix} p_{11} \\ p_{12} \\ p_{13} \\ p_{21} \\ p_{22} \\ p_{23} \\ p_{31} \\ p_{32} \end{bmatrix} &= \begin{bmatrix} p_{11} \\ p_{12} \\ p_1 - p_{11} - p_{12} \\ p_{21} \\ p_{22} \\ p_2 - p_{21} - p_{22} \\ p_1 - p_{11} - p_{21} \\ p_2 - p_{12} - p_{22} \end{bmatrix} \\
 &= \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ -1 & -1 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & -1 & 0 & 1 \\ -1 & 0 & -1 & 0 & 1 & 0 \\ 0 & -1 & 0 & -1 & 0 & 1 \end{bmatrix} \begin{bmatrix} p_{11} \\ p_{12} \\ p_{21} \\ p_{22} \\ p_1 \\ p_2 \end{bmatrix} \\
 &= \mathbf{X}\boldsymbol{\beta}. \tag{4}
 \end{aligned}$$

The MLEs can be obtained in any generalized linear modeling program, such as SAS *Proc GENMOD* [2], without any additional programming or iteration loops. In these programs, the outcome is the count n_{jk} , the covariates are the appropriate row of $\mathbf{X}$ in equation (4) without an intercept, and we specify a linear link with Poisson errors (we actually must include n_{33} as a value of the outcome, as described in [1]). Firth [3] also describes a method for obtaining the linear model for the p_{jk} 's using Latin squares. Another method found in the literature for obtaining the MLE under homogeneity uses Lagrange multipliers [4].

After the estimates of the cell probabilities under marginal homogeneity have been obtained, a likelihood-ratio statistic can be used to test whether marginal homogeneity holds. This statistic is approximately χ^2 with $R - 1$ **degrees of freedom** under the null. Alternately, a Wald statistic [5] can be used. It does not require the use of iterative techniques, since only the estimates of the cell probabilities for the saturated model are needed. The MLE of p_{jk} for the saturated model (with $R^2 - 1$ nonredundant probabilities) is

$$\hat{p}_{jk} = \frac{n_{jk}}{n} \tag{5}$$

and the MLEs of the marginal probabilities are $\hat{p}_{j+} = n_{j+}/n$ and $\hat{p}_{+j} = n_{+j}/n$. Suppose that we let the vector

$$\mathbf{U} = [\hat{p}_{1+} - \hat{p}_{+1}, \dots, \hat{p}_{R-1,+} - \hat{p}_{+,R-1}]' \tag{6}$$

contain the first $R - 1$ differences in the marginal probabilities (the R th difference is redundant). Under the null of marginal homogeneity, $E(\mathbf{U}) = \mathbf{0}$. If we let $\hat{\mathbf{V}}$ be the estimated **covariance** matrix of the vector $\mathbf{U}$ under the alternative (see [5]), then the Wald test statistic for homogeneity is the quadratic form

$$X^2 = \mathbf{U}'\hat{\mathbf{V}}^{-1}\mathbf{U} \tag{7}$$

which will be approximately χ^2 with $R - 1$ degrees of freedom under the null. If, instead of estimating the variance under the alternative in equation (7), we let $\hat{\mathbf{V}}$ be the estimated covariance of $\mathbf{U}$ under the null of homogeneity, and if there are only two rows and columns in the table ($R = C = 2$), then (7) reduces to

$$X^2 = \frac{(n_{12} - n_{21})^2}{n_{12} + n_{21}} \tag{8}$$

The test statistic in equation (8) is popularly known as *McNemar's test* for equality of correlated proportions [6].

In the crossover study discussed earlier, the outcomes "success", "partial success", and "failure" are examples of ordered categorical data. Suppose that we want to test for marginal homogeneity, taking this ordering into account. We can put an ordinal model on the margins, such as the proportional-odds model [7], and test whether the parameters of the proportional-odds models in the two margins are the same. The test statistics are similar to those given for the nominal case above. The Wald test for marginal homogeneity for proportional-odds marginal models can be obtained in SAS *Proc CATMOD* [8] using methods derived in [9]. The likelihood-ratio statistic can be obtained in a **generalized linear models** program, but will require some additional programming. More details on marginal modeling can be found in [10], Chapter 9 and in the article on marginal models.

Loglinear Models

The models just discussed involved testing whether the marginal probabilities of the table are equal. Now, we discuss models which describe the relationship among the cell probabilities of the $R \times R$ table. One such model for the cell probabilities is a symmetry model, in which

$$p_{jk} = p_{kj}, \quad \text{for } j \neq k \tag{9}$$

Note that symmetry implies marginal homogeneity since, under equation (9),

$$p_{j+} = \sum_{k=1}^R p_{jk} = \sum_{k=1}^R p_{kj} = p_{+j} \quad (10)$$

In fact, when $R = C = 2$, marginal homogeneity and symmetry are identical, and both imply that $p_{12} = p_{21}$.

For modeling purposes, symmetry is most easily written as a loglinear model. Loglinear models for contingency tables are usually written in terms of the expected cell counts

$$m_{jk} = E(n_{jk}) = np_{jk} \quad (11)$$

In terms of the expected cell counts, symmetry is written as

$$m_{jk} = m_{kj}, \quad \text{for } j \neq k \quad (12)$$

Then, the symmetry loglinear model is

$$\log m_{jk} = \mu + \beta_j + \beta_k + \beta_{jk} \quad (13)$$

where $\beta_{jk} = \beta_{kj}$, with the appropriate identifiability constraints on the parameters, such as $\beta_R = 0$ and $\beta_{Rj} = \beta_{jR} = 0$ for $j = 1, \dots, R$. Since $\beta_{jk} = \beta_{kj}$, it is easy to show that $m_{jk} = m_{kj}$, and symmetry holds for equation (13).

The MLEs for the expected cell counts under symmetry are

$$\hat{m}_{jj} = n_{jj} \quad \text{and} \quad \hat{m}_{jk} = \frac{n_{jk} + n_{kj}}{2} \quad (14)$$

The estimated cell probabilities are just $\hat{p}_{jk} = \hat{m}_{jk}/n$. Intuitively, since symmetry does not concern the diagonal cells, the estimated expected diagonal counts are just the observed diagonal counts. Also, an estimated off-diagonal count is just the average of the observed counts in cells jk and kj . Under the symmetry model, we only need to estimate $R(R-1)/2$ off-diagonal probabilities on one side of the diagonal, so we have placed $R(R-1)/2$ constraints on the cell probabilities under the null, and the likelihood-ratio test statistic, score test statistic, or Wald test statistic for symmetry are approximately χ^2 with $R(R-1)/2$ degrees of freedom. The score test

statistic (equivalent to Pearson's χ^2 for this problem) is the simplest [11]:

$$X^2 = \sum_{j < k} \frac{(n_{jk} - n_{kj})^2}{n_{jk} + n_{kj}} \quad (15)$$

Recall that, when $R = C = 2$, marginal homogeneity and symmetry are identical, so that equation (15) is also a test statistic for marginal homogeneity when $R = 2$, and is identical to the McNemar test statistic discussed earlier.

The symmetry loglinear model puts many constraints on the probabilities. A loglinear model that has fewer constraints (and more parameters) does not force the row and column main effects in equation (13) to be equal,

$$\log m_{jk} = \mu + \alpha_j + \beta_k + (\alpha\beta)_{jk} \quad (16)$$

where $(\alpha\beta)_{jk} = (\alpha\beta)_{kj}$. The loglinear model in equation (16) is called *quasisymmetry* [12]. If symmetry holds, then $\alpha_j = \beta_j$. The Bradley-Terry model [13] for *paired comparisons* is a special case of this quasisymmetry model.

Using the identifiability constraints $\alpha_R = 0$, $\beta_R = 0$, and $(\alpha\beta)_{Rj} = (\alpha\beta)_{jR} = 0$ for $j = 1, \dots, R$, the interaction parameter $(\alpha\beta)_{jk}$ is the log-odds ratio for the j th and R th rows and k th and R th columns; that is,

$$(\alpha\beta)_{jk} = \log \left(\frac{p_{jk} p_{RR}}{p_{jR} p_{Rk}} \right) \quad (17)$$

Then, in the quasisymmetry model, since $(\alpha\beta)_{jk} = (\alpha\beta)_{kj}$, the log-odds ratio for the j th and R th rows and k th and R th columns equals the log-odds ratio for the k th and R th rows and j th and R th columns. In particular, these log-odds ratios are symmetric.

One last loglinear model that we discuss is a *quasi-independence* model. If the row and column variables are independent, then

$$p_{jk} = p_{j+} p_{+k} \quad (18)$$

or, equivalently, in terms of the loglinear model,

$$\log m_{jk} = \mu + \alpha_j + \beta_k \quad (19)$$

In repeated measures studies, most of the agreement is often on the diagonal, so that the diagonal elements are longer than expected under independence, with independence holding in the off-diagonal

4 Contingency Table, Square

elements. A simple loglinear model that expresses such a relationship is the quasi-independence loglinear model,

$$\log m_{jk} = \mu + \alpha_j + \beta_k + \gamma_j I(j = k) \quad (20)$$

where $I(j = k)$ equals 1 for diagonal elements $j = k$ and 0 for off-diagonal elements. For off-diagonal elements, equation (20) is identical to equation (19), and, if $\gamma_j > 0$, then the diagonal elements are longer than expected under independence.

When the rows and columns are ordered, these loglinear models can be extended by assigning scores to the rows and columns (see, for example [14]). For more details on loglinear models, see [11].

Conditional Models

Often in longitudinal studies, we are interested in transitions or change in states, such as the response at time 2 given the response at time 1. In general, in crossover designs, polling studies, or employment studies (mover–stayer studies), investigators are interested in these conditional probabilities for the column variable given the row variable. When the row variable represents a response at time 1, and column variable represents the response at time 2, we model the probability of response k at time 2 given response j at time 1:

$$p_{k|j} = \Pr[Y_{i2} = k | Y_{i1} = j], \quad j = 1, \dots, R \quad (21)$$

Suppose that, in an clinical trial on subjects with arthritis for the effectiveness of a single treatment, the subjects are observed once before treatment, then are given the new treatment, and then observed again. Suppose that the possible outcomes at the two times are “no pain”, “mild pain”, and “severe pain”. Then, we are interested in the changes in pain, as modeled by the conditional probabilities of pain status at time 2 given the pain status at time 1. If there are two levels ($R = 2$), then we can apply logistic regression to the model given in equation (21), treating Y_{i1} as a **covariate**. If ($R > 2$) and the levels are not ordered, multinomial logistic regression can be used; if the levels are ordered (as in this example), an ordinal logistic model such as the proportional-odds model [7] can be used.

Measures of Association and Agreement

For general ($R \times C$) tables, we are often interested in the association between the row and column variables. For a (2×2) table, the odds ratio is a popular measure of association. In an ($R \times R$) square table, the log-odds ratios, as described above, can be used to measure association. For the row and column variables to be associated, you should be able to predict one from another. For example, if the odds ratio is zero, the row and column variables in a (2×2) are perfectly negatively associated. In repeated measures studies, and, in particular, interrater reliability studies, in which two investigators rate each subject in the study, we are interested in how well the row and column variables (the two ratings on each subject) agree. When two ratings agree, most of the observations in the contingency table will be on the diagonal (most ratings are similar). Two variables can be highly associated, but agreement between the two could be very low. Suppose that both diagonal elements in a (2×2) table are zero: then the raters completely disagree, and agreement (by any measure) is very low. However, the odds ratio is zero, and, as discussed above, the two variables are perfectly negatively associated. The κ coefficient [15] is a popular measure of agreement corrected for chance agreement.

Contingency Table

We start by defining a two-way contingency table. Suppose that each of a sample of n individuals is classified according to each of two separate criteria, and each of these criteria can take only a finite number of distinct values. Let us take as an example a study to assess factors associated with women's attitudes toward mammography [1, p. 220]. Each of 309 women has been classified according to:

1. Her "Mammography Experience", which has as its possible values "Never", "Over one year ago", and "Within the past year".
2. Her response to the question "How likely is it that a mammogram could find a new case of breast cancer?", which has as its possible values "Not likely", "Somewhat likely", and "Very likely".

Let the mammography experience correspond to the *rows* of the table and the response to the question about the detection of breast cancer to the *columns*. Although it happens in this particular example that each of the rows and columns has a natural ordering, this is not necessary to the definition of a contingency table. Then the resulting 3×3 *table* of frequencies or counts is, say, (n_{ij}) , where

1. n_{ij} is the number of individuals in row i and column j for $i = 1, \dots, I$ and $j = 1, \dots, J$.
2. I and J are, respectively, the total numbers of rows and columns of the table, here 3, 3. Let n be the total sample size, so that n is the sum of entries of the table; we can then write $n = \sum \sum n_{ij}$.

Note that in our construction of this *cross tabulation* or contingency table, we assume that each individual of the sample of size n is classified into exactly one of the IJ categories of the table, these categories being mutually exclusive and exhaustive. Written less formally, this means that the IJ categories do not overlap in any way, and together they cover all possibilities.

Of course, exactly how the sample is collected for a particular study is of great importance in the subsequent statistical analysis. In classical contingency table analysis, it is assumed that the n individuals form a *random sample* from a population:

this means that we assume that each individual is classified independently of the others, and each has the same probability, say p_{ij} , of being classified into row i and column j . Thus $\sum \sum p_{ij} = 1$. Our assumption that we have a random sample has the consequence that the probability distribution of the variable (n_{ij}) is multinomial; that is, the frequency function $p[(n_{ij})|p]$ is

$$n! \prod_i \prod_j \left(\frac{p_{ij}^{n_{ij}}}{n_{ij}!} \right)$$

provided that $n_{ij} \geq 0$ and $\sum \sum n_{ij} = n$.

In this case we say that (n_{ij}) is multinomial, with parameters n and (p_{ij}) .

To continue with the above example of the attitudes toward mammography data, the results of our survey are shown in Table 1.

These data show a dramatic and self-evident association between rows and columns: in other words, the women's responses to the question about the detection of breast cancer depend strongly on their mammography experience. This can be seen even more clearly by presenting the data from this sample in terms of the *row percentages*. Rounded to the nearest whole number for clarity, these are shown in Table 2.

Presenting the data in this way shows more clearly how the response to the question depends on the mammography experience. Another illuminating way to show this effect would be by using three

Table 1 Mammography: the counts

Mammography experience	Detection of breast cancer		
	Not likely	Somewhat likely	Very likely
Never	13	77	144
Over one year ago	4	16	54
Within the past year	1	12	91

Table 2 Mammography: the row percentages

Mammography experience	Detection of breast cancer			
	Not likely	Somewhat likely	Very likely	Total
Never	6	33	61	100
Over one year ago	5	22	73	100
Within the past year	1	11	87	100

2 Contingency Table

bar charts, overlaid on the same graph, with each corresponding to a different row of the table. There are several possible analyses we can carry out on this particular table, such as a simple summary in terms of percentages, a graphical summary, or a statistical test of independence, which we describe below. None of these analyses can establish whether the association between rows and columns is a *causal* one. This is an inherent limitation of the purely statistical approach. In the current example, the column variable might be thought of as a response to the row variable, which is an explanatory variable, or **covariate**. But the simple two-way contingency table cannot directly tell us the mechanism by which the explanatory variable affects the response variable. In any case, in the current example, there could be a mixture of several complex mechanisms which act simultaneously.

The Hypothesis of Independence, H_0 , and the Chi-square Test

With the notation introduced above, that

$$p_{ij} = \Pr(\text{row} = i, \text{column} = j) \quad (1)$$

for $i = 1, \dots, I$, $j = 1, \dots, J$, we see that the hypothesis of independence of rows and columns may be written as

$$H_0 : p_{ij} = p_{i+}p_{+j} \quad (2)$$

for all i, j , where $p_{i+} = \sum_j p_{ij}$ is the probability that Row = i , and $p_{+j} = \sum_i p_{ij}$ is the probability that Column = j .

Observe that an equivalent way of writing H_0 is

$$H_0 : \frac{p_{ij}}{p_{i+}} = p_{+j} \quad (3)$$

for all i, j . Now p_{ij}/p_{i+} is the probability that the column is j , conditional on the row being i : we write this as $P(\text{Column} = j | \text{Row} = i)$. Thus the hypothesis of independence of rows and columns is equivalent to the statement that the distribution of the variable column, conditional on the value of the variable row being i , is the same for all values of i : in this case we say that these conditional distributions are *homogeneous*.

To test the null hypothesis of independence H_0 , we compute Pearson's χ^2 statistic, which is defined as

$$\chi^2 = \sum_i \sum_j \frac{(n_{ij} - e_{ij})^2}{e_{ij}} \quad (4)$$

where e_{ij} are conventionally called the *expected values*, and are defined by

$$e_{ij} = \frac{(n_{i+}n_{+j})}{n} \quad \text{for all } i, j \quad (5)$$

and n_{i+} and n_{+j} are the row and column totals, respectively, defined by $n_{i+} = \sum_j n_{ij}$ for all i and $n_{+j} = \sum_i n_{ij}$ for all j . (A pedantic but more accurate description of (e_{ij}) is “the maximum-likelihood estimates of the expected values of (n_{ij}) under H_0 ”.) We know that, under the null hypothesis H_0 , the distribution of χ^2 is, for large n , approximately χ_f^2 , where f , the **degrees of freedom**, are $(I - 1)(J - 1)$. Hence for a significance test of H_0 with approximate **significance level** α , we reject H_0 if

$$\chi^2 \geq \chi_f^2(\alpha), \quad (6)$$

the right-hand side being the upper α point of the χ_f^2 distribution, which we can find from statistical tables: typically we would take α as 0.01 or 0.05. Thus we have approximately arranged that, for large n , our test gives

$$\Pr(\text{reject } H_0 | H_0 \text{ true}) \leq \alpha \quad (7)$$

This is what we mean by saying that the test is of approximate *size* α .

χ^2 tests are described in depth in another article. The value of the χ^2 statistic for the numerical example given above is 24.15, which lies well above 18.47, the 0.001 point of the χ_4^2 distribution. Thus for these data, the null hypothesis of independence of the women's response to the question about the detection of breast cancer and their “Mammography Experiences” is rejected, as our preliminary look at the table suggested would be the case.

From the point of view of scientific enquiry, a statistical significance test is a crude and blunt instrument. If we found that the value of χ^2 was significant, we would usually want to investigate in some detail *why* the null hypothesis of independence fails to fit. It is good statistical practice to compare the *adjusted residuals*

$$\frac{(n_{ij} - e_{ij})}{[e_{ij}(1 - \hat{p}_{i+})(1 - \hat{p}_{+j})]^{1/2}} \quad (8)$$

where $\hat{p}_{i+} = (n_{i+}/n)$, $\hat{p}_{+j} = (n_{+j}/n)$, with the standard **normal distribution**. Thus any residual greater than about 1.5 in absolute value is “interesting”, and

the corresponding cell (i, j) of the table is special in some way and deserves investigation.

Under the null hypothesis H_0 , the sufficient statistics for the unknown parameters $((p_{i+}), (p_{+j}))$ are $((n_{i+}), (n_{+j}))$. One consequence of this is that the observed values of these statistics must agree exactly with the corresponding expected values: thus

$$n_{i+} = e_{i+} \quad \text{for each } i, \text{ and } n_{+j} = e_{+j} \quad \text{for each } j \quad (9)$$

This is a special case of a general result for exponential families, and we shall see examples of the same result when we consider multiway tables in the final section.

A test statistic which is equivalent to χ^2 for large sample size is the *deviance*, conventionally denoted by G^2 . It is derived from the ratio of maximized likelihoods. For the example of testing H_0 , G^2 is defined by

$$G^2 = 2 \sum \sum n_{ij} \log \left(\frac{n_{ij}}{e_{ij}} \right) \quad (10)$$

and for the numerical example given above G^2 has the value 26.80; recall that the value of χ^2 was 24.15.

Both χ^2 and G^2 are appropriate test statistics for sampling setups other than the straightforward single multinomial one introduced above. For example, suppose the contingency table (n_{ij}) were collected with the row totals

- (n_{i+}) fixed, and
- $(n_{ij}|n_{i+})$ independently and multinomially distributed, with
- (n_{ij}) multinomial parameters $n_{i+}, (\theta_{ij})$,
- where $\sum_j \theta_{ij} = 1$ for each i .

Then the statistics χ^2 and G^2 are the appropriate test statistics for testing $H: \theta_{ij} = \phi_j$ for all i, j , for some (unknown) ϕ_j such that $\sum \phi_j = 1$; in other words, the null hypothesis of homogeneity of row distributions.

Yet another way of writing H_0 is

$$H_0 : \log(p_{ij}) = \alpha_i + \beta_j \quad \text{for all } i, j \quad (11)$$

for some α, β such that $\sum p_{ij} = 1$. One reason for writing H_0 in this form is that it enables us to see that it is a *loglinear* hypothesis; that is, the log of the probabilities can be written as a function which is linear in the unknown parameters, which in this case are $(\alpha_i), (\beta_j)$.

Computational Aspects

Contingency table analysis, both by χ^2 tests and by small-sample “exact” methods, is easily achieved in many statistical software packages. Usually we can ask for direct computation of the appropriate χ^2 statistic, with associated residuals and significance tests. More sophisticated software will allow us to test complex hypotheses of independence by fitting models using one or both of iterative proportional fitting (IPF) or generalized linear modeling (GLM). IPF may be computationally more efficient than the GLM approach, since in using GLM for contingency table analysis we are ignoring the particular structure of the parameters. For example, in using GLM to test for independence in a two-way contingency table, we use an iterative technique (effectively the *Newton–Raphson*) to solve the maximum-likelihood equations when in fact five minutes with a pencil and paper would show us that iteration is unnecessary: there is a closed-form solution. But an advantage of the GLM approach is that it is more suited to the problem of choosing the simplest possible model consistent with a given dataset. Most statisticians are familiar with the use of GLM in any case, and so this advantage outweighs the possible gain in computational efficiency of IPF. The GLM approach may be rather more forbidding for the less mathematical user, but has definite advantages when we come to consider cross tabulations which are more complex than just the two-way ones. We discuss *multiway* contingency tables in the last section of this article. Although there are several possible probability distributions available for GLMs, there is no multinomial distribution. This is not a problem, provided that we are fitting a *log-linear* model, such as H_0 as written in its final form above. Thus for testing independence in a two-way contingency table we can use the Poisson distribution as a “surrogate” for the multinomial, so that we can compute the appropriate deviance for testing independence for the multinomial model by pretending that (n_{ij}) are observations on independent Poisson

4 Contingency Table

variables. This is a special case of a general result, relating Poisson and multinomial loglinear models.

Quasi-Independence

For some two-way contingency tables with a special structure, it may be obvious that the null hypothesis of independence H_0 cannot possibly be expected to fit, because it is far too “severe”. However, a weaker hypothesis which is chosen to represent a version of independence, or quasi-independence, may be helpful in the interpretation of the data. For example, Altham [2] discusses the data on initial and final ratings of 121 stroke patients in Table 3, taken from [3].

The rows of the 5×5 table correspond to the patient’s state on admission to hospital, and the columns to his state when discharged. These states have possible values A, B, C, D , and E , ranging from A as the least severe to E as the most severe. The resulting contingency table is *triangular*, because the patient’s state on being discharged is never worse than his initial state. Because of this constraint, the hypothesis of independence of rows and columns cannot possibly hold. But if we assume that the frequencies (n_{ij}) for $1 \leq j \leq i \leq 5$ come from a multinomial distribution with corresponding parameters (p_{ij}) , then it may still be helpful to fit a hypothesis of *quasi-independence* H_{qi} , say:

$$H_{qi} : p_{ij} = \alpha_i \beta_j, \quad \text{for all } j \leq i \quad (12)$$

for some (α_i) , (β_j) . This is another loglinear hypothesis, and so may be tested by treating the (n_{ij}) as independent Poisson variables. For the data given here, the deviance for testing H_{qi} has value 9.60, $df = 6$, indicating a reasonable fit. Similar models may be appropriate for the type of “triangular” data arising from capture–recapture studies in ecology, where, for example, a bird first ringed in 1975 may

be observed in any one of the 10 successive years, but of course a bird first ringed in 1977 could not have appeared in the 1975 count.

Quasi-independence models for square contingency tables (omitting the diagonal entries) are known as *mover–stayer* models in the sociological context. This hypothesis of quasi-independence is one of several models especially suitable for a square contingency table; others in this class are models of symmetry, marginal homogeneity, and quasisymmetry.

Exact Tests of Independence

For tables with small frequencies, the large-sample approximation of the distribution of χ^2 , or equivalently of the distribution of G^2 , to the χ^2 distribution may be doubtful. Most software will give appropriate “warning messages” if the “expected counts” e_{ij} are too small, less than five being a conservative interpretation of “too small” here. In this case the statistician will need to use an exact method. For a 2×2 table, Fisher’s exact test, which is based on the hypergeometric distribution, is appropriate, and it has been generalized, say, to $I \times J$ tables by using the multivariate hypergeometric distribution: this is the result of conditioning the multinomial distribution on both the row and column frequency totals, under the null hypothesis of independence of rows and columns.

For example, consider the 2×2 contingency table in Table 4.

In carrying out a χ^2 test on this table, we are essentially asking whether the proportion $8/16$ is different from the proportion $20/23$. The χ^2 statistic is 4.67, with corresponding P value = 0.0307. But the software warns that the expected counts may be too low for the large-sample approximation to be valid, and it is easy to see that e_{11} , which is $16 \times 11/39$, is 4.5. For the sake of comparison, we do a two-sided Fisher exact test, and find that the corresponding P value is 0.0272. So either method would lead us to reject the null hypothesis of independence of rows and columns.

Multiway Contingency Tables

An example of a four-way contingency table is given in Table 5. These data have been slightly adapted for pedagogic purposes from a dataset on adolescents supplied by Professor I.J. Goodyer of Cambridge University, Developmental Psychiatry. For further discussion of the original data, see [4].

One purpose in collecting such a dataset is to find a model that explains how the four variables “Gender”, “Depression status”, “Behavior”, and “Anxiety” are interrelated.

For example, we can see from the two-way marginal Table 6 that the prevalence of depression among girls is 17%, compared with only 8% as the corresponding figure for boys. (The χ^2 statistic for this 2×2 table is 4.82, which is significant when referred to χ^2_1 .) Similarly, the two-way marginal Table 7, for which the corresponding χ^2 statistic is 7.42, suggests that there is a strong positive association between anxiety and behavioral symptoms.

However, we can see that this piecemeal and *ad hoc* approach to the data analysis is rather unsatisfactory. Looking at the pairwise marginal tables can raise some interesting suggestions, but it may also

be misleading because it possibly conceals important features of the data, as we shall see later. Furthermore, even for a four-way contingency table there are six possible pairwise marginal tables to be examined, so that it is clear that for large tables, for example seven-dimensional, we need a more focused modeling strategy.

We return to the above practical example when we have discussed types of independence for multiway contingency in a formal way.

Suppose that the rows, columns, layers, etc., of the multiway table are labeled A, B, C , etc. There are many different types of independence between these variables that are possible. This makes analysis of multiway contingency tables interesting and complex. Fortunately, the relationship between the variety of types of independence and loglinear models fits naturally within the GLM framework. We will once again make use of the relationship between the Poisson and the multinomial in the context of loglinear models.

An example with only three variables, say A, B , and C , serves to illustrate the methods used in tables of dimension higher than two. Suppose that A, B , and C correspond, respectively, to the rows, columns, and layers of the three-way table. Let

$$p_{ijk} = \Pr(A = i, B = j, C = k) \quad \text{for } i = 1, \dots, I, \\ j = 1, \dots, J, k = 1, \dots, K \quad (13)$$

so that $\sum p_{ijk} = 1$, and let (n_{ijk}) be the corresponding observed frequencies, assumed to be observations from a multinomial distribution, parameters $n, (p_{ijk})$.

There are eight different hypotheses corresponding to types of independence between A, B , and C that we now consider. Assume in all of these that the parameters given are such that $\sum p_{ijk} = 1$.

$$H_0 : p_{ijk} = p_{i++}p_{+j+}p_{++k} \quad \text{for all } i, j, k \quad (14)$$

thus H_0 corresponds to A, B , and C independent.

$$H_1 : p_{ijk} = p_{i++}p_{+jk} \quad \text{for all } i, j, k \quad (15)$$

thus H_1 corresponds to A independent of (B, C) .

(Likewise, we could consider the hypothesis B independent of (A, C) , and the hypothesis C independent of (A, B) .)

$$H_2 : \frac{p_{ijk}}{p_{i++}} = \left(\frac{p_{ij+}}{p_{i++}} \right) \left(\frac{p_{i+k}}{p_{i++}} \right) \\ \text{for all } i, j, k \quad (16)$$

Table 5 2^4 table from psychiatry

		Behavioral symptoms		No		Yes	
		Anxiety symptoms		No	Yes	No	Yes
Girls	Depression = no			85	14	10	2
Girls	Depression = yes			8	4	7	4
Boys	Depression = no			107	13	8	3
Boys	Depression = yes			2	3	3	4

Table 6 A pairwise summary from Table 5

	Depression	
	No	Yes
Girls	111	23
Boys	131	12

Table 7 Another pairwise summary from Table 5

		Anxiety symptoms	
		No	Yes
Behavioral symptoms	No	202	34
Behavioral symptoms	Yes	28	13

6 Contingency Table

Thus H_2 is equivalent to

$$\Pr(B = j, C = k | A = i) = \Pr(B = j | A = i) \times \Pr(C = k | A = i) \quad \text{for all } i, j, k \quad (17)$$

and so H_2 corresponds to the hypothesis that, for each i , conditional on $A = i$, the variables B and C are independent. In this case we say that B and C are independent, conditional on A . (Likewise, we can define two similar hypotheses by interchanging A , B , and C .)

Independence and conditional independence between variables can be more clearly understood by showing suitable *association graphs*. In this graphical representation of the hypotheses, we represent the variables A , B , and C by the *vertices* of the graph, with links between these vertices representing dependence, and absence of links representing independence. Thus

H_0 corresponds to no links between any of A , B , and C .

H_1 corresponds to a link between B and C only, and A as an isolated point.

H_2 corresponds to a link between A and B , and a link between A and C : thus B and C are linked only through A ; see the diagram below.

The theory of association graphs is a useful and elegant one, particularly suitable for displaying and understanding the structure of high-dimensional tables.

Finally, we consider

$$H_3 : p_{ijk} = \alpha_{jk}\beta_{ik}\gamma_{jk} \quad \text{for all } i, j, k, \quad \text{for some } \alpha, \beta, \gamma \quad (18)$$

This hypothesis, which is symmetric in A , B , and C , cannot be given an interpretation in terms of conditional probability (see Figure 1). It corresponds to saying that the *interaction* between any two of the three factors, say A and B , given the level of the third factor, say C , is independent of the level of C . We say that H_3 corresponds to “no three-way interaction” between A , B , and C .

One way of writing this formally is to say that for each i, j the odds ratio describing the dependence

Figure 1 B and C conditionally independent, given A

between A and B

$$\frac{(p_{ijk}p_{Ijk})}{(p_{iJk}p_{Ijk})} \quad (19)$$

is the same for all k .

The eight hypotheses are related to one another as follows: for any given probabilities (p_{ijk}) ,

H_0 implies H_1 , which in turn implies H_3 , and
 H_0 implies H_2 , which in turn implies H_3 , and
 H_1 and H_2 are together equivalent to H_0 .

Thus H_0 is the strongest hypothesis and H_3 is the weakest.

All of the eight hypotheses above may be written as loglinear hypotheses and hence tested within the GLM framework with the Poisson distribution and log link function. Since the log is the *canonical link function* for the Poisson distribution, it is the *default* link function for the Poisson in GLM terms.

For example, we may rewrite H_2 as

$$H_2 : \log(p_{ijk}) = \phi_{ij} + \psi_{ik} \quad \text{for all } i, j, k \quad (20)$$

for some ϕ, ψ . In the GLM notation for interactions between factors, this corresponds to the model

$$A * B + A * C \quad \text{or, equivalently, } A * (B + C)$$

We pause to explain briefly the GLM notation for interactions between factors. For example, consider the model

$$A * B + A * C$$

In the context of loglinear models, this means that we can write $\log(p_{ijk})$ as

$$\log(p_{ijk}) = \mu + \alpha_i + \beta_j + \gamma_k + (\alpha\beta)_{ij} + (\alpha\gamma)_{ik} \quad (21)$$

for all i, j, k . Here the set of parameters $[(\alpha\beta)_{ij}]$ is termed $A.B$, the AB interaction, the set $[(\alpha\gamma)_{ik}]$ the AC interaction, and the sets (α_i) , (β_j) , (γ_k) are, respectively, the main effects of A , B , and C denoted by A , B , C .

For parameter identifiability in our computations we will need to impose constraints on (α_i) , and so on. We assume in the numerical examples that follow that the *corner-point* constraints are imposed; thus

$$\alpha_1 = 0, \quad \beta_1 = 0, \quad \gamma_1 = 0, \quad (\alpha\beta)_{1j} = 0 \quad (22)$$

and so on, so that any parameter with a subscript 1 anywhere is set to zero. Different software may impose a different set of constraints: this is always a confusing point for a beginner.

In the same GLM notation, H_0 , H_1 , and H_3 correspond, respectively, to $A + B + C$, $A + B * C$, and $(B * C + A * B + A * C)$.

For completeness, we will also define the *saturated* model H_s , say, which makes no independence statement about A , B , and C :

$$H_s: \log(p_{ijk}) = \rho_{ijk} \quad \text{for all } i, j, k \quad (23)$$

for some ρ : in GLM notation this is simply

$$A * B * C$$

In terms of our association graph, this corresponds to all three links being present between the vertices A , B , and C .

Example

Consider the $2 \times 2 \times 2$ table shown in Table 8.

For example, A might correspond to “agree with a controversial statement” (such as “women are not inherently better than men at looking after children”, B might be the educational level (below or above average), and C might be the gender (men/women).

Table 8 A 2^3 table

	$C = 1$		$C = 2$	
	$A = 1$	$A = 2$	$A = 1$	$A = 2$
$B = 1$	17	23	36	50
$B = 2$	29	14	59	24

As our baseline model, we first fit the saturated model

$$A * B * C$$

This is bound to give a perfect fit, with deviance and df both zero. So this first step in the model fitting might not appear to be a useful exercise. However, inspection of the resulting *parameter estimates* together with their *standard errors* suggests that the three-factor interaction term, $A.B.C$ can be dropped from the model, since the estimate of $A.B.C$ is -0.197 with $se = 0.561$. So our next step is to fit $(A + B + C) * (A + B + C)$, which gives a deviance of 0.12, with 1 df. Comparison with χ^2_1 shows that this model, which is H_3 , is a good fit. Thus there is no three-way interaction between A , B , and C , and so, for example, we can say that the way in which the response to the question A depends on educational level is the same for both men and women.

Again, we compare the parameter estimates with their standard errors, and find that the pairwise interaction $A.C$ is -0.068 , with $se = 0.28$. This suggests that $A.C$ should now be dropped from the model, and indeed the resulting model $(A + C) * B$ has deviance 0.18 (2 df). So this model is a good fit. It states that conditional on the educational level, the response to A is independent of the gender.

This model can be rewritten as $A * B + B * C$, and this has the consequence that the *observed and fitted frequencies* for the two-way marginal table $A * B$ must agree exactly, and similarly for the $B * C$ marginal table.

Inspection of the parameter estimates and their standard errors for this model shows that $B.C$ can also be dropped from the model, leading to the model $A * B + C$, which has deviance 0.34 (3 df). But this final step would not make sense if the data were collected with *fixed* totals in the $B.C$ marginal table, since under the model $A * B + C$ we would not necessarily have exact agreement between the observed and fitted frequencies of the $B.C$ table.

The Relationship between Binomial Logistic Regression and Loglinear Models in a Multiway Contingency Table

In a multiway contingency table, it may not be appropriate to treat the variables, say A , B , C , etc., symmetrically. For example, it may be more natural

8 Contingency Table

to treat A as a *response* variable, and B , C , etc., as *explanatory* variables.

In particular, if the number of levels of A is two, for example, corresponding to “yes, no”, then it may make the analysis easier to interpret if we carry out a binomial logistic regression of A on the factors B , C , etc.

Such an analysis is not essentially different from a loglinear analysis. We can see from the following considerations that there must be certain exact correspondences between the two approaches. To be specific, take the case in which (Y_{ijk}) is multinomial, parameters n , (p_{ijk}) and suppose $i = 1, 2$. Write y_{+jk} as $y_{1jk} + y_{2jk}$. Then $Y_{1jk}|y_{+jk}$ are independent binomial variables, parameters y_{+jk} , θ_{jk} , where

$$\theta_{jk} = \frac{p_{1jk}}{p_{+jk}} \quad (24)$$

So, for example, the model $A * B + B * C + C * A$ for (p_{ijk}) can be shown to be equivalent to the model for logit $\theta_{jk} = \log[\theta_{jk}/(1 - \theta_{jk})]$,

$$\text{logit } \theta_{jk} = \beta_j + \gamma_k \quad (25)$$

For example, we could use the data from Table 8 above, with A as the response variable, so that we use the binomial proportions 17/40, 29/43, 36/86, and 59/83 as the responses corresponding to the factors (B,C) as (1,1), (2,1), (1,2), and (2,2). In this case it may be seen that the deviance and the fitted frequencies for the logit model $B + C$ are *exactly* the same as those for loglinear model $A * B + B * C + C * A$ with data for the $2 \times 2 \times 2$ and the multinomial model, as above.

We now return to the 2^4 contingency table, Table 5. The simplest model consistent with these data is (gender + anxiety symptoms + behavioral symptoms) * depression. This model has deviance 4.91, with 8 df. For a relatively complex table, a good way to find the simplest reasonable model is to start by fitting the saturated model, and then “step down”, discarding the unnecessary parameters, using the Akaike Information Criterion (AIC) as the guide to when to stop the stepping down process.

The final model here shows the key role of depression in explaining the dependence in the four-way table: conditional on the depression status, the two variables anxiety and behavior are independent of each other and are also independent of gender.

Figure 2 A graphic model for psychiatry data

Its graphical representation is a graph in which the three vertices “gender”, “anxiety symptoms”, and “behavioral symptoms” are linked to depression, and no other links are present (see Figure 2).

This final model also shows that summarizing the data by certain 2×2 tables, for example by *collapsing* over the variable gender and depression, may be a misleading way to investigate the association between variables. To put this more technically, for the current example with the final model, the two-way marginal table anxiety symptoms $\times$ behavioral symptoms is not among the sufficient statistics for the unknown parameters.

The danger in obtaining misleading results by collapsing a contingency table is known as *Simpson’s paradox* (also known as *Yule’s paradox*).

This brief article has introduced the topic of contingency tables, with particular discussion of types of independence for multiway tables. The reader will have realized that in none of the methods described above is any attention paid to the *order* of the categories of a variable: for example, if A takes as possible values 1, 2, 3, and 4, the above analyses would all remain the same if these levels were renamed as *apples*, *pears*, *oranges*, *bananas*. In this sense our treatment of the variables so far has been entirely *nominal*. This approach may not always be the most sensible one to follow. For example, both rows and columns of Table 1 are ordered. We might prefer our analysis to recognize this fact.

This article represents a brief introduction to the topic of contingency tables, and is not an exhaustive coverage of the available methods. For more comprehensive coverage, the reader is referred to the two textbooks by Agresti [5, 6].

Statistical Efficiency

Introduction

In 1922, Ronald Fisher [1], one of the founders of modern statistics, wrote his fundamental paper. *On the Mathematical Foundations of Theoretical Statistics*. In that paper he stated that “The object of statistical method is the reduction of data.” He then identified “three problems which arise in the reduction of data”. These are

1. *Specification* – choosing the right mathematical model for a population.
2. *Estimation* – methods to calculate, from a sample, estimates of the parameters of the hypothetical population.
3. *Distribution* – properties of statistics derived from samples.

Later, Colin Mallows, a distinguished researcher at AT&T Bell laboratories, added a “zeroth problem” – considering the *relevance of the observed data*, and other data that might be observed, to the substantive problem [2].

Kenett and Thyregod [3] present the statistical consulting cycle to solve real problems as a five-step cycle:

- (1) problem elicitation,
- (2) data collection,
- (3) data analysis,
- (4) findings formulation, and
- (5) findings presentation (see Figure 1).

Academia typically focuses only step (3), the data analysis step. The application of statistics requires the full cycle. The three problems addressed by Fisher focus on steps (2) and (3). The zeroth problem identified by Mallows relates to steps (1) and (2). Practical

statistical efficiency, introduced below, addresses the full life cycle.

Definition of Practical Statistical Efficiency

To expand the view of statistical methods, Godfrey [4, 5] and later, Kenett *et al.* [6, 7] suggest evaluating statistical work using a formula of practical statistical efficiency (PSE). The PSE formula of Kenett *et al.* [6] accounts for eight components and is computed as follows:

$$PSE = V\{D\} \times V\{M\} \times V\{P\} \times V\{PS\} \times P\{S\} \times P\{I\} \times T\{I\} \times E\{R\} \quad (1)$$

where

$V\{D\}$: value of the data actually collected,

$V\{M\}$: value of the statistical method employed,

$V\{P\}$: value of the problem to be solved,

$V\{PS\}$: value of the problem actually solved,

$P\{S\}$: probability level that the problem actually gets solved,

$P\{I\}$: probability level the solution is actually implemented,

$T\{I\}$: time the solution stays implemented, and

$E\{R\}$: expected number of replications.

These components can be assessed qualitatively, using expert opinions, or quantitatively, if the relevant data exists.

A straightforward approach to evaluate PSE is to use a scale of “1” for not very good to “5” for excellent. This method of scoring can be applied uniformly for all PSE components. Some of the PSE components can be also assessed quantitatively. $P\{S\}$ and

Figure 1 The statistical consulting cycle

2 Statistical Efficiency

$P\{I\}$ are probability levels, $T\{I\}$ can be measured in months, $V\{P\}$ and $V\{PS\}$ can be evaluated in euros, dollars, or pounds. $V\{PS\}$ is the value of the problem actually solved, as a fraction of the problem to be solved. If this is evaluated qualitatively, a large portion would be “4” or “5”, a small portion “1” or “2”. $V\{D\}$, the value of the data actually collected is related to Fisher’s zero problem presented in Mallows [2]. Whether PSE terms are evaluated quantitatively or qualitatively, PSE is a conceptual measure rather than a numerically precise one. A more elaborated approach to PSE evaluation can include differential weighing of the PSE components and/or nonlinear assessments.

A PSE Case Study

An old family-owned company decided, in 1998, to modernize their management of the company. Key performance indicators (KPIs) including efficiency, staff absence, and waste were adopted and the concept proved so useful that the original 39 KPIs were increased to 50. There were several early wins, for example a 90% reduction in out loading errors to a major customer and an improvement in performance of parallel shifts from 54 and 68 to 80% each. A questionnaire was given to staff to find out how they felt about the KPIs. It was found that staff did not like the staff absence KPIs because they felt powerless to influence them but did relate to waste KPIs because they are traditionally given in real terms rather than percentage. So “staff absence” was changed to staff attendance and KPIs focused on output using both quantities and money made and lost. Reporting changed from displaying the daily performance of 10 machines on a page to displaying weekly performance of one machine per page. This meant that charts could be placed near to machines and operators could observe their performance. It also led to a clearer understanding of causes of downtime. It was then decided to take the plunge and change from reporting efficiency to reporting utilization as a much more realistic and meaningful way to assess performance. Performance appeared to drop from 80 to 70% but it was felt that staff were ready for the psychological blow and eventually performance on this measure is gradually improved. The tea packers embraced the quality improvement project wholeheartedly and initially had a specific problem to solve: they had two

apparently identical packing lines and yet one produced 54% efficiency and the other produced 68% with the same staff. The problem was eventually located to the availability of the engineers to mend the line when problems occurred. The PSE components for this case study have been assessed qualitatively as

$V\{D\}$: value of the data actually collected = 4,

$V\{M\}$: value of the statistical method employed = 3,

$V\{P\}$: value of the problem to be solved = 4,

$V\{PS\}$: value of the problem actually solved = 4,

$P\{S\}$: probability level that the problem actually gets solved = 5,

$P\{I\}$: probability level the solution is actually implemented = 5,

$T\{I\}$: time the solution stays implemented = 3, and

$E\{R\}$: expected number of replications = 4.

so that $PSE = 57\,600$.

Kenett *et al.* [6] refer to five case studies (including the one above), and derive qualitatively scores for the eight components of PSE. The cases are referred to as *tea*, *drink*, *metal*, *utility*, and *filter* and the results are shown in Table 1.

A radar plot of these scores is presented as Figure 2.

It can be seen from Figure 2 that the scores are generally high for the longevity ($E\{R\}$ and $T\{I\}$) and probability components for all five case studies and the difference comes in the values. In particular the $V\{D\}$, value of the data. This value reflects the effort put into the project. A similar comment applies to the $V\{M\}$, value of the method used. When the problem is of low priority, resources are not made available for

Figure 2 Practical statistical efficiency evaluation of the five case studies

Table 1

Case	$E\{R\}$	$T\{I\}$	$P\{I\}$	$P\{S\}$	$V\{PS\}$	$V\{P\}$	$V\{M\}$	$V\{D\}$	PSE
Tea	4	3	5	5	4	4	3	4	57 600
Drink	4	4	3	3	4	3	2	1	3456
Metal	4	3	3	4	5	1	1	1	720
Utility	5	5	4	3	4	5	4	4	96 000
Filter	4	5	5	5	4	5	5	5	250 000

methodology to be as good as possible. For example, in the heavy metal company, the time available to the operative involved and his expertise limited the methodology to the most basic charts.

In all of these case studies, the $V\{PS\}$ value of the problem actually solved is high. In the less successful case studies, the worth was not appreciated and the resources required to deal with the side effects were not available.

The Statistical Efficiency Conjecture

Kenett *et al.* [7] study empirically 21 case studies where PSE is evaluated along with the maturity level of the industrial organization from a management perspective. They formulate the *statistical efficiency conjecture* that links management maturity with the impact level of problem solving and improvements driven by statistical methods. The maturity level to the management of industrial organizations can be summarized and classified using a four-step *quality ladder* [8]. The four approaches are (a) fire fighting, (b) inspection, (c) process control, and (d) quality by design. To each management approach, corresponds a particular set of statistical methods and the quality ladder maps each management approach with appropriate statistical methods. The statistical efficiency conjecture states that organizations higher up on the quality ladder achieve higher values of PSE. The implication being that moving up the quality ladder is justified on practical grounds using effectiveness and efficiency criteria.

RON S. KENETT

Sigma Level of a Process

The sigma level is a measure of the quality of a characteristic of a process or product. It is based on defects per million opportunities (DPMO), and, for continuous metrics only, is also related to process

capability. Higher quality (that is, lower DPMO) corresponds to higher sigma level. For example, sigma levels of 2, 3, 4, 5, and 6, correspond to DPMO values of 308 538 66 807 6210 233 and 3.4, respectively.

Defects per Million Opportunities

Defects per million opportunities (DPMO) is a measure of the quality of a characteristic of a process or product. DPMO is calculated by determining the number of defects found in a sample according to the equation

$$DPMO = \frac{(\text{Defects} \times 1 \text{ million})}{(\text{Number of units in the sample} \times \text{Opportunities per unit})} \quad (1)$$

Here, opportunities per unit is defined to be the number of defects that could possibly occur in a single unit of a product or a single execution of a process.

C_p, C_{pk}

C_p and C_{pk} are indices used to express the capability to meet the specifications for a product or process characteristic. C_p and C_{pk} are calculated for stable, normally distributed data according to the equations

$$C_p = \frac{(\text{Upper specification limit} - \text{Lower specification limit})}{6 \times (\text{Short-term process standard deviation})} \quad (1)$$

$$C_{pk} = \frac{\text{Min}(\text{Upper specification limit} - \text{Mean}, \text{Mean} - \text{Lower specification limit})}{3 \times (\text{Short-term process standard deviation})} \quad (2)$$

Note that C_{pk} accounts for the location of the data (through its average or mean value), whereas C_p does not. C_{pk} is defined for either one- or two-sided specification limits, whereas C_p is defined only for

two-sided limits. For these reasons, C_{pk} is usually the preferred capability metric in practice. C_p is sometimes called the *potential process capability*, since, in the case of two-sided specifications, it provides the value that C_{pk} would attain for a perfectly centered process. Because these indices are calculated using a measure of short-term variability, they will generally

be higher than the corresponding long-term capability measures, P_p and P_{pk} .

P_p, P_{pk}

P_p and P_{pk} are indices used to express the capability to meet specifications for a product or process characteristic. Higher values denote better capability. P_p and P_{pk} are calculated for stable, normally distributed data according to the equations:

Note that P_{pk} accounts for the location of the data (through its average or mean value), whereas P_p does not. P_{pk} is defined for either one- or two-sided specification limits, whereas P_p is defined only for two-sided limits. For these reasons, P_{pk} is usually the preferred metric in practice. Because these indices are calculated using a measure of long-term variability, they will generally be lower than the corresponding short-term capability measures, C_p and C_{pk} (see C_p, C_{pk}).

$$P_p = \frac{(\text{Upper specification limit} - \text{Lower specification limit})}{6 \times (\text{Long-term process standard deviation})} \quad (1)$$

$$P_{pk} = \frac{\text{Min}(\text{Upper specification limit} - \text{Mean}, \text{Mean} - \text{Lower specification limit})}{3 \times (\text{Long-term process standard deviation})} \quad (2)$$

Defects per Unit

Defects per unit (DPU) is a measure of the quality of a characteristic of a process or product. DPU is calculated by determining the total number of defects

found in a sample according to the equation:

$$DPU = \frac{\text{Total defects}}{\text{Number of units observed}} \quad (1)$$

Accelerated Life Tests: Bayesian Models

Introduction and Overview

When dealing with high-reliability components/systems, it is not unusual to conduct tests in a more severe environment than the actual use environment. Such tests are called *accelerated life tests* (ALTs) and are usually conducted with the purpose of inducing early failures to reduce the time and cost of testing. The important statistical issue in ALTs is to make inferences about the failure behavior of the items at the user environment based on **failure data** obtained under more severe environments. In recent years there has been an increasing interest in developing Bayesian methods to make inferences from ALTs; see for example Mazzuchi and Soyer [1], van Dorp *et al.* [2], Mazzuchi *et al.* [3], and van Dorp and Mazzuchi [4, 5]. As a result of using complicated time transformation functions and/or ramping functions in step-stress ALTs, Bayesian inferences from these models have become extremely difficult. To deal with intractable predictive and posterior distributions, the previous approaches used large-sample approximations or approximate methods of inference such as the linear Bayes. Only a few of the earlier Bayesian work in ALTs, such as Blackwell and Singpurwalla [6] and Mazzuchi and Soyer [1], have considered models that allow time transformation functions that change with stress environment.

In this chapter we consider Bayesian models that allow dynamic time transformation functions, and propose different modeling strategies. We focus specifically on hierarchical Bayes models, similar to those described by Lindley and Smith [7], and dynamic models as in Mazzuchi and Soyer [1], and develop Bayesian computational methods for making inferences using **Markov chain Monte Carlo** (MCMC) approaches. The attractive feature of the MCMC methods is that they enable generation of samples from the posterior and predictive distributions without having to obtain the exact distributional forms. Thus, unlike the previous approaches, we can perform Bayesian analyses fully by computing all the posterior and predictive distributions of interest.

In the following section, we present a basic parametric accelerated **life testing** model assuming a Weibull **life distribution** and several time transformation functions. We discuss the difficulties involved in computing the posterior and predictive distributions using conventional techniques and present alternative inference based on MCMC methods. In the section titled “Extensions of the Basic Parametric Model”, we consider hierarchical and Markov models as novel extensions of the basic parametric model to allow for dynamic time transformation functions and discuss inference and reliability predictions using MCMC methods. In the section titled “Analysis of Accelerated Life Testing Data”, we illustrate our approaches using two real-life testing examples, discuss model comparison, and investigate the appropriateness of dynamic time transformation functions.

A Parametric ALT Model

An accelerated test environment is created typically by increasing the level of one or more stress variables (temperature, voltage, etc.) to values that are higher than those at normal operating conditions. For simplicity, in our development we assume that the environment is defined by a single stress variable. Extension to the multivariable case is straightforward. To introduce some notation, let S_i denote the level of the stress variable at the i th accelerated test environment and assume that test will be conducted at K accelerated levels of the stress variable that are specified in advance. As noted before, our main objective is to make predictive inferences about the failure behavior of items at the use-stress environment, S_u , based on the data from the K accelerated testing environments, where $S_i > S_u$ for $i = 1, 2, \dots, K$. It is also possible to incorporate testing at the use environment with the proposed procedure, but in our development we assume that no testing is conducted at S_u .

We assume that under the i th accelerated test environment, the failure behavior of the items can be described by a Weibull model with density

$$p(x_i|\lambda_i, \beta) = \beta\lambda_i x_i^{\beta-1} e^{-\lambda_i x_i^\beta} \quad (1)$$

with scale parameter, $\lambda_i > 0$ and shape parameter, $\beta > 0$. We will denote the above model as $(X_i|\lambda_i, \beta) \sim \text{Weib}(\lambda_i, \beta)$. The failure rate of the

2 Accelerated Life Tests: Bayesian Models

model is given by

$$m_i(x_i | \beta, \lambda_i) = \beta \lambda_i x_i^{\beta-1} \quad (2)$$

where the values $\beta > 1 (<1)$ imply an increasing (decreasing) failure rate distribution, and when $\beta = 1$ the exponential model arises as the special constant failure rate case. The above model implies that the scale parameter, λ_i , depends on the stress environment, but the shape parameter, β , does not, which is a common assumption in the literature (see for example Nelson [8] and Mazzuchi *et al.* [3]). It is common to assume a functional relationship between the failure rate and applied stress level. Such a relationship is referred to as a *time transformation function*. The Arrhenius law and the power law models are two of the most commonly used time transformation functions (Mann *et al.* [9]).

Assuming a power law model, the relationship between the scale parameter and the applied stress level in the i th accelerated test environment is given by

$$\lambda_i = \theta_1 S_i^{\theta_2} \quad (3)$$

where $\theta_1 > 0$ and θ_2 are unknown coefficients. Alternatively, an Arrhenius law model assumes that

$$\lambda_i = \exp \{ \theta_1 - \theta_2 / S_i \} \quad (4)$$

In both cases, the aging effect is captured by the shape parameter β , whereas the effect of the stress environment on the failure behavior is captured by functional parameters θ_1 and θ_2 .

Bayesian Inference for the ALT Model

Assume that n_i items are tested for t_i units of time at the i th accelerated environment with level S_i . Let X_{ij} denote the time to failure of the j th item tested under the i th environment with realization x_{ij} , $j = 1, 2, \dots, r_i \leq n_i$, where r_i denotes the number of failures observed during the observation period $(0, t_i]$. As noted by Mazzuchi *et al.* [3], using this notation, we can easily consider the complete sample (no censoring) case, where testing continues until all items have failed, as well as the type I and type II censoring cases. Specifically, the no censoring case is obtained with $t_i = \infty$; type I censoring case is obtained with $t_i < \infty$; and type II censoring case where testing continues until the r th failure is obtained with $t_i = x_{i(r_i)}$, where $x_{i(r_i)}$ is the r_i th failure

time at the i th accelerated environment. In what follows, we will assume that testing is conducted simultaneously at all stress levels, but the case of sequential testing from one stress level to another can also be accommodated.

Let D_i denote the test data from i th accelerated stress environment, that is,

$$D_i = \{n_i, r_i, x_{i1}, \dots, x_{ir_i}\} \quad (5)$$

Assuming conditional independence of the failure times $\{x_{ij}\}$ given the stress levels $\{S_i\}$, and the parameters β, θ_1 , and θ_2 , the likelihood function of λ_i and β from the i th accelerated stress environment is obtained as

$$\mathcal{L}_i(\lambda_i, \beta; D_i) = (\beta \lambda_i)^{r_i} \left\{ \prod_{j=1}^{r_i} (x_{ij})^\beta \right\} \exp \{-\lambda_i T_i(\beta)\}, \quad i = 1, \dots, K \quad (6)$$

where

$$T_i(\beta) = \begin{cases} \sum_{j=1}^{r_i} (x_{ij})^\beta + (n_i - r_i) t_i^\beta & \text{type I censoring} \\ \sum_{j=1}^{r_i} (x_{ij})^\beta + (n_i - r_i) (x_{i(r_i)})^\beta & \text{type II censoring} \\ \sum_{j=1}^{n_i} (x_{ij})^\beta & \text{no censoring} \end{cases} \quad (7)$$

and λ_i is defined either by equation (3) or (4). We note that in the case of no censoring $r_i = n_i$ in equation (6). Thus, the likelihood function of β, θ_1 and θ_2 given all the data $D = \{D_1, D_2, \dots, D_K\}$ is

$$\mathcal{L}(\theta_1, \theta_2, \beta; D) = \prod_{i=1}^K \mathcal{L}_i(\lambda_i, \beta; D_i) \quad (8)$$

The Bayesian approach requires specification of a prior distribution for β, θ_1 , and θ_2 . The joint posterior distribution can then be obtained as

$$p(\theta_1, \theta_2, \beta | D) \propto \mathcal{L}(\theta_1, \theta_2, \beta; D) p(\theta_1, \theta_2, \beta) \quad (9)$$

where $p(\theta_1, \theta_2, \beta)$ is the joint prior distribution. As noted by Mazzuchi *et al.* [3], the posterior distribution in equation (9) cannot be obtained in any

tractable form for any choice of the prior $p(\theta_1, \theta_2, \beta)$ in equation (9). Thus, to perform a fully **Bayesian analysis**, we will use the Gibbs sampler, an MCMC method, which is easy to implement in this case. The Gibbs sampler enables us to generate samples from the posterior distribution $p(\theta_1, \theta_2, \beta|D)$, which can then be used to make assessments about the failure behavior at the use stress environment in our problem. This is achieved without actually computing the distributional form by obtaining successive drawings from the full conditional distributions $p(\theta_1|\theta_2, \beta, D)$, $p(\theta_2|\theta_1, \beta, D)$, and $p(\beta|\theta_1, \theta_2, D)$. The process starts with a vector of arbitrary starting values of the parameters, $(\theta_1^{(0)}, \theta_2^{(0)}, \beta^{(0)})$, and continues by iteratively generating samples from the full conditional distributions (see Gelfand and Smith [10] for more details).

We note that the implementation of the Gibbs sampler requires the availability of the full conditional distributions. If the full conditional distributions are not of any known form or if they do not exist in closed form, some type of random number generation method must be employed to facilitate the implementation of the Gibbs sampler. If the full conditional distributions are log concave, one can use the efficient adaptive rejection sampling (ARS) method of Gilks and Wild [11]. Unlike standard rejection sampling methods, ARS avoids any maximization steps and therefore can be easily adopted at each iteration of the Gibbs sampler.

In our development for the power law model we will assume a gamma prior for θ_1 , denoted as $\Gamma[a, b]$, and we will denote the priors for θ_2 and β as $p(\theta_2)$ and $p(\beta)$, respectively. Furthermore, we assume that *a priori* θ_1, θ_2 , and β are independent. Under the power law model, with the given choice of priors, the full conditional distributions are given by

$$p(\theta_1|\theta_2, \beta, D) \propto \left\{ \theta_1^{\sum_{i=1}^K r_i} \exp \left[-\theta_1 \sum_{i=1}^K S_i^{\theta_2} T_i(\beta) \right] \right\} \times \theta_1^{a-1} \exp \{-b\theta_1\} \quad (10)$$

$$p(\theta_2|\theta_1, \beta, D) \propto \left\{ \prod_{i=1}^K S_i^{r_i \theta_2} \right\} \exp \left[-\theta_1 \sum_{i=1}^K S_i^{\theta_2} T_i(\beta) \right] p(\theta_2) \quad (11)$$

and

$$p(\beta|\theta_1, \theta_2, D) \propto \beta^{\sum_{i=1}^K r_i} \left\{ \prod_{i=1}^K \left(\prod_{j=1}^{r_i} (x_{ij})^\beta \right) \right\} \times \exp \left[-\theta_1 \sum_{i=1}^K S_i^{\theta_2} T_i(\beta) \right] p(\beta) \quad (12)$$

Note that equation (10) implies $(\theta_1|\theta_2, \beta, D) \sim \Gamma \left[a + \sum_{i=1}^K r_i, b + \sum_{i=1}^K S_i^{\theta_2} T_i(\beta) \right]$, whereas for any reasonable prior form for $p(\theta_2)$ and $p(\beta)$, the posterior conditionals in equations (11) and (12) cannot be obtained as a familiar form. However, they are both log concave if the priors $p(\theta_2)$ and $p(\beta)$ are log concave since both conditional log likelihoods are log concave. Thus the ARS method can be implemented to sample from the posterior densities in equations (11) and (12) at each iteration of the Gibbs sampler.

Once a sample $\{\theta_1^{(j)}, \theta_2^{(j)}, \beta^{(j)}\}_{j=1}^J$ is obtained from the posterior distribution $p(\theta_1, \theta_2, \beta|D)$, all the marginal posterior distributions and the posterior **moments** for the θ_1, θ_2 , and β can be computed from the sample. Given the data D from the K accelerated environments, inferences at the use-stress environment S_u can be easily made by using the posterior sample. For example, the predictive reliability at the use-stress environment is given by

$$R(x_u|D) = \int R(x_u|\theta_1, \theta_2, \beta) \times p(\theta_1, \theta_2, \beta|D) d\theta_1 d\theta_2 d\beta \quad (13)$$

where

$$R(x_u|\theta_1, \theta_2, \beta) = e^{-\lambda_u x_u^\beta} \quad (14)$$

and λ_u is given by equation (3) or (4). The integral in equation (13) can be computed by using a Monte Carlo average using the posterior sample as

$$R(x_u|D) \simeq \frac{1}{J} \sum_{j=1}^J R(x_u|\theta_1^{(j)}, \theta_2^{(j)}, \beta^{(j)}) \quad (15)$$

which is the expected reliability at mission time x_u . We can also make probability statements about the reliability at mission time x_u by using a histogram estimate based on $R(x_u|\theta_1^{(j)}, \theta_2^{(j)}, \beta^{(j)})$ $j = 1, \dots, J$. Similarly, expected time to failure at the use stress environment can be obtained. The above setup can

be easily modified to incorporate different priors. For example, for the power law model we may assume a lognormal prior for θ_1 and a normal prior for θ_2 .

Extensions of the Basic Parametric Model

Earlier work by Blackwell and Singpurwalla [6] and Mazzuchi and Soyer [1] considered time transformation functions that change with the stress environment. These authors claimed that such a change is likely to happen owing to changes in the basic failure mechanism with changes in the stress level, and introduced non-Gaussian Kalman filter type models for ALT, and used approximate Bayesian methods for inference.

In what follows we present two models that describe changes in the time transformation function. The first model is a hierarchical Bayes model in the sense of Lindley and Smith [7] and assumes exchangeability of the parameters of the time transformation function. The second model is a first-order Markov model similar to what is considered by Mazzuchi and Soyer [1]. We note that in both cases the likelihood functions (6) and (8) will still be valid with changes reflected in λ_i . We focus on the power law model, but extension to the Arrhenius law is straightforward.

A Hierarchical (Exchangeable) Bayesian Model

To allow for changes in the time transformation function, we rewrite the power law model (3) as

$$\lambda_i = \theta_{1i} S_i^{\theta_2} \quad (16)$$

where the parameter θ_{1i} depends on the stress as reflected by the index i . Assume θ_{1i} s are conditionally independent with $\theta_{1i} \sim \Gamma[a, b]$, where a and b are random quantities with hyperprior $p(a, b)$. This implies that $\{\theta_{1i}\}, i = 1, \dots, K$, is an exchangeable sequence. If we further assume *a priori* independence of β and θ_2 , and of θ_{1i} s, we can recast the ALT model into a hierarchical Bayesian model as follows:

$$(X_i | \lambda_i, \beta) \sim \text{Weib}(\lambda_i, \beta) \quad (17)$$

$$\lambda_i = \theta_{1i} S_i^{\theta_2} \quad (18)$$

$$(\theta_2, \beta) \sim p(\theta_2) p(\beta) \quad (19)$$

$$(\theta_{1i} | a, b) \sim \Gamma[a, b] \quad (20)$$

$$(a, b) \sim p(a, b) \quad (21)$$

For any choice of priors in equations (17–21), the posterior inference cannot be performed analytically and thus we use a Gibbs sampler. The full conditionals for $\{\theta_{1i}\}$ are given by

$$(\theta_{1i} | a, b, \theta_1^{(-i)}, \theta_2, \beta, D) \sim \Gamma \left[a + r_i, b + S_i^{\theta_2} T_i(\beta) \right] \quad (22)$$

where $\theta_1^{(-i)} = \{\theta_{1j}; j \neq i\}$. Assuming $p(a, b) = p(a)p(b)$, and $b \sim \Gamma[c, d]$, the full conditional for b is obtained as

$$(b | \theta_1, \theta_2, \beta, a, D) \sim \Gamma \left[c + aK, d + \sum_{i=1}^K \theta_{1i} \right] \quad (23)$$

where $\theta_1 = (\theta_{1i}; i = 1, \dots, K)$. Similarly, the full conditional of a is

$$p(a | \theta_1, \theta_2, \beta, b, D) \propto \left[\frac{b^a}{\Gamma(a)} \prod_{i=1}^K (\theta_{1i})^{a-1} \right] p(a) \quad (24)$$

which is log concave as long as $p(a)$ is a log-concave density.

For θ_2 , we have

$$p(\theta_2 | \theta_1, \beta, a, b, D) \propto \left\{ \prod_{i=1}^K S_i^{r_i \theta_2} \right\} \exp \left[- \sum_{i=1}^K \theta_{1i} S_i^{\theta_2} T_i(\beta) \right] p(\theta_2) \quad (25)$$

which is log concave for a log-concave prior. Finally, for β , we get

$$p(\beta | \theta_1, \theta_2, a, b, D) \propto \beta^{\sum_{i=1}^K r_i} \left\{ \prod_{i=1}^K \left(\prod_{j=1}^{r_i} (x_{ij})^\beta \right) \right\} \times \exp \left[- \sum_{i=1}^K \theta_{1i} S_i^{\theta_2} T_i(\beta) \right] p(\beta) \quad (26)$$

which is also log concave for a log-concave prior $p(\beta)$. Thus, we can use the ARS method to sample from the conditionals for θ_2 and β .

Having obtained the posterior samples, we focus on the predictive reliability at the use stress

$$R(x_u | D) = \int R(x_u | \theta_{1u}, \theta_2, \beta) \times p(\theta_{1u}, \theta_2, \beta | D) d\theta_{1u} d\theta_2 d\beta \quad (27)$$

Given the posterior samples we can approximate equation (27) as

$$R(x_u|D) \simeq \frac{1}{J} \sum_{j=1}^J R(x_u|\theta_{1u}^{(j)}, \theta_2^{(j)}, \beta^{(j)}) \quad (28)$$

where $\theta_{1u}^{(j)}$ is generated from the gamma density $p(\theta_{1u}|\alpha^{(j)}, b^{(j)})$, conditional on the posterior realizations $(a^{(j)}, b^{(j)})$.

A Markov (Dynamic) Model

An alternate modeling strategy for capturing changes in the time transformation function is to consider a first-order Markov structure on $\alpha_i = \ln \theta_{1i}$ in equation (16). Since S_i and S_{i-1} are ordered neighboring stress environments, $S_i < S_{i-1}$, for $i = 1, \dots, K$, we assume that

$$(\alpha_i|\alpha_{i-1}, \phi, \tau) \sim N(\phi\alpha_{i-1}, \tau^{-1}) \quad (29)$$

where ϕ and τ are unknown quantities. Initially, we assume that $\alpha_0 \sim N(\mu_0, \tau^{-1})$. This is a generalization of the model in Mazzuchi and Soyer [1]. Note that equation (29) can be represented as a first-order autoregressive AR(1) dynamic model as

$$\alpha_i = \phi\alpha_{i-1} + \epsilon_i, \epsilon_i \sim N(0, \tau^{-1}) \quad (30)$$

The use stress can be considered as the $(K+1)$ st level in the above setup, that is, $\alpha_u = \alpha_{K+1}$. In cases where the stresses are not equally spaced, the precision τ can be discounted by a function $f(S_i, S_{i-1})$ as $\tau_i = \tau f(S_i, S_{i-1})$. A suitable choice for f is $f(S_i, S_{i-1}) = S_i/S_{i-1}$, where $S_i < S_{i-1}$.

Specification of the Markov model can be completed by assuming independent priors as $\tau \sim \Gamma(a, b)$ and $p(\phi)$ in the above. Although $-1 < \phi < 1$ would imply a stationarity of equation (30), it is not strictly necessary for our analysis, so we choose a normal prior for ϕ for convenience; $\phi \sim N(\mu_\phi, \tau_\phi^{-1})$. Finally, we assume independent priors on β and θ_2 . Thus, for $0 < i < K$, the full conditional of α_i is given by

$$\begin{aligned} p(\alpha_i|\alpha^{(-i)}, \theta_2, \phi, \beta, \tau, D) \\ \propto \exp \left[\alpha_i r_i - e^{\alpha_i} S_i^{\theta_2} T_i(\beta) \right. \\ \left. - \frac{\tau}{2} ((\alpha_i - \phi\alpha_{i-1})^2 + (\alpha_{i+1} - \phi\alpha_i)^2) \right] \quad (31) \end{aligned}$$

which is log concave. For $i = K$, that is, for the smallest stress environment the full conditional is obtained as

$$\begin{aligned} p(\alpha_K|\alpha^{(-K)}, \theta_2, \phi, \beta, \tau, D) \\ \propto \exp \left[\alpha_K r_K - e^{\alpha_K} S_K^{\theta_2} T_K(\beta) - \frac{\tau}{2} (\alpha_K - \phi\alpha_{K-1})^2 \right] \quad (32) \end{aligned}$$

which is also a log-concave density. For α_0 it can be shown that

$$\begin{aligned} (\alpha_0|\alpha, \theta_2, \phi, \beta, \tau, D) \\ \sim N \left[\frac{\mu_0 + \phi\alpha_1}{1 + \phi^2}, (\tau(1 + \phi^2))^{-1} \right] \quad (33) \end{aligned}$$

where $\alpha = \{\alpha_i; i = 1, \dots, K\}$, and for precision τ

$$(\tau|\alpha_0, \alpha, \theta_2, \phi, \beta, D) \sim \Gamma(a^*, b^*) \quad (34)$$

with parameters $a^* = a + (K+1)/2$ and $b^* = b + 1/2[(\alpha_0 - \mu_0)^2 + \sum_{i=1}^K (\alpha_i - \phi\alpha_{i-1})^2]$. The full conditional of ϕ is

$$\begin{aligned} p(\phi|\alpha_0, \alpha, \theta_2, \tau, \beta, D) \\ \propto \exp \left[-\frac{\tau}{2} \sum_{i=1}^K (\alpha_i - \phi\alpha_{i-1})^2 \right] p(\phi) \quad (35) \end{aligned}$$

If the prior on ϕ is normal, that is, $\phi \sim N(\mu_\phi, \tau_\phi^{-1})$, then the full conditional of ϕ will be a normal given by

$$\begin{aligned} (\phi|\alpha_0, \alpha, \theta_2, \tau, \beta, D) \\ \sim N \left[\frac{\tau_\phi \mu_\phi + \tau \sum_{i=1}^K (\alpha_i \alpha_{i-1})}{\tau_\phi + \tau \sum_{i=1}^K \alpha_{i-1}^2}, \left(\tau_\phi + \tau \sum_{i=1}^K \alpha_{i-1}^2 \right)^{-1} \right] \quad (36) \end{aligned}$$

For any other log-concave prior, the full conditional of ϕ is not available in closed form but is log concave.

The full conditionals of θ_2 and β are log concave and are given by

$$\begin{aligned} p(\theta_2|\alpha_0, \alpha, \phi, \tau, \beta, D) \\ \propto \left\{ \prod_{i=1}^K S_i^{r_i \theta_2} \right\} \exp \left[-\sum_{i=1}^K e^{\alpha_i} S_i^{\theta_2} T_i(\beta) \right] p(\theta_2) \quad (37) \end{aligned}$$

and

$$\begin{aligned}
& p(\beta|\alpha_0, \alpha, \theta_2, \tau, \phi, D) \\
& \propto \beta^{\sum_{i=1}^K r_i} \left\{ \prod_{i=1}^K \left(\prod_{j=1}^{r_i} (x_{ij})^\beta \right) \right\} \\
& \times \exp \left[- \sum_{i=1}^K e^{\alpha_i} S_i^{\theta_2} T_i(\beta) \right] p(\beta) \quad (38)
\end{aligned}$$

Once the posterior analysis is completed, we can obtain the predictive reliability at the use stress using equation (28), where $\theta_{1u} = \exp(\alpha_u)$ and $\alpha_u = \alpha_{K+1}$. Given the posterior samples, we can approximate the predictive reliability via equation (28) with $\theta_{1u}^{(j)} = \alpha_u^{(j)}$ and $\alpha^{(j)}$ is generated from the normal density $p(\alpha_u|\alpha_K^{(j)}, \phi^{(j)}, \tau^{(j)})$ for each posterior realization $(\alpha_K^{(j)}, \phi^{(j)}, \tau^{(j)})$.

Analysis of Accelerated Life Testing Data

In this section we illustrate the Bayesian analysis of the presented models using two accelerated life testing datasets, investigate the appropriateness of dynamic time transformation functions, and discuss model comparison. While doing so, we first discuss the deviance information criterion (*DIC*) for comparing our models.

Model Comparison

In comparing the performance of basic parametric model with hierarchical and Markov extensions presented above, computation of the Bayes factors (see Kass and Raftery [12] for a comprehensive review) is difficult. The marginal likelihoods for the competing models, which are needed to compute the Bayes factor, cannot be directly approximated from the Gibbs sampler.

An alternative approach is to use a model selection criterion such as the *DIC* of Spiegelhalter *et al.* [13]. For a generic parameter vector Θ , *DIC* is defined as

$$DIC = \bar{D} + p_D \quad (39)$$

where $D = -2 \log \mathcal{L}(\Theta)$, is two times the negative loglikelihood, $\bar{D} = E_{\Theta|\text{data}}[D]$ and $p_D = \bar{D} - D(\hat{\Theta})$, where $\hat{\Theta}$ is the posterior mean. The *DIC* has the general “fit+complexity” form used by many model selection criteria. In equation (39) $\bar{D}$ represents the “goodness of the fit” of the model where p_D represents a complexity penalty as reflected by the effective number of parameters of the model.

Example: Breakdowns of an Insulating Fluid

In what follows, we illustrate the use of our methodology to the ALT data published in Nelson [8]. The data is given in Table 1 and represents the times to

Table 1 Times to breakdown of an insulating fluid (in minutes) under various values of the stress

38 Kv	36 Kv	34 Kv	32 Kv	30 Kv	28 Kv	26 Kv

—	—	36.71	—	—	—	—
—	—	72.89	—	—	—	—

breakdown of an insulating fluid subjected to various voltage levels. The accelerated stress levels are given by 26, 28, 30, 32, 34, 36, and 38 Kv and we are interested in making inference for the breakdown times for the insulating fluid at the use stress of 22 Kv. Following the analysis of Nelson [8] and Mazzuchi *et al.* [3], we assume a power law model for the time transformation function for the data.

We consider three models to analyze these data: the basic parametric model, the hierarchical Bayesian model, and the Markov model. Comparison among them will be made on the basis of the *DIC*. Due to our unfamiliarity with the problem, we will use diffuse priors in our analysis. In all models we choose a uniform prior in the range (0, 10) for the shape parameter β and a uniform prior in the range (0, 100) for θ_2 . In the parametric model of Section 2, the prior for θ_1 is $\Gamma[0.01, 0.01]$. In the hierarchical Bayes model, we use independent gamma priors for a and b in equations (17–21) with the parameters 0.01 and 0.01. In the Markov model, the prior for ϕ is uniform over $(-1, 1)$ and for τ it is $\Gamma[0.01, 0.01]$.

A comparison of the four models using *DIC* is given in Table 2. We note that the *DIC*s for the three models are all very similar with the parametric model having the lowest *DIC*. It is interesting to note that the hierarchical and Markov models estimate p_D , the effective number of parameters, as 4 or 5. Thus, the data do not seem to support the hypothesis that the time transformation function varies with the stress level.

This conclusion is also supported by Figure 1, where we present the posterior distribution θ_1 under the parametric model (denoted by P) and the posterior distributions of $\theta_{11}, \dots, \theta_{17}$ under the hierarchical model. We note that the posterior distributions of θ_{1j} s do not change much from one stress level to the other.

In Figure 2, we present the marginal posterior distributions of β , θ_1 , and θ_2 under the basic model. The posterior distribution of β is concentrated around 0.8, implying a decreasing failure rate at any stress level. The distribution of parameter θ_2 is concentrated

Figure 1 Comparison of posterior distributions of θ_1 and θ_{1j} s

around high positive values, implying that the failure rate increases with stress level as expected.

The predictive reliability function for the use stress $S_u = 22$ Kv is given in Figure 3 with 0.05 and 0.95 reliability bounds. We note that the items are quite reliable at the use-stress level as implied by high-reliability values for $X_u < 10\,000$, which is expected in ALTs.

Example: Rolling Bearing Data

The second dataset we consider is taken from Nelson [14, pp. 156] and it represents complete life data from a load ALT of rolling bearings. Four test loads were used and 10 bearings were tested at each of the test loads as illustrated in Table 3. The author suggested a Weibull model with a power law relationship. Life data is given in 10^6 revolutions. The data was analyzed using the three models and a power law time transformation function as in the section titled “Example: Breakdowns of an Insulating Fluid”.

A comparison of the three models using *DIC* is given in Table 4. Note that the *DIC*s under hierarchical and Markov models are considerably lower than that of the basic parametric model. The estimated effective number of parameters, p_D , is given as six under both of these models implying that there are four different θ_{1j} s. Thus, there is evidence that the time transformation function changes with stress level in this data. We can also see this by looking at the posterior distributions of θ_{1j} s in the hierarchical model. These are shown in Figure 4 and compared with the distribution of θ_1 in the parametric

Table 2 Model comparison using *DIC*

Model	<i>DIC</i>	p_D
Parametric model	607.85	3.33
Hierarchical Bayes model	609.77	4.57
Markov model	609.66	4.66

Figure 2 Posterior distributions of β , θ_1 , and θ_2 in the parametric model

Figure 3 Predictive reliability function at $S_u = 22$ Kv

Table 3 Times to failure of roll bearings (in 10^6 revolutions) under various loads

0.87 Load	0.99 Load	1.09 Load	1.18 Load
1.67	0.80	0.012	0.073
2.20	1.00	0.18	0.098
2.51	1.37	0.20	0.117
3.00	2.25	0.24	0.135
3.90	2.95	0.26	0.175
4.70	3.70	0.32	0.262
7.53	6.07	0.32	0.27
14.70	6.65	0.42	0.35
22.76	7.05	0.44	0.386
37.40	7.37	0.88	0.456

model (denoted by P in Figure 4). The differences in the distributions are easily notable in this case. Similar results are obtained for the Markov model. Posterior distributions of the hyperparameters a and b are presented in Figure 5. We note that the posterior distributions for both of these parameters are very peaked even though the priors are flat.

Table 4 Model comparison using DIC

Model	DIC	p_D
Parametric model	114.82	3.02
Hierarchical Bayes model	109.08	5.59
Markov model	109.43	6.03

The posterior distributions of β and θ_2 for the hierarchical Bayes model are shown in Figure 6. The posterior distribution of β is concentrated around values greater than 1 implying increasing failure rate for the items at a given load. The posterior distribution of θ_2 is peaked around 20, showing a sharp increase in failure rate with increasing load.

In view of the above, the claim that the time transformation function may change with the stress environment is supported by some ALT data. On the basis of our analysis, it seems that both the hierarchical and dynamic models are able to capture such changes.

Concluding Remarks

In this article we have presented Bayesian analyses of two classes of parametric models for ALTs where the time transformation function changes with the stress environment. Our results show that such models may be more appropriate than the static models in some ALTs. In our setup, we have considered a power law model for the time transformation function and assumed a Weibull failure model. The approach can be easily extended to other time transformation functions and failure models. Alternatively, a semiparametric generalization of the models can be considered by relaxing the parametric assumptions on

Figure 4 Posterior distributions of θ_1 and θ_{1j} s under the hierarchical model

Figure 5 Posterior distributions of a and b under the hierarchical model

Figure 6 Posterior distributions of β and θ_2 under the hierarchical model

the distributions of the parameters of the time transformation function. Although semiparametric models have been used in Bayesian **survival analysis** (see for example, Kuo and Mallick [15]), consideration of these models are new in ALT literature. The semiparametric ALT models use mixtures of Dirichlet processes and inference for these involves the use of MCMC methods. Such work is presently under consideration.

Brainstorming

Introduction

Brainstorming is the term coined in the 1950s by advertising executive Alex Osborn [1] to describe a group process for generating ideas on a selected topic. It can be used whenever a diverse set of original ideas, approaches, theories, or points of view is desired. For example, brainstorming has been used in designing products and services [2], identifying topics for quality and reliability improvement efforts [3], collecting multiple theories about the causes of problems [4], generating potential solutions to problems or innovative changes to work flow [5], and engaging employees in improvement efforts [6].

Background, Principles, and Models

The psychologist Guilford [7] identified five traits associated with highly creative output in idea generation:

- *Fluency*: the rate of flow of ideas; roughly measured by the number of ideas generated in a given period of time.
- *Flexibility*: the ability to free-associate; roughly measured by the number of categories or themes represented in a stream of ideas.
- *Originality*: the ability to identify uncommon items; subjectively judged as the difference between the ideas and the usual approaches to the topic.
- *Awareness*: the ability to imagine beyond the immediate reality; subjectively judged as the ratio of conceptual to concrete content in the conversation within a group.
- *Drive*: Individuals' willingness in a group setting to take social risks and be unconventional in pursuit of a goal; subjectively judged by analysis of each individual's participation, and the absence of judgmental communication (verbal and non-verbal).

In each case, more is better. While subsequent studies [8] have added to Guilford's list, they also consistently reaffirm the importance of these five core traits.

Osborn [1] applied Guilford's research to the practical problem of generating ideas in an advertising agency. In order to create an environment that was conducive to creativity, Osborn suggested four rules:

- Criticism is ruled out.
- Freewheeling is welcomed; the wilder the ideas, the better.
- Quantity is wanted.
- Combination and improvement are sought.

Subsequent authors have variously restated or added to these (see [2] for example), but Osborn's basic rules remain the core of the brainstorming technique, and are widely used for group facilitation. Less well known today is Osborn's complete model for brainstorming (see Table 1). The power of brainstorming lies in the thoughtful application of the full approach.

Process

Craft a succinct statement of the issue

The issue statement should not be too broad, as this typically leads to only vague ideas. At the same time, the statement should not be so specific that it restricts thinking. For example, "How can we make our products and services more reliable?" is probably too broad and vague. Focusing on a specific product or service line, or on a few prominent failure modes, will likely produce more useful ideas. On the other

Table 1 Osborn's complete process for brainstorming

Fact finding

Problem definition: picking out and pointing up the problem

Preparation: gathering and analyzing the pertinent data

Idea finding

Idea production: generating a large number of thoughts and approaches to the problem

Idea development: selecting from among the resultant ideas and reprocessing then into even better ideas (by means of modification, combination, extraction of key concepts, and so on)

Solution finding

Evaluation: verifying the tentative solutions by means of tests and data collection

Adoption: deciding on and implementing the final solution

hand, “How do the policies of the purchasing department contribute to lack of reliability?” immediately shuts down other avenues of thinking that might lead to improved reliability.

Prepare background information and invite participants

Brainstorming will yield better results if all participants in the idea generation session know something about the issue. This might involve gathering data (*see Statistics in Data and Information Quality*) on current performance, knowledge of how others approach similar issues (*see Benchmarking in Project Definition*), or information about what has already been tried. Some experts further encourage formal observation in the field [2]. For example, in preparation for a brainstorming session to discuss possible causes of delayed shipments, a planning group might summarize data by product lines or geography, as well as identify themes uncovered in analysis of customer complaints and observations of the process.

Present this background information thoughtfully. The intent is to generally inform everyone and stimulate new insights. Avoid overwhelming or implying a specific line of thinking.

Idea generation sessions most often involve relatively small groups of 5–12 individuals, but can be conducted with groups numbering in the hundreds (with appropriate attention to equal participation and idea capture). Select participants from among the various stakeholders associated with the issue, along with a few individuals with uncommon backgrounds, skills, or points of view. For example, a session to identify new product ideas in a telecommunications company might include design engineers, managers, marketing personnel, customers (current and potential) – along with an anthropologist who can provide insight about social communication, or a child who simply often questions “why?”

Send the preparation information several days in advance and encourage participants to come to the idea generation session with a few ideas already in mind. This often results in participants noticing useful insights from chance observations prior to the session [9]. For example, a participant invited to the brainstorming session on delayed shipments described above might notice a geographic and seasonal pattern in the data and, while watching the television weather report, be stimulated to think about

integrating weather forecasts into the shipment routing system.

Prepare the physical space for the idea generation session

Idea generation works best in oversized rooms with flexible furnishings, where one can create an interactive and appropriately playful environment [2, 10].

Plan appropriate technology for recording ideas. This might include individual pads of paper, an easel pad for the group, audio or video recording equipment, or computers. The key factors to consider in selecting idea-recording technology are that it not inhibit active participation or slow down the rapid flow of ideas.

Begin the session with a brief review of the background information, an introduction to brainstorming methodology, and a warm-up exercise

The goal is to create a comfortable, nonthreatening, and information-rich atmosphere. Briefly go over the traits of creative thought and rules of brainstorming in order to clearly distinguish the session from other types of meetings. A 5–10 min warm-up exercise (for example, “How many different uses can we find for ordinary wire coat hangers?”) helps illustrate the desired atmosphere of fluency, flexibility, originality, awareness, and drive that one wants the group to apply to the issue that is the subject of the session.

Refocus the group on the issue statement and ask for ideas

Individual facilitators and organizations have a variety of preferences about how to orchestrate this group input. For example, some solicit group members in turn, while others allow them to voice ideas as they emerge. Some facilitators ask individuals to first write down several ideas in silence, and then share these with the group. Resources on brainstorming offer other variants [9, 11].

Be prepared to help the group through any lulls in the flow by either introducing an idea that opens up a new category, or injecting provocations. Osborn [1] supplied a list of verbs, like “magnify” or “substitute”, for use in quickly creating provocations. For example, one could ask, “How could we magnify certain failure modes if we desired, and what additional causes of the overall problem does that suggest that we haven’t yet thought about?” Others suggest removing taken for granted resources [12] or

creating an outrageous scenario that would demand fresh thinking [13]. For example, “What if we had to do this with no staff?” or “What if an earthquake destroyed our factory?” (see [5, 9, 11] and **Creativity Tools** for additional tools). Such provocations often reenergize the group and result in renewed fluency and originality.

Idea generation on the subject topic is typically limited to no more than 30–45 min. Additional topics can be handled in a similar period following a break.

Review, clarify, and initially process the ideas

The group can now eliminate redundant ideas, and obviously light-hearted ones. In the fast pace of the session, ideas might have been incompletely captured. These can now be embellished and clarified. If it seems useful, the group could categorize ideas. However, do not allow vague, high-level categories to take the place of the concrete and more specific ideas that were generated.

Conduct a formal harvesting of the best ideas

If the group has responsibility for acting on the ideas and time is available, immediately transition into selecting ideas for further work. For example, a quality improvement team brainstorming about possible causes of defects might select several theories and plan for **data collection**.

If action depends on others, or on the allocation of significant resources, the idea generation session should close with a brief description of how the ideas will be harvested by decision makers at a later time. For instance, ideas might be referred to a new product development committee, multidepartmental quality improvement council, or specific managers. Kotter and Cohen [14] speak of the importance of a guiding coalition of key decision makers who have access to the resources needed to bring about change. The odds of implementation are increased when these individuals are personally involved in selecting the ideas (see **Change Management, Stakeholder Assessment in**).

In either case, the harvesting group should first agree on the selection criteria. Examples include, cost, potential impact, immediately actionable *versus* longer term, or potential acceptance by employees. Any simple decision-making tool can then be used to select the ideas that best fit the criteria (see, for example [15]).

Plan for the further development, testing, and eventual implementation of ideas

The process of brainstorming is not complete until at least some of the ideas are acted upon (see Table 1). Organizations use a variety of project management (see **Project Management, Stage-Gate Approach to**) and improvement methodologies (see **Kaizen; Statistical Quality Control; Six Sigma**) to accomplish this. The key point is that failure to act on the ideas is likely to create an organizational culture that undermines future attempts at brainstorming.

Discussion

Research and Evaluation of Brainstorming

Experimental research on brainstorming tends to conclude that group brainstorming is no more effective, and in some studies is less effective, than idea generation by individuals [16].

However, Sutton and Hargadon [17] point out that these studies often fundamentally misrepresent how brainstorming is practically applied in organizations. The experimental study subjects, most often university students, typically have no prior or expected future relationship. They often have no particular interest or knowledge about the topic. Groups are often led by students, who are briefly presented the rules of brainstorming, and then asked to oversee 10–15 min of idea generation. Quantity of ideas is the most commonly measured result, with only a minority of studies assessing quality of ideas.

In contrast, observational research in organizations suggests that individuals in these settings bring a variety of subject matter expertise. Organizational groups most often have histories and expectations of future interactions, and care a great deal about the topics they are working on. Although quantity of ideas (fluency) is important within the process of idea generation, in the end, the effort only needs to yield a single successful idea to have a positive outcome for the organization. Sutton and Hargadon [17] provide case study evidence for the effectiveness of brainstorming, as practiced in organizational settings, and conclude that the experimental research, although rigorous and interesting, is largely irrelevant.

Strengths of Brainstorming

Group brainstorming is an efficient, effective, and flexible way to combine the knowledge and insights

of group members. It promotes **team building** by stressing equality among group members; deferral of judgment; and appreciation for the varying backgrounds, knowledge sets, and experiences of members.

Weaknesses of Brainstorming

An implicit assumption in brainstorming is that group members naturally have fresh insights and creative thoughts on the given topic and these simply need to be invited out. This might not always be the case. Group members who are immersed in “the way we have always done it” can become perceptually blocked from seeing in new ways [2, 6, 9]. When this occurs, a brainstorming session can generate a long list of items, none of which are significantly different from ideas that have been stated before. Additional tools for observation and creative thinking should be used in conjunction with the rules of brainstorming to create fresh, more creative insights (see, for example [9, 11–13] and **Creativity Tools**).
